Who This Book Is For	xxiii
Why a Fleet-Level Textbook	xxiii
What This Book Covers	xxiv
Suggested Reading Paths	xxvi
Conventions	xxvi
Companion Resources	xxvii
Prerequisites	xxvii
Beyond This Book	xxviii
Using This Book in a Course	xxviii
Copyright and Licensing	xxviii
Acknowledgments	xxix
Origins	xxix
Collaborators and Colleagues	xxix
Support	xxix
A Note on AI Assistance	xxxi
Notation	xxxiii
The Iron Law of ML Systems	xxxiii
The Degradation Equation	xxxiv
The Energy Corollary	xxxiv
Deep Learning Notation	xxxv
Performance, Serving, and Memory Notation	xxxv
Units and Precision	xxxvi
Quick Reference: Resolving Collisions	xxxvii
Distributed Systems Notation	xxxvii
Main Matter	
Chapter 1 Introduction	3
1.1 The Scale Moment	4
1.2 The Fleet Stack: A Hierarchy of Architecture	8
1.3 AI Scaling Laws	12
1.4 Constraints of Scale	19

1.5	The C ³ Taxonomy: Foundations of Scale	22
1.6	Foundational Concepts	25
1.7	The Structure of This Textbook	28
1.8	Fallacies and Pitfalls	29
1.9	Summary	30

Part I The Fleet

Fleet Principles	35
-------------------------	-----------

Chapter 2 Compute Infrastructure	39
---	-----------

2.1	The Infrastructure Walls	40
2.2	Accelerator Spectrum	40
2.3	The Memory Wall	49
2.4	The Node	74
2.5	The Rack	88
2.6	The Pod	92
2.7	Infrastructure Technologies That Move the Walls	95
2.8	Fallacies and Pitfalls	97
2.9	Summary	99

Chapter 3 Network Fabrics	103
----------------------------------	------------

3.1	The Synchronization Backbone	104
3.2	How ML Networking Inverts Data-Center Assumptions	106
3.3	Level 1: Wire and Link	108
3.4	Level 2: Transport and the Performance Model	110
3.5	Level 3: Switch and Topology	116
3.6	Level 4: Fabric Behavior (Congestion, Routing)	124
3.7	Level 5: Cluster Design and Case Studies	129
3.8	Network Virtualization	130
3.9	Monitoring and Debugging	131
3.10	Network Technologies That Move the Ceiling	133
3.11	Fallacies and Pitfalls	135
3.12	Summary	136

Chapter 4 Data Storage	139
-------------------------------	------------

4.1	The Fuel Line	140
4.2	How ML Workloads Invert Storage Assumptions	141
4.3	The ML Storage Hierarchy	146
4.4	The Data Pipeline Equation	162
4.5	GPUDirect Storage and the CPU Bypass	170
4.6	Storage Economics	173
4.7	Checkpoint Storage	177
4.8	Retrieval Infrastructure: Vector Indexes	181
4.9	The Synthetic Fuel Line	182
4.10	Fallacies and Pitfalls	183
4.11	Summary	184

Part II Distributed ML

Distributed ML Principles	189
----------------------------------	------------

Chapter 5 Distributed Training	193
---------------------------------------	------------

5.1	Why Distribution Is Necessary	194
5.2	The Distributed Training Step	197

5.3	Data Parallelism	198
5.4	Scaling Efficiency and Convergence	211
5.5	Model Parallelism	223
5.6	FP8 for distributed training	235
5.7	Hybrid Parallelism	236
5.8	Multi-Model Training: RLHF and Alignment	241
5.9	Parallelism Strategy Comparison	245
5.10	From Principles to Systems	246
5.11	Fallacies and Pitfalls	247
5.12	Summary	250
Chapter 6	Collective Communication	253
6.1	From Parallelism to Communication Patterns	254
6.2	Mapping the Terrain: Network Performance Modeling	258
6.3	Choosing the Vehicle: Collective Operation Primitives	263
6.4	Engineering the Flow: AllReduce Algorithms	268
6.5	Hierarchical Communication	277
6.6	Gradient Compression Under Bandwidth Scarcity	282
6.7	The Communication Library Landscape	288
6.8	Communication-Computation Overlap	293
6.9	Fallacies and Pitfalls	295
6.10	Summary	296
Chapter 7	Fault Tolerance	301
7.1	Failure Analysis at Scale	302
7.2	Hardware Fault Taxonomy	318
7.3	Software Faults	327
7.4	Check-and-Verify: Defending Against Silent Data Corruption	329
7.5	Fault Injection Tools and Frameworks	330
7.6	Checkpointing: Preserving Progress	333
7.7	Failure Detection and Recovery	341
7.8	Elastic Recovery	346
7.9	Serving Fault Tolerance	350
7.10	Graceful Degradation	354
7.11	Distributed Debugging and Observability	358
7.12	Case Studies	363
7.13	Fallacies and Pitfalls	366
7.14	Summary	369
Chapter 8	Fleet Orchestration	373
8.1	The Scheduling Problem	374
8.2	Orchestration Paradigms	384
8.3	Topology-Aware Scheduling	393
8.4	Elastic Scheduling	398
8.5	Cost Optimization	402
8.6	Custom ML Schedulers	407
8.7	Serving Resource Management	411
8.8	Multi-Tenancy and Quotas	417
8.9	Debugging Cluster Utilization	422
8.10	Fallacies and Pitfalls	426
8.11	Summary	428

Part III Deployment at Scale

Chapter 9 Performance Engineering	433
9.1 The Memory Wall and Roofline Diagnosis	434
9.2 Serving Regimes: Batch Size and Prefill-Decode	442
9.3 Operator Fusion and Kernel Engineering	445
9.4 Precision Engineering	449
9.5 Graph Compilation	453
9.6 Algorithmic Performance Transformations	460
9.7 Communication-Computation Overlap	461
9.8 System Profiling	464
9.9 Measurement at Scale	471
9.10 The Optimization Playbook: A 70B LLM Case Study	473
9.11 Fallacies and Pitfalls	477
9.12 Summary	479
Chapter 10 Inference at Scale	483
10.1 The Economics and Architecture of Inference	484
10.2 Serving Architecture Dimensions	491
10.3 Batching Strategies at Scale	494
10.4 Memory and Decode-Time Management	513
10.5 Model Sharding for Inference	528
10.6 Load Balancing and Request Routing	538
10.7 Multi-Tenancy and Isolation	549
10.8 Autoscaling and Global Infrastructure	555
10.9 Weight Quantization for Serving	566
10.10 Case Studies	572
10.11 Fallacies and Pitfalls	578
10.12 Summary	579
Chapter 11 Edge Intelligence	581
11.1 The Edge Learning Paradigm	582
11.2 Design Constraints	588
11.3 Model Adaptation	598
11.4 Data Efficiency	607
11.5 Federated Learning: Algorithms	612
11.6 Federated Learning: Systems at Scale	618
11.7 Continual Adaptation Under Edge Budgets	627
11.8 Production Integration	629
11.9 Putting the Pillars Together	634
11.10 Engineering Challenges and Mitigations	636
11.11 Fallacies and Pitfalls	643
11.12 Summary	644
Chapter 12 ML Operations at Scale	647
12.1 From Single-Model to Platform Operations	648
12.2 The N-Models Problem	649
12.3 Fleet Economics and Utilization	660
12.4 Multi-Model Management	670
12.5 CI/CD for ML at Scale	677
12.6 Monitoring at Scale	697
12.7 Platform Engineering	707
12.8 Feature Store Operations	721
12.9 Organizational Patterns	728
12.10 Case Studies	730
12.11 Production Debugging and Incident Response	733
12.12 Fallacies and Pitfalls	739
12.13 Summary	740

Part IV The Responsible Fleet

Responsible Fleet Principles	745
Chapter 13 Security & Privacy	747
13.1 The Expanded Attack Surface	748
13.2 Learning from Security Breaches	752
13.3 Systematic Threat Analysis and Risk Assessment	754
13.4 Model-Specific Attack Vectors	759
13.5 Hardware-Level Security Vulnerabilities	773
13.6 When ML Systems Become Attack Tools	782
13.7 Comprehensive Defense Architectures	784
13.8 Differential Privacy	806
13.9 Security and Privacy Maturity Model	816
13.10 Fallacies and Pitfalls	817
13.11 Summary	819
Chapter 14 Robust AI	821
14.1 The Silent Failure Problem	822
14.2 Real-World Robustness Failures	824
14.3 A Unified Framework for Robust AI	828
14.4 Environmental Shifts	834
14.5 Input-Level Attacks and Model Robustness	843
14.6 Adversarial Defenses	852
14.7 Data Poisoning Defenses	856
14.8 Fallacies and Pitfalls	859
14.9 Summary	860
Chapter 15 Sustainable AI	863
15.1 The Energy Ceiling	864
15.2 Energy Measurement and Modeling	872
15.3 Carbon Footprint Calculation	885
15.4 Data Center Energy and Resource Consumption	889
15.5 Training vs. Inference Energy Analysis	904
15.6 Hardware Lifecycle and E-Waste	912
15.7 Mitigation Strategies	917
15.8 Policy, Regulation, and the Path Forward	926
15.9 Fallacies and Pitfalls	928
15.10 Summary	929
Chapter 16 Responsible AI	933
16.1 The Governance Imperative	934
16.2 Core Principles and the ML Lifecycle	936
16.3 Responsible AI Across Deployment Environments	954
16.4 Bias Detection and Fairness Monitoring	959
16.5 Privacy, Unlearning, and Robustness Mitigations	965
16.6 Explainability and Interpretability	972
16.7 Sociotechnical Dynamics	979
16.8 Implementation Challenges and AI Safety	988
16.9 Fallacies and Pitfalls	1001
16.10 Summary	1002

Synthesis

Chapter 17 Conclusion	1007
17.1 Synthesizing Distributed ML Systems	1008
17.2 Six Principles of Distributed ML Systems	1008
17.3 The Complete Production System	1011
17.4 Competencies Mastered	1013
17.5 The Fleet Stack as Discipline	1013
17.6 Engineering Intelligence at Scale	1015
17.7 Fallacies and Pitfalls	1015
17.8 Summary	1016

Dedication

*For Kari,
who gave me the time this book required
and never asked for it back.*

*And for Nora and Maya,
the reason any of it matters.*

Foreword

Coming soon.

Author's Note

WHEN A NEW MODEL is announced, the world looks at the model. It almost never looks at the fleet. Behind every frontier model, however, stands tens of thousands of accelerators held in lockstep across a network where one slow link can stall the whole run, cooled by systems that move megawatts of heat, kept alive by protocols that treat failure not as an exception but as a scheduled event. None of this fits in the announcement. The model gets the paper. The fleet gets a footnote, if that.

This book is an argument that the fleet deserves more than a footnote. We have built vast distributed systems before, but none quite like this one, because none of the others had to be right about two things at once. The telephone network had to stay available; it never had to converge. The internet had to deliver the packet; it never had to preserve the gradient inside it. A fleet has to do both. It must move data the way any distributed system does, and it must keep the mathematics of learning intact while it moves. A node that drops out does not only cost capacity; it can break the synchronization a training step depends on, and a single broken step can corrupt days of work. That double obligation, computational and statistical, sustained at the scale of a small campus, is the engineering this book makes visible.

The obligation does not end when training does. A model that cannot be trained is an idea, not a system. A model that cannot be served is a research result, not a product. A model that cannot be governed is a liability, not an asset. At every stage, from the first allocated node to the last served request, the fleet decides what is possible and what remains imagined.

The question under every chapter is easy to ask and hard to answer: what it takes to build not one machine learning system but a thousand, make them work as one, and run them responsibly. I believe that is a defining engineering problem of this generation, and that the people who take it on, the ones who rarely get the headline, deserve a book that treats it as one.

Cambridge, Massachusetts
2026

Preface

Who This Book Is For

THIS book is for anyone who understands machine learning on a single machine and now faces the challenge of making it work at scale. The problems of scale are not the problems of a single node, only bigger. They are qualitatively different: networks partition, hardware fails as a statistical certainty, and the societal impact of every design decision is amplified by millions of users.

The scope ranges from designing the physical substrate of an AI data center, to scaling training beyond the limits of a single accelerator, to reasoning about what happens when a production fleet serves a global user base. Throughout, the focus is on the physics of distribution—the invariants that govern every fleet-scale ML system regardless of the framework, the model, or the era.

Why a Fleet-Level Textbook

In 2012, training AlexNet took five to six days on two GPUs (Krizhevsky et al. 2012). By 2023, public GPT-4-class estimates placed frontier training at roughly 25,000 GPUs running for about three months (SemiAnalysis 2023); OpenAI did not disclose the actual hardware configuration (OpenAI et al. 2023). This is not the same engineering problem at a larger scale. It is a categorically different engineering problem.

On a single machine, performance is governed by the memory wall—the gap between processor speed and memory bandwidth. In a distributed cluster, a new wall emerges: the bisection bandwidth wall, where the minimum network bandwidth that bisects the cluster caps total system throughput. Data no longer moves through local hierarchies alone; it traverses optical fabrics governed by the speed of light between racks and across continents. Hardware failures, rare enough on a single machine to be treated as exceptions, become routine statistical events at fleet scale. A training job that does not plan for failure *will* fail.

These are not operational annoyances. They are physical constraints—as fundamental and as permanent as the memory wall, Amdahl’s Law, or the energy cost of data movement. They require their own engineering discipline, with its own invariants:

- **The Bisection Bandwidth Theorem:** The performance of a distributed system is limited by the minimum bandwidth that bisects the network topology.
- **The Fleet Law:** Every training step pays a communication tax that grows with cluster size while per-node computation shrinks.
- **The Young-Daly Checkpoint Law:** The optimal checkpoint interval balances the cost of writing state against the expected cost of lost work due to failure.
- **The Serving Cost Dominance Law:** For high-traffic production models, cumulative inference operational expenditure can exceed the one-time training cost, making serving efficiency a lifecycle optimization target.
- **The Fairness Impossibility Law:** No system can simultaneously satisfy calibration, equalized odds, and demographic parity when base rates differ between groups.

If single-machine ML systems engineering asks “*what can one machine build?*”, then fleet-scale ML systems engineering asks “*what can a thousand machines build together, and at what cost to reliability, efficiency, and society?*”

That final clause is what sets fleet-scale engineering apart. A single machine affects its user; a fleet affects everyone its outputs touch, across millions of decisions per second. At that scale, reliability, efficiency, and fairness stop being features and become engineering constraints as binding as bandwidth or power. A system that scales but cannot be trusted has not been engineered. It has only been enlarged.

This book provides that foundation. It follows the Hennessy and Patterson pedagogical model, extending the quantitative, principles-first approach to the distributed scale (Hennessy and Patterson 2011; Hennessy and Patterson 2019; Patterson and Hennessy 2017). Just as their work taught a generation to reason about processor performance from first principles, this book teaches the reader to reason about fleet performance—replacing intuition about distributed systems with measurement, and ad hoc scaling with engineering.

Introduction to Machine Learning Systems taught the bricks: the tensors, kernels, memory hierarchies, and optimization loops that compose any single-node system. A fleet is not built from more bricks. It is an orchestra. A single musician can produce music of remarkable beauty, but an orchestra is not simply many musicians playing at once. It requires a conductor, a score, precise synchronization, and the ability to recover gracefully when a player drops out. The acoustics of the concert hall shape the sound in ways that no individual instrument can control. The principles that govern orchestral performance—coordination, communication latency, fault tolerance, and the physics of the performance space—are categorically different from those that govern a solo performer. ML fleets work the same way. A training cluster, a serving fleet, and an edge deployment are vastly different systems, but beneath them sit the same building blocks: parallelism strategies, collective communication primitives, checkpoint protocols, scheduling algorithms, and the trade-offs between throughput, latency, fault tolerance, and cost.

What This Book Covers

This book focuses on the **Machine Learning Fleet**: the warehouse-scale computer where the network is the bus, power density is the speed limit, and failure is not an exception but a statistical certainty. This is the unit of modern ML computation, where models too large for any single device are trained across thousands of accelerators, served to millions of users, and governed by constraints that span engineering, economics, and society.

The content is organized into four parts:

- **Part I: The Fleet** builds the physical substrate of the AI data center from the ground up: the landscape of distributed ML systems, the silicon and cooling of compute infrastructure, the network fabrics that connect thousands of accelerators, and the scalable data storage that feeds training pipelines.
- **Part II: Distributed ML** establishes the logic of distribution beyond a single machine: the parallelism strategies (data, tensor, and pipeline) for training models too large for single devices, the collective communication primitives that synchronize gradients, the fault tolerance mechanisms that ensure reliability when failure is routine, and the orchestration systems that manage the fleet.
- **Part III: Deployment at Scale** takes the trained model from the cluster to the world: performance engineering for efficiency, inference serving at massive scale, edge intelligence for resource-constrained devices, and the operational lifecycle required to manage production fleets.
- **Part IV: The Responsible Fleet** confronts the forces that determine whether the fleet serves its users or harms them: security and privacy, robust system design, environmental sustainability, and responsible engineering as constraints as fundamental as power density or bisection bandwidth.

These four parts trace a path through the **Fleet Stack**, a layered abstraction that extends the classical ML systems stack to the distributed scale. At the bottom, **Facility & Accelerators** and **Fabric & Storage** form the physical substrate. Above them, **Distributed Execution** and **Reliability & Control** manage parallel work, communication, scheduling, and recovery. Higher still, **Runtime & Serving** and **Operations** take models to users and manage the production lifecycle. At the top, **Assurance** and **Governance & Sustainability** turn trust, risk, policy, and environmental cost into

engineering constraints. Each layer provides an abstraction to the layer above and consumes the layer below. Engineering decisions at the bottom constrain possibilities at the top.

Throughout the book, a margin figure highlights which layer each chapter addresses, providing a navigation cue at every chapter opening:

Part IV	Governance & Sustainability auditability, policy, carbon budgets, accountable release	
	Assurance security, privacy, robustness, risk controls	
Part III	Operations SLOs, monitoring, drift, incidents, lifecycle	
	Runtime & Serving kernels, inference, batching, routing, KV cache, edge	
Part II	Reliability & Control checkpointing, recovery, schedulers, placement	
	Distributed Execution parallelism strategies, collectives, synchronization	
Part I	Fabric & Storage topology, bandwidth, storage tiers, data movement	
	Facility & Accelerators power, cooling, racks, GPUs/TPUs, HBM	

The full stack above shows each row with its scope, grouped into the four Parts of the book. The Roman numerals (I–IV) mark those Parts; the row intensity marks emphasis. The stack uses one Volume II accent color throughout so that shade, not hue, carries the chapter-focus signal.

In the margin figures throughout the book, the intensity of each layer reflects how strongly the chapter engages that tier—brighter (higher intensity) means the chapter’s primary focus; dimmer (lower intensity) means contextual relevance as constraints propagate upward. Consider three chapters that illustrate how the emphasis shifts:

Compute Infrastructure			Distributed Training			Responsible AI		
Part IV	Governance		Part IV	Governance		Part IV	Governance	
	Assurance			Assurance			Assurance	
Part III	Operations		Part III	Operations		Part III	Operations	
	Serving			Serving			Serving	
Part II	Control		Part II	Control		Part II	Control	
	Execution			Execution			Execution	
Part I	Fabric		Part I	Fabric		Part I	Fabric	
	Facility			Facility			Facility	

In Compute Infrastructure, the bottom row dominates because the chapter is about silicon, power, cooling, and physical deployment. In Distributed Training, **Distributed Execution** is brightest while **Reliability & Control** remains visibly relevant because large training runs depend on scheduling and recovery. In Responsible AI, **Governance & Sustainability** is primary while **Assurance** stays strong because accountability depends on measurable trust and risk controls. The same stack, three different stories: decisions made at one layer ripple through the layers above and below it.

Small visual notes sit in the margins wherever a relationship is fastest to grasp by eye. They are reading aids, not figures to cite later. At fleet scale, this visual grammar makes bandwidth gaps, failure blast radius, checkpoint ratios, and edge-energy trade-offs visible without interrupting the argument. When a miniature uses a log scale, it says so inside the image.

Each part builds on the previous one, so sequential reading is recommended. The reading paths below offer alternatives for readers with specific goals.

Suggested Reading Paths

Readers with different backgrounds and goals can choose among several paths through the material:

The Complete Path involves reading all chapters in sequence, following the causal chain of constraints that governs the ML fleet. The physical silicon and cooling limits dictate the wiring of the data center, which determines how data is supplied. With the hardware built, the algorithms partition the math across it, requiring precise network routing mechanics and the ability to survive inevitable hardware loss. This surviving fleet must be scheduled, tuned, and scaled out to serve millions of users. Finally, deploying at this scale demands rigorous operational frameworks that are inextricably linked to defending the system and ensuring it serves society responsibly. This path develops every concept from first principles of distribution.

The Infrastructure Path focuses on the physical fleet and orchestration. Readers should focus on Part I (Compute Infrastructure, Network Fabrics, Scalable Data Storage) and Fleet Orchestration. This path builds a deep understanding of the physical and operational substrate.

The Scaling Path provides depth in distributed training. Readers should skim Part I for infrastructure vocabulary, then focus on Distributed Training, Collective Communication, Fault Tolerance, and Performance Engineering.

The Production Path covers deployment and operations. After the introduction, readers should move to Inference at Scale, Operations at Scale, Edge Intelligence, and the Responsible Fleet chapters. This path covers everything from serving architecture to governance.

Conventions

This book uses a small set of typographic conventions to mark what each piece of prose is doing.

Bold marks first definitions

A term in **bold** within body prose is its formal first introduction in the volume. Each term receives this treatment exactly once. Subsequent appearances are unbolded; by then the term is part of the working vocabulary the chapter carries forward.

Every machine learning system has a **dual mandate**: it must manage statistical uncertainty and physical constraints simultaneously.

The bold is a contract: register this term, it will recur. A matching index entry in the back of the book points to the defining occurrence, providing a way to return to it.

Bold also appears in a second, structural role: as a functional label at the start of an item inside a callout box or a summary bullet—for example, **Recommendation**:, **Trade-off**:, or **Result**:. In that context, the bold is scaffolding rather than a first definition.

Italics carry specific rhetorical jobs

Italics are not used for general emphasis. Every italic span in this book performs one of a small number of specific jobs:

- **Direct opposition:** *training vs. inference, logical vs. physical.*
- **Impossibility, stated as physical, mathematical, or logical law:** “sub-10 ms systems *cannot* use distant cloud infrastructure—physics forbids it.”
- **Word used as word:** “the term *gradient* refers to a vector of partial derivatives.”
- **Thesis punchline:** a single italicized sentence that captures the controlling insight of a section, for example *Data is Source Code.*

An italicized word is performing one of these jobs. A word that is not italicized carries no implicit emphasis.

Callouts have visual identities that match their job

Callout boxes are not decoration. Each type signals a specific kind of content, so the visual identity announces what the box contains before the reader engages with it.

Callout	Contains
Definition	Formal definition of a key term, with its significance, distinction from the nearest neighbor concept, and a common pitfall
Example	Historical case or concrete scenario, structured as context, insight, and systems lesson
Perspective	Analytical observation or mathematical nuance that enriches the surrounding argument
Notebook	Worked calculation walked through step by step, with values computed inline from the book’s constants; intermediate tables and equations are the math itself
Checkpoint	Self-check questions to verify understanding of the preceding section
War Story	Real production failure, structured as context, failure, consequence, and lesson
Lighthouse	Recurring workloads characterized by a profile (parameters, FLOPs, dominant constraint), used as anchored case studies across multiple chapters
Principle	Canonical book principle or invariant referenced from later chapters
Theorem	Formal, equation-backed result or bound, stated with its conditions and applied in later quantitative analysis
Takeaways	Four to seven most important results from a chapter, in summary form
Chapter Connection	Bridge from the chapter just ended to the chapter beginning, naming the open question the next chapter addresses

When a callout contains a table, figure, or equation, that artifact is part of the callout’s pedagogical unit, not decoration. A Lighthouse’s profile *is* its characterization. A Notebook’s intermediate tables *are* the worked math. Reading these as separated artifacts loses the teaching arc. Standalone reference tables, by contrast, sit between paragraphs as numbered artifacts the reader returns to via @tbl- references; the list of tables at the back of each volume collects them. Both forms are valid; the visual marker (callout vs. standalone) tells the reader which one they are looking at.

Companion Resources

Whichever path readers choose, this book is part of a broader learning ecosystem. The complete text, interactive Colab notebooks, lecture slides, exercises, hands-on labs, and supplementary materials for every chapter are available online at mlsysbook.ai.

This book is built in the open. Its full text, figures, and build system are public, and contributions from readers worldwide have sharpened every chapter. Visit mlsysbook.ai/git to report an issue, suggest an improvement, or contribute directly.

Prerequisites

Readers should bring the following background:

- **Single-machine ML systems:** Understanding of ML workflows, neural network training, model optimization, and deployment on a single machine. Readers should be comfortable reasoning about memory hierarchies, computational graphs, and hardware-software interactions.
- **Programming:** Fluency in Python, including functions, classes, and data manipulation with NumPy. Familiarity with at least one ML framework (PyTorch, TensorFlow, or JAX).
- **Mathematics:** Comfort with linear algebra, basic calculus, and probability at the undergraduate level.

The following background is helpful but not required:

- **Distributed systems:** Familiarity with networking concepts (TCP/IP, bandwidth, latency), parallelism, and basic distributed computing deepens understanding of the fleet infrastructure and training chapters.
- **Cloud infrastructure:** Experience with container orchestration (Kubernetes, Docker) or cluster schedulers (Slurm) provides useful operational context.
- **Production engineering:** Understanding of monitoring, observability, and site reliability practices will enrich the deployment and operations chapters.

Beyond This Book

This book covers the Machine Learning Fleet as it exists today: warehouse-scale training clusters, global serving infrastructure, and the governance challenges of operating at scale. Topics at the research frontier—including fully autonomous fleet management, next-generation interconnects, neuromorphic computing at scale, and formal verification of fleet-level safety properties—extend beyond this scope but represent active areas of investigation.

Using This Book in a Course

This book grew out of CS249r at Harvard University and the [TinyML edX professional certificate](#) program. That teaching reinforced an insight that carries to fleet scale: the same physics governs every level of the hierarchy. Bandwidth, energy, and failure set the limits on a microcontroller and on a data center alike. What changes with scale is not the physics but which limit binds, and a new binding limit is a new engineering problem. On one machine, the memory wall dominates. Across a fleet, bisection bandwidth and routine hardware failure take over, and what was once a rare exception becomes the constraint the entire system is designed around. The physics is continuous; the engineering is not.

The book is designed to support a one-semester advanced course covering the full distributed ML systems stack. Instructors may also select individual parts for shorter modules:

- **Parts I–II** (The Fleet and Distributed ML) suit an advanced half-semester on distributed training infrastructure.
- **Parts III–IV** (Deployment at Scale and The Responsible Fleet) suit an applied half-semester on production ML at scale.

For survey courses or executive programs, the four Part introductions and their governing principles alone provide a condensed overview of the quantitative laws that govern fleet-scale ML systems.

Slides, assignments, and instructor materials for the advanced sequence are available at mlsysbook.ai.

Origins

Earlier teaching on TinyML grew out of the realization that the constraints governing milliwatt devices are the same constraints governing data-center accelerators. This book grew out of a different realization, one that came from working on ML Fleet Efficiency as a visiting researcher at Google. Peter Mattson, who had been a collaborator on MLPerf, made that opportunity possible. What I encountered there changed how I think about ML systems: the engineering required to coordinate thousands of accelerators into a single coherent system is a discipline unto itself, and that discipline had no textbook.

That work introduced me to the ML Productivity Goodput (MPG) metric, fleet-level heterogeneity at a scale I had not seen before, and the daily reality of failure as a statistical certainty rather than an exception. The gap between what practitioners knew and what was written down was enormous. The researchers who built these systems published individual results, but the connective tissue between those results, the principles that made them cohere into a discipline, existed only in the heads of the people doing the work. This book is an attempt to document that connective tissue.

Collaborators and Colleagues

I learned most of what I know about fleet-scale systems from the ML Fleet Efficiency team at Google: Arissa Wongpanich, Tayo Oguntebi, Jose Baiocchi Paredes, Yu Emma Wang, Phitchaya Mangpo Phothilimthana, Ritwika Mitra, and Zongwei Zhou. Naveen Kumar led that effort, and the way he thought about fleet-level optimization shaped how I think about it still. Robert Hundt pushed my understanding of performance engineering at scale. Together, Naveen and Robert showed me what fleet-level efficiency looks like from the inside. David Kanter continued the MLPerf collaboration, and our discussions on benchmarking distributed systems sharpened the quantitative methodology that runs through every chapter. Greg Diamos provided invaluable perspective on scaling laws and their origins at Baidu, where some of the earliest work on large-scale distributed training took shape.

The researchers whose papers fill the bibliography of this book deserve particular acknowledgment. Practitioners and researchers who built the systems, measured the failures, and published what they learned discovered the principles taught here, rather than inventing them for this textbook. This book synthesizes their work into a coherent narrative. The debt is to them.

Support

The Harvard Data Science Initiative, Harvard Extension School, and the National Science Foundation supported this work; the Edge AI Foundation and ICTP supported educational outreach and scholarships; and our industry partners provided infrastructure and tooling that enabled practical experimentation.

At MIT Press, Susan Hartman believed in this project from the beginning and guided both volumes from an open-source experiment to published textbooks. Her editorial judgment and support made this book real. I am equally grateful to MIT Press for agreeing to keep this book available as open access. A textbook about a discipline shaped by the open-source community should be accessible to everyone in it.

For the complete and most up-to-date list of all GitHub contributors, please visit the online version at mlsysbook.ai. For those interested in contributing, please consult our [GitHub repository](#).

Every GitHub star is a signal that someone cares about this material, is learning from it, and believes the work matters. The online community of learners, with their questions, their curiosity, and their willingness to engage with an unfinished textbook, kept this project moving when the scope felt overwhelming.

Finally, I thank my wife and my children. I wrote this book in the hours that belonged to them: weekends that disappeared into revisions, evenings that stretched past midnight, mornings when I was present but not quite there. They never complained. They asked how the writing was going, brought me coffee, and gave me the space to finish. Whatever merit this book has, their patience and their support made it possible.

A Note on AI Assistance

Every chapter of this book was researched, written, and rewritten by me. I also used AI tools throughout. What follows is more than the disclosure MIT Press requires of authors who use AI. It is a statement of the standard I held the book to, and a claim about what authorship means when the tools are this capable.

The standard is traceability. Every quantitative claim in these pages originates in a Python computation cell whose source code ships with the book. Every citation has been verified against its primary source. Every cross-reference resolves to a stable anchor. Every number in prose was computed by a purpose-built [infrastructure modeling engine](#) developed for this textbook — not typed by hand. A pre-commit test suite — over thirty automated checks spanning unit consistency, inline-reference resolution, cross-reference integrity, notation canonicity, and citation hygiene — enforces these invariants on every commit. AI tools made parts of this rigor mechanically tractable. The enforcement infrastructure certifies it.

Authorship is thinking. Which concepts belong in this book and which do not. How to sequence the chapters so that each idea arrives only after the reader has the tools to understand it. Which worked examples to trace end-to-end, and which numbers to compute so the reader can verify the argument independently. What level to pitch each explanation at — rigorous enough for a graduate engineer, concrete enough for a student encountering systems thinking for the first time. Where students will get stuck, because I have taught this material and watched them get stuck. These are judgment calls that no tool can make, because they require knowing the reader. I used AI tools throughout this process to brainstorm framings, explore alternatives, and pressure-test my reasoning. The choices are mine.

In practice, AI was genuinely useful for writing code — the computation cells, the pre-commit checks, the worked examples that are essentially programs. It helped me survey literature I then read in the original, draft passages I then rewrote substantially, and audit the manuscript for consistency across hundreds of cross-references, thousands of index entries, and tens of thousands of lines of prose. The pattern throughout was the same: the tool proposes, the human ratifies.

This pattern is older than the present moment. In 1683 Joseph Moxon printed the first English-language manual on printing, *Mechanick Exercises on the Whole Art of Printing*, using the press it described. Three centuries later Donald Knuth wrote *The TeXbook* in TeX, the typesetting system he created so his own books could exist. A book about ML systems infrastructure, written without the infrastructure it describes, would be a contradiction. The toolmaker documents the tool with the tool.

The reliability gap I describe in section 1.4.1 — that fleet-scale ML systems cannot be made failure-free, only engineered to recover — applies to AI-assisted authoring with equal force. The standard I held this book to is the standard I want you to demand of every system you ship: the tool can propose, but only an engineer can ratify. MIT Press does not list AI tools as authors because they cannot assume ethical and legal responsibility for their work. The same is true of every engineered system. Authorship is the assumption of that responsibility, and it belongs to the human.

Notation

Machine Learning Systems spans **Machine Learning** (computer science/statistics) and **Systems** (computer architecture/hardware). Each field developed its notation independently, and many symbols mean different things depending on the community, paper, or literature using them. This collision creates real confusion when the disciplines merge. The conventions below establish a single notation for eliminating ambiguity.

Consider a simple statement: *“Increasing B improves throughput.”* To an ML researcher, B means batch size. To a hardware engineer, B means bandwidth. Both interpretations are correct in their respective fields, but in ML Systems we need both concepts in the same equation—hence the need for a single, consistent convention.

The Iron Law of ML Systems

THE fundamental performance equation of this book, introduced in the opening chapter, is:

$$T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}}$$

Each variable was chosen deliberately to avoid collision with standard ML terminology.

Symbol	Definition	Unit	Why This Symbol?
T	Time	seconds	Unambiguous. Wall-clock time for an operation.
D_{vol}	Data Volume	bytes	Avoids collision with D (Dataset Size). In scaling laws, D means training tokens. Here we need bytes moved through memory. The subscript disambiguates.
BW	Bandwidth	bytes/s	Avoids collision with B (Batch Size). Physics uses B for bandwidth, but every ML paper uses B for batch size. We preserve the ML convention.
O	Operations	FLOPs	Total floating-point operations. Clean in equations (vs. “Ops”).
R_{peak}	Peak Rate	FLOP/s	Avoids collision with P (Parameters). Roofline models use P for peak performance, but ML universally uses P for parameter count. We preserve the ML convention.
η_{hw}	Efficiency	—	Hardware utilization ($0 \leq \eta_{\text{hw}} \leq 1$). Avoids collision with learning rate (η).
L_{lat}	Latency	seconds	Avoids collision with $\mathcal{L}$ (Loss). Fixed overhead time (kernel launch, network RTT). The subscript distinguishes from the loss function.

Why these choices matter

Without careful notation, sentences become ambiguous:

“Reducing D improves performance.”

The sentence has two possible readings:

- Reducing **dataset size** (fewer training samples) can speed training but may reduce accuracy.
- Reducing **data volume moved** (for example, through compression or quantization) can speed inference, with accuracy effects that depend on the technique and calibration.

With our notation, we can write precisely:

“Reducing D_{vol} through FP32-to-INT8 quantization cuts parameter memory traffic to one quarter while D (training data) remains unchanged.”

Our notation makes such ambiguity explicit: “*BW limits throughput*” is unambiguous.

Subscripted variants

When a multi-letter quantity name takes a descriptive subscript (for example, distinguishing storage bandwidth from network bandwidth), wrap both the root and the subscript in `\text{}`:

- $\text{BW}_{\text{disk}}, \text{BW}_{\text{network}}, \text{BW}_{\text{accelerator}}$
- $D_{\text{vol}}, R_{\text{peak}}, L_{\text{lat}}, \eta_{\text{hw}}$
- $E_{\text{move}}, E_{\text{compute}}, E_{\text{total}}$

Without `\text{}`, math mode renders each letter as an italic variable and the spacing collapses to look like a product, not a label.

The Degradation Equation

The silent failure mode of ML systems is captured by the degradation equation introduced in the opening chapter. Some symbols below (such as τ) appear in chapter prose rather than in the block equation itself; defining them centrally keeps the canonical form unambiguous when they do appear.

$$\text{Accuracy}(t) \approx \text{Accuracy}_0 - \lambda \cdot \mathcal{D}(P_t \| P_0)$$

Symbol	Definition	Unit/Type	Notes
$\text{Accuracy}(t)$	Accuracy at Time t	Scalar	Model accuracy after the model has been deployed for time t .
Accuracy_0	Initial Accuracy	Scalar	Model accuracy at deployment time.
λ	Sensitivity	Scalar	Model sensitivity to distribution shift. Architecture-dependent. (<i>Not wavelength.</i>)
P_t	Current Distribution	Distribution	The data distribution at time t . (<i>Not parameters—use P for parameter count.</i>)
P_0	Training Distribution	Distribution	The data distribution at training time.
$\mathcal{D}(P_t \ P_0)$	Statistical Divergence	Scalar ≥ 0	Measures how far P_t has drifted from P_0 . Common choices: KL divergence, total variation, Wasserstein. (<i>Calligraphic to avoid collision with D = dataset size.</i>)
τ	Drift Threshold	Scalar > 0	Retraining is triggered when $\mathcal{D}(P_t \ P_0) > \tau$.

The Energy Corollary

The energy cost of ML workloads follows from the iron law of ML systems and decomposes as:

$$E_{\text{total}} \approx D_{\text{vol}} \times E_{\text{move}} + O \times E_{\text{compute}}$$

Symbol	Definition	Unit	Notes
E_{total}	Total Energy	joules	Total energy consumed by an ML workload, decomposed into data-movement and compute terms.
E_{move}	Energy per Byte Moved	joules/byte	Energy cost of data movement. Dominates total energy ($E_{\text{move}} \gg E_{\text{compute}}$).
E_{compute}	Energy per Operation	joules/FLOP	Energy cost of a single arithmetic operation.

Deep Learning Notation

We follow standard deep learning conventions (Goodfellow et al. 2016) with explicit disambiguation for systems variables.

Symbol	Definition	Dimensions/Type
B	Batch Size	Integer. The number of samples processed in parallel. (<i>Never bandwidth.</i>)
P	Parameters	Integer. The total count of trainable weights in a model. (<i>Never peak FLOP/s.</i>)
D	Dataset Size	Integer. Number of training samples or tokens. (<i>Never data volume in bytes—use D_{vol}.</i>)
S	Sequence Length	Integer. Number of tokens or time steps.
d	Hidden Dimension	Integer. Size of the hidden state vector.
d_{head}	Attention Head Dimension	Integer. Per-head hidden dimension in attention layers.
N_L	Number of Layers	Integer. Total number of layers in a network.
N_{heads}	Number of Attention Heads	Integer. Number of attention heads in a multi-head attention layer.
H_{KV}	Number of Key-Value Heads	Integer. Number of key-value heads in grouped-query or multi-query attention.
ℓ	Layer Index	Integer. Index for a layer. Use instead of bare L when indexing layers, since L collides with loss and latency.
$\mathcal{L}$	Loss Function	Scalar. The objective function minimized during training.
η	Learning Rate	Scalar. Step size for the optimizer. (<i>Never bare for hardware efficiency—use η_{hw}.</i>)
θ	Model Weights	Vector/Matrix. The set of all learnable parameters.
$p(x)$	Distribution	Probability mass/density for a random variable. Use lowercase $p(\cdot)$ for generic distributions to avoid collision with P (parameter count).
$p(y x)$	Conditional Distribution	Conditional probability/density. Use this form for generic label relationships; reserve P_0 and P_t for the degradation equation's training/current distributions.
$\Pr(E)$	Event Probability	Probability of an event E . Use for event statements such as $\Pr(\text{batch} = 0)$; use $p(x)$ and $p(y x)$ for distributions.

Local matrix algebra may use A , B , and C for operands when the equation explicitly introduces matrices (for example, GEMM $C = \alpha AB + \beta C$). This is a local linear-algebra convention, not a global override of B as batch size.

Performance, Serving, and Memory Notation

Reusable performance and serving quantities follow the same collision-avoidance rule as the iron law. Rates use R or descriptive Greek symbols; request counts use Q_{req} rather than overloading N ; queue utilization uses a subscripted ρ so bare ρ remains available for other ratio models.

Symbol	Definition	Unit/Type	Notes
I	Arithmetic Intensity	FLOP/byte	Workload FLOPs per byte moved. The roofline model uses I as the independent variable.
I_{ridge}	Roofline Ridge Point	FLOP/byte	$I_{\text{ridge}} = R_{\text{peak}}/\text{BW}$. Prefer this explicit form over starred shorthand so the meaning remains clear in prose.
R_{attain}	Attainable Compute Rate	FLOP/s	Roofline rate: $R_{\text{attain}} = \min(R_{\text{peak}}, I \times \text{BW})$. Uses R , not T , because this quantity is a rate.
MFU	Model FLOPs Utilization	Dimensionless	Useful model FLOP/s divided by available peak FLOP/s. Text acronym avoids overloading η .
r_{comp}	Compression Ratio	Dimensionless	Uncompressed size divided by compressed size. A compressed payload has size M/r_{comp} ; the subscript avoids bare C collisions.

Symbol	Definition	Unit/Type	Notes
Q_{req}	Request Concurrency	requests	Average in-flight requests in a stable serving system. Avoids collision with N as device count in distributed settings.
λ_{arr}	Arrival Rate	requests/s	Request arrival rate. The subscript avoids collision with λ as degradation sensitivity or failure rate.
T_{lat}	Request Time in System	seconds	End-to-end queueing/serving latency for Little’s Law. Distinct from L_{lat} , the fixed-latency term in the iron law.
$T_{\text{svc}}(B)$	Batch Service Time	seconds	Time to serve a batch of size B .
$\mu_{\text{eff}}(B)$	Effective Service Rate	requests/s	Batched service rate, typically $\mu_{\text{eff}}(B) = B/T_{\text{svc}}(B)$.
ρ_{serv}	Serving Utilization	Dimensionless	Queue/server utilization. Use instead of bare ρ , which is reserved for communication-computation ratio in distributed contexts.
M_{total}	Total Memory Footprint	bytes	Sum of explicit memory components; avoids bare M ambiguity.
M_{weights}	Weight Memory	bytes	Memory occupied by model parameters.
$M_{\text{gradients}}$	Gradient Memory	bytes	Memory occupied by stored gradients.
$M_{\text{optimizer}}$	Optimizer-State Memory	bytes	Momentum, variance, master weights, and related optimizer buffers.
$M_{\text{activations}}$	Activation Memory	bytes	Retained activations for the backward pass or serving intermediates.
s_{elem}	Element Storage Size	bytes/element	Bytes per stored tensor element.

Units and Precision

- **Physical units:** This book uses SI (metric) units throughout, including meters, kilograms, seconds, watts, and °C, consistent with standard engineering and scientific practice. Where source data was originally reported in imperial units, we convert to SI and note the original values parenthetically. A space always separates the number from the unit (for example, 100 ms, 2 TB/s).
- **Data and memory:** We use **decimal SI prefixes only**: KB = 10^3 bytes, MB = 10^6 , GB = 10^9 , TB = 10^{12} . We do not use binary-prefixed units in prose; all capacities, throughputs, and model sizes are reported in decimal units (for example, 80 GB, 2 TB/s, 102 MB).
- **Compute:** We distinguish operation counts from rates. Total work uses FLOPs (for example, GFLOPs, TFLOPs), while throughput uses FLOP/s with decimal prefixes (for example, GFLOP/s, TFLOP/s).
 - 1 TFLOP = 10^{12} FLOPs
 - 1 TFLOP/s = 10^{12} FLOPs per second
 - Arithmetic intensity conventionally uses FLOP/byte as a unit ratio (floating-point operations per byte moved). This is a ratio unit, not a total-work symbol or throughput symbol.
- **Currency:** Dollar amounts use the dollar sign (\$); unless otherwise noted, dollar-denominated costs are U.S. dollars (USD).
- **Precision:**
 - **FP64:** Double precision (8 bytes)
 - **FP32:** Single precision (4 bytes)
 - **TF32:** TensorFloat-32 (19-bit compute format, commonly stored as FP32)
 - **FP16:** Half precision (2 bytes, standard range)
 - **BF16:** Brain float (2 bytes, wide dynamic range)
 - **FP8:** Quarter precision (1 byte, E4M3 or E5M2 format)
 - **FP4:** 4-bit floating-point format
 - **INT8:** 8-bit integer (1 byte)

- **INT4**: 4-bit integer; lower integer precisions follow the same uppercase INT_n pattern (for example, INT3, INT2)

Quick Reference: Resolving Collisions

Common collision points in ML Systems literature include:

Symbol	ML Meaning	Systems Meaning	Our Convention
B	Batch Size	Bandwidth	Batch Size . Use BW for bandwidth.
P	Parameters	Peak FLOP/s	Parameters . Use R_{peak} for peak rate.
D	Dataset Size	Data Volume	Dataset Size . Use D_{vol} for bytes moved.
L	Loss	Latency	Loss ($\mathcal{L}$). Use L_{lat} for latency.
η	Learning Rate	Efficiency	Learning Rate . Use η_{hw} for efficiency.

The general principle: **ML conventions take precedence for single letters**; systems concepts get subscripts or multi-letter symbols. This reflects the primary audience (ML practitioners learning systems) and preserves compatibility with the vast ML literature.

Distributed Systems Notation

Distributed-systems work introduces a second layer of notation for coordination, communication, and reliability. Some symbols below are reserved for synchronization, repair, and gradient-sizing contexts; defining them centrally keeps the canonical form unambiguous when they appear. The central equation is the **Fleet Law** (the distributed step time law):

$$T_{\text{step}}(N) = \frac{T_{\text{compute}}}{N} + T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}}$$

Symbol	Definition	Unit	Notes
N	Number of Devices	Integer	Accelerator count in a distributed job. (<i>Not parameters—use P.</i>)
$T_{\text{step}}(N)$	Distributed Step Time	seconds	Wall-clock time for one training step at scale N .
T_{compute}	Single-Device Compute Time	seconds	Forward + backward pass on one device.
$T_{\text{comm}}(N)$	Communication Time	seconds	Time for collective operations (AllReduce, AllGather). Grows with N .
T_{overlap}	Overlapped Time	seconds	Communication hidden behind computation. Reduces effective overhead.
T_{sync}	Synchronization Time	seconds	Total nonoverlapped synchronization or coordination cost per step.
ρ	Communication-Computation Ratio	Dimensionless	$\rho = T_{\text{comm}}(N)/(T_{\text{compute}}/N)$. Values near or above 1 indicate communication-bound scaling.

The α - β communication model

Network communication time decomposes into a fixed latency and a bandwidth-dependent transfer:

$$T(n) = \alpha + \frac{n}{\beta}$$

Symbol	Definition	Unit	Notes
$T(n)$	Communication Time	seconds	Wall-clock time to transmit a message of size n across one link.
α	Network Latency	seconds	Fixed per-message overhead. (<i>Not learning rate—context disambiguates.</i>)
β	Link Bandwidth	bytes/s	Effective throughput per link.
n	Message Size	bytes	Size of the payload (for example, gradient tensor).
n^*	Crossover Point	bytes	$n^* = \alpha \cdot \beta$. Below n^* : latency-bound. Above: bandwidth-bound.

The LogGP extension

LogGP refines the α - β model by separating network latency, processor overhead, and long-message injection gaps. The standard names are short, but the book uses descriptive subscripts for the highest-collision term.

Symbol	Definition	Unit	Notes
$T_{\text{long}}(n)$	LogGP Long-Message Time	seconds	Transfer time for an n -byte long message. Reuses n from the α - β model.
L_{LogGP}	LogGP Network Latency	seconds	Standard LogGP latency parameter; subscript avoids bare L collisions.
o_{send}	Sender Overhead	seconds	Processor/NIC overhead to initiate a message.
o_{recv}	Receiver Overhead	seconds	Processor/NIC overhead to complete a message.
g	Message Injection Gap	seconds	Minimum interval between consecutive message injections.
G	Long-Message Gap per Byte	seconds/byte	Per-byte long-message gap; distinct from β link bandwidth.

Scaling efficiency

$$\eta_{\text{scaling}} = \frac{T_1}{N \times T_N} \leq 1$$

Symbol	Definition	Unit	Notes
η_{scaling}	Scaling Efficiency	Dimensionless	Fraction of ideal linear speedup achieved. 1.0 is the theoretical limit.
T_1	Single-Device Time	seconds	Baseline wall-clock time on one device.
T_N	N-Device Time	seconds	Wall-clock time on N devices.

Fault tolerance and reliability

System reliability degrades with scale. Assuming independent components with exponential failure distributions, the system reliability across N components is:

$$R_{\text{system}}(t) = e^{-N\lambda t}$$

The aggregate exponent uses the system-level rate $N\lambda$, where λ is the per-component failure rate under the independent, identical-component assumption. The exponent $N\lambda t$ is dimensionless, so t must use the same time unit as λ (hours, when λ comes from FIT-derived rates below).

The optimal checkpoint interval balances I/O cost against rework cost:

$$\tau_{\text{opt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$$

The formula uses *system-wide* MTBF (the failure interval for the whole job), not *component* MTBF; substituting the per-component value would overestimate τ_{opt} by $\sqrt{N}$. For dimensional consistency, T_{write} and $\text{MTBF}_{\text{system}}$ must be in the same time units. Industry-standard MTBF is reported in hours; to combine with seconds-scale write times, convert: $\text{MTBF}_s = \text{MTBF}_h \times 3600$. The result τ_{opt} then carries the same time unit chosen for the inputs.

Symbol	Definition	Unit	Notes
$R_{\text{system}}(t)$	Reliability Function	Probability	Probability of no failure across the whole system before time t .
λ	Per-Component Failure Rate	failures/hours	Per-component failure rate; the system-wide rate is $N\lambda$ under independent, identical components. The industry-standard reporting unit is FIT (failures per 10^9 device-hours): $\lambda_{\text{hour}} = \text{FIT} \times 10^{-9}$. (Not sensitivity—context disambiguates.)
MTBF	Mean Time Between Failures	hours	Average time between consecutive failures. $\text{MTBF}_{\text{system}} = \text{MTBF}_{\text{component}}/N$.
MTTF	Mean Time To Failure	hours	Component lifetime metric derived from FIT rates. Distinct from system-level MTBF when repair/replacement cycles are modeled.
MTTR	Mean Time To Repair	hours	Average recovery time after a failure.
τ_{opt}	Optimal Check-point Interval	seconds	Young-Daly formula. Minimizes total wasted time.
T_{write}	Check-point Write Time	seconds	Time to persist model state to storage.

Parallelism dimensions

3D parallelism partitions the training workload across three orthogonal dimensions:

$$N_{\text{total}} = d \times p \times t$$

Symbol	Definition	Unit	Notes
N_{total}	Total Device Count	Integer	Product of the three parallelism dimensions. The total accelerators across the job.
d	Data Parallelism	Integer	Number of model replicas. (Also <i>hidden dimension</i> —context disambiguates.)
p	Physical Pipeline Stages	Integer	Number of physical pipeline stages in model-depth partitioning.
t	Tensor Parallelism	Integer	Degree of intra-layer partitioning (model width). (Also <i>time</i> —context disambiguates.)
m	Microbatch Count	Integer	Number of microbatches used to fill and drain the pipeline.
b_{pipe}	Pipeline Bubble Fraction	Dimensionless	Fraction of pipeline GPU-time spent idle; avoids bare b .
V	Virtual Pipeline Stages per Device	Integer	Number of interleaved virtual chunks assigned to each physical pipeline stage.
M	Message Payload Size	bytes	Total size of a gradient, model-state, activation, or compressed message payload to communicate.

Fleet capacity factors

Fleet-scale capacity calculations compound local model efficiency, scaling efficiency, and operational goodput.

Symbol	Definition	Unit	Notes
f_{compute}	Useful Compute-Time Fraction	Dimensionless	$(T_{\text{compute}}/N)/T_{\text{step}}(N)$. Measures how much step time is useful local arithmetic after distribution.
f_{overhead}	Overhead Fraction	Dimensionless	Fraction of wall time lost to pipeline bubbles, checkpoints, failure recovery, maintenance, or other nonproductive overheads.
η_{goodput}	Goodput Ratio	Dimensionless	Fraction of allocated wall time that produces useful training work; often $\eta_{\text{goodput}} = 1 - f_{\text{overhead}}$.
R_{eff}	Effective Fleet Throughput	FLOP/s	$R_{\text{eff}} = (N R_{\text{peak}}) \times \text{MFU} \times \eta_{\text{scaling}} \times \eta_{\text{goodput}}$.

Compression economics

Compression models compare codec overhead against the communication time saved by reducing the payload.

Symbol	Definition	Unit	Notes
$T_{\text{transfer}}(x)$	Transfer Time for Payload x	seconds	Communication time for an x -byte payload under the relevant link or collective model.
$T_{\text{compressed}}$	Compressed Communication Time	seconds	Total time after encode, transfer of M/r_{comp} , and decode.
T_{encode}	Codec Encode Time	seconds	Local compression overhead before transfer.
T_{decode}	Codec Decode Time	seconds	Local decompression overhead after transfer.

Serving memory at scale

Symbol	Definition	Unit	Notes
M_{KV}	KV-Cache Memory	bytes	Key-value cache footprint for autoregressive serving.

Additional collision points

The distributed context introduces further symbol collisions beyond those noted in the base notation:

Sym-bol	ML Mean-ing	Distributed Meaning	Our Convention
N	—	Number of Devices	Device Count in distributed context (accelerators, not host nodes).
α	—	Network Latency	Network latency in α - β model. Context disambiguates.
λ	Sensitivity	Failure Rate	Context-dependent. Sensitivity in degradation; failure rate in reliability.
d	Hidden Dimension	Data Parallelism Degree	Context-dependent. Parallelism in 3D notation; hidden dim in architectures.

Sym- bol	ML Mean- ing	Distributed Meaning	Our Convention
t	—	Tensor Paral- lelism/Time	Context-dependent. Tensor parallelism in 3D notation; time in reliability.
τ	Drift Thresh- old	Local Inter- val/Delay	Avoid bare reuse. Use τ_{ckpt} for generic checkpoint intervals, τ_{opt} for the Young-Daly optimum, and τ_{stale} for gradient staleness.

Additional units

- **Network throughput:** Reported in both bytes/s (GB/s, TB/s) and bits/s (Gbps) depending on convention. InfiniBand and Ethernet specifications use Gbps; application-level throughput uses GB/s. We note the convention on first use.
- **Power in sustainability contexts:** Physical power may use explicitly subscripted $P_{\dots}$ variables (for example, P_{IT} , P_{dynamic} , P_{average}) when the surrounding section is about power or energy. Bare P remains reserved for parameter count.

MAIN MATTER

Introduction

Purpose

Why do the engineering principles that work on single machines break down at production scale?

Machine learning at scale has a physics of its own. On one node, performance is governed by the memory wall: data must reach the accelerator fast enough to keep the math busy. In a distributed cluster, that same problem stretches across machines. Data must move through network links between racks, and the slowest shared crossing can limit the entire job. Hardware failures also change character. When a single-accelerator training job fails, it is an inconvenience; when one node in a 10,000-node cluster fails, it can stall the machine learning fleet this chapter defines. This discontinuity explains why mastery of single-machine ML is no longer sufficient: scale is not more of the same, but fundamentally different engineering terrain requiring different principles, different architectures, and different ways of thinking about what makes systems work. That terrain carries a societal dimension that small models do not, because its impact is amplified by the billions of users these systems serve: when a local model exhibits bias, the harm is contained; when a foundation model exhibits bias, it propagates through digital life. In C³ terms, the discipline this book builds is the physics of distribution, where compute, communication, and coordination turn algorithmic choices into questions of topology, fault tolerance, security, and governance. Each Volume II part introduces the principles for one layer of that progression: fleet foundations, distributed execution, deployment at scale, and responsible operation. Later chapters return to those Volume II principles as the system grows, without collapsing them into the Volume I principle set.

Learning Objectives

- Explain how Compute, Communication, and Coordination replace single-node Data-Algorithm-Machine constraints in production fleets
- Apply the fleet law to estimate coordination tax and classify scaling regimes
- Analyze scaling-law limits when reliability, network bandwidth, power, or governance constraints dominate growth
- Diagnose fleet-scale distribution risks using reliability gaps, consistency-availability trade-offs, communication intensity, and routine failure rates
- Synthesize fleet-stack design principles across physical infrastructure, operational control, and societal governance

1.1 The Scale Moment

MACHINE learning on a single accelerator is governed by local memory hierarchy and arithmetic intensity: the physics of silicon. The boundary left open by Volume I appears when that local machine is no longer the system. As models move from research prototypes to global services, the binding constraints move outward into racks, networks, power delivery, and recovery machinery. That change is not a smooth extrapolation; it is the **Scale Moment**.

The scale moment is the physical and operational transformation that occurs *when* models cross the three fundamental walls: memory, network, and energy. These three walls are the canonical triad this volume navigates by. On one accelerator the memory wall binds; as we move from a single GPU to a machine learning fleet comprising thousands of nodes, the network wall replaces the local memory wall as the primary performance bottleneck. Its hard limits are bisection bandwidth, the aggregate bandwidth across the narrowest cut that splits the fleet, and speed-of-light latency. Serving billions of users then hits the energy wall, making thermodynamic efficiency a first-order engineering requirement. Crossing those walls opens a reliability gap alongside them, making hardware failure a routine event rather than a rare exception.

Between 2012 and the mid-2020s, public and third-party estimates place training compute growth from roughly 10^{18} FLOPs for AlexNet to approaching 10^{25} FLOPs for leading large models, roughly seven orders of magnitude. The difference is qualitative, not merely quantitative: Compute, Communication, and Coordination now turn algorithmic choices into questions of topology, fault tolerance, security, and governance.

Consider a GPT-4-class training scenario using a hypothetical A100-class cluster of 25,000 GPUs running for 90 days. These values are illustrative rather than disclosed by OpenAI (OpenAI et al. 2023). In a cluster of this size, the probability of at least one failure over an interval t , $\Pr(\text{failure before } t) = 1 - e^{-t/\text{MTBF}_{\text{system}}}$, becomes a binding constraint. The worked example below establishes the arithmetic for one cluster; section E.1.2 formalizes the MTBF cascade that governs failure rates across multi-thousand-GPU fleets, so a reader can predict the interruption cadence for any fleet size.

Fleet reliability collapses as node count climbs.

Napkin Math 1.1: Scale and reliability

Problem: A training run for a GPT-4-class model uses 25,000 GPUs. If each individual GPU has a mean time between failures (MTBF) of 50,000 hours (the canonical data center-grade figure used for fleet-scale reliability examples), how often will the training job be interrupted by hardware failure?

Math:

1. **System MTBF:** The system MTBF is the component MTBF divided by the number of independent GPUs. With this scenario's values, 50,000 hours divided by 25,000 GPUs is about 2 hours.
2. **Daily failure rate:** 24 hours divided by 2 hours is about 12 failures per day.

3. **Total annual failures:** 25,000 GPUs times (8,760 hours divided by 50,000 hours) is about 4,380 failures per year.

Systems insight: In this regime, the system is always in a state of partial failure. Traditional software recovery (manual restart) collapses; the system must be architected for fault tolerance as a first-class citizen. Hardware can no longer be treated as a reliable abstraction; it is a probabilistic resource that requires constant, automated state preservation (checkpointing).

Meta’s published Llama 3 training run shows the same reliability arithmetic in a real large-scale system.

📌 War Story 1.1: The training run that failed every few hours (2024)

Context: Meta reports training Llama 3 405B on 16,384 H100 GPUs for a 54-day pretraining run (Dubey et al. 2024).

Failure mode: At that scale, failures were not rare disruptions. The run experienced 419 unexpected interruptions, averaging one interruption every few hours.

Consequence: Training at that scale became an exercise in continuous recovery: checkpointing, automated diagnosis, and restart workflows determined whether the cluster produced useful model progress or burned time waiting for humans.

Systems lesson: The scale moment turns reliability from a hardware specification into a distributed-systems design requirement. A fleet-scale model is trained by the recovery machinery as much as by the optimizer.

The recovery machinery that defined the Llama 3 run exists because cluster sizes exploded; to see why a run now needs hundreds of restart cycles, it helps to trace the compute trajectory that pushed fleets to this scale. The history of machine learning is defined by scale: each major capability leap has emerged from the ability to apply computation at previously impossible scales, making systems engineering central to AI advancement.

Compute requirements have grown exponentially. AlexNet trained on two GTX 580 GPUs for approximately 5–6 days (Krizhevsky et al. 2012). BERT required 64 Tensor Processing Unit (TPU)¹ chips for 4 days, roughly 6,144 chip hours (Devlin et al. 2019).

GPT-3 consumed an estimated 3.14×10^{23} FLOPs during training on V100 GPUs in a Microsoft high-bandwidth cluster (Brown et al. 2020). The surrounding Microsoft infrastructure for this era reached roughly 10,000 GPUs, which is the cluster-size anchor used in figure 1.1. PaLM trained on 6,144 TPU v4 chips for roughly 60 days, consuming approximately 10^{24} FLOPs (Chowdhery et al. 2022). OpenAI’s GPT-4 report did not disclose model size, training hardware, or training compute, so the GPT-4-class scenario in this section should be read as illustrative rather than a published configuration (OpenAI et al. 2023). These examples sit within the rapid training-compute growth trend documented by earlier compute-trend studies (Amodei and Hernandez 2018; Sevilla et al. 2022). Table 1.1 makes the scale shift explicit: training budgets move from single-machine experiments into distributed systems where hardware count, wall-clock time, and operational coordination are part of the model design.

Table 1.1: Training Compute Evolution: Growth in hardware scale and training duration across published landmarks and an illustrative GPT-4-class scenario, showing why distributed systems become central as training budgets move from 10^{18} -scale to the largest training runs.

Model	Year	GPUs/TPUs	Training Time	Estimated FLOPs
AlexNet	2012	2 GPUs	5–6 days	$\sim 10^{18}$
BERT-Large	2018	64 TPUs	4 days	$\sim 10^{20}$
GPT-3	2020	1,024 V100 GPUs (run est.)	at least 29 days	3.14×10^{23} FLOPs
PaLM	2022	6,144 TPUs	~60 days	$\sim 10^{24}$

¹ | **Tensor Processing Unit (TPU):** Google’s custom ASIC, built around a 256×256 systolic array, a grid of multiply-accumulate cells that passes partial sums between neighboring cells, trading GPU flexibility for 15–30× better performance-per-watt on matrix-heavy ML workloads. The fleet-scale consequence is *what* matters here: TPU v4 pods reach 1.1 EFLOP/s aggregate, but their dedicated Inter-Chip Interconnect (ICI), at 4,800 Gb/s per chip, is *what* makes them a single distributed computer rather than a collection of fast chips. Without that interconnect, BERT’s 64-chip training would have been communication-bound long before it was compute-bound.

Model	Year	GPUs/TPUs	Training Time	Estimated FLOPs
GPT-4-class scenario	2023	~25,000 GPUs (illustrative)	~90 days (illustrative)	~10 ²⁵ scenario

Training compute is only one dimension. Figure 1.1 traces the related growth in cluster size itself by plotting the number of accelerators used to train landmark models over the past decade.

Figure 1.1: The Cluster Size Explosion: Number of accelerators used to train landmark models, 2012–2024. Verified counts from published papers are shown as filled circles; the GPT-3 estimate (hollow marker) reflects approximate cluster size from Microsoft infrastructure announcements rather than a precise published count. The dashed trend line indicates approximately 2× annual growth in cluster size, a rate that outpaces Moore’s Law and motivates the infrastructure challenges developed throughout the book.

Figure 1.1 reveals that cluster sizes have grown by roughly four orders of magnitude in just over a decade, from two GPUs for AlexNet to over 16,000 H100s for Llama 3. This empirical trajectory is the foundation of the scale moment: leading models have required far larger accelerator fleets than earlier deep-learning landmarks. The curve alone, however, does not explain *which* constraint breaks first. Large language-model training, recommendation serving, and federated mobile learning all encounter fleet scale, but each stresses a different part of the system.

 Lighthouse 1.1: Lighthouse archetypes at scale

Lighthouse Archetypes are the canonical workloads that keep the scale moment concrete throughout this book. At this point, their role is to show that “more machines” is not one engineering problem: the dominant constraint depends on what must cross the fleet boundary. The full roster with the C³ taxonomy mapping and binding-constraint analysis appears at section 1.6.1.

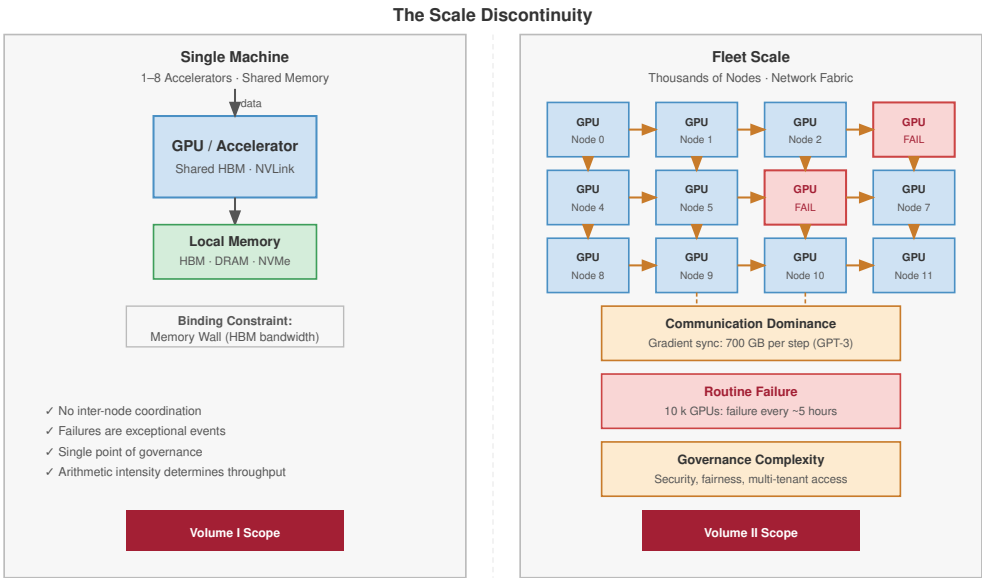

- **Archetype A (GPT-4/Llama-3):** Very large language models move from memory bounds on one device to multi-node model parallelism and pipeline parallelism, so communication becomes the bottleneck.

- **Archetype B (DLRM at Scale):** Deep Learning Recommendation Model (DLRM) workloads move from fitting embedding tables in local memory to **Embedding Sharding** across hundreds of nodes, so sparse all-to-all traffic becomes the bottleneck.
- **Archetype C (Federated MobileNet):** Mobile inference and on-device adaptation move from one device to federated learning across billions of devices, so unreliable clients, privacy constraints, and stragglers become the bottleneck.

These archetypes turn the growth curve into an engineering question. The same increase in accelerator count can produce a network wall, an embedding-shard bottleneck, or a fleet of unreliable edge participants. Where the archetypes focus attention on the workload, a parallel set of systems lenses does the same for the substrate, directing attention to data-center physics, network topology, and distributed consistency. Combined with the rise of federated learning², that diversity has transformed ML from a discipline where algorithms dominate to one where systems engineering determines success. A sophisticated algorithm that cannot scale often provides less practical value than a simpler algorithm deployed efficiently across scalable infrastructure.

The transition from single-machine to distributed training introduces qualitative changes in system behavior. Figure 1.2 contrasts the two regimes: the single-machine world governed by the memory wall vs. the fleet-scale world governed by communication dominance, routine failure, and governance complexity.

2 | **Federated Learning:** A distributed learning paradigm where models are trained across millions of decentralized edge devices holding local data. Chapter 11 analyzes the privacy and coordination challenges of federated fleets.

Scale changes the nature of the problem, not just its magnitude.

Figure 1.2: The Scale Discontinuity: Single-machine systems (left) are governed by local memory bandwidth and operate with no inter-node coordination, exceptional failures, and a single point of governance. Fleet-scale systems (right) introduce communication dominance, routine hardware failure, and governance complexity as first-order engineering constraints.

The discontinuity captured in figure 1.2 is qualitative, not merely quantitative: at fleet scale, the binding constraint shifts from silicon to the network fabric, and the engineering discipline shifts from optimization to resilience. The unit of compute is no longer a single server but a **Machine Learning Fleet**: a massive, interconnected distributed system that must act as a single coherent engine.

Definition 1.1: Machine learning fleet

Machine Learning Fleet is a distributed system of thousands of interconnected accelerators, storage arrays, and network fabrics designed to operate as a single coherent computer.

1. **Significance:** It coordinates synchronous state across all nodes, where the total time T is governed by the Slowest Worker (Straggler). It requires Bisection Bandwidth (BW_{bisect}) that scales with the aggregate compute capacity (R_{peak}) of the fleet.
2. **Distinction:** Unlike Traditional Clusters (for example, Spark, MapReduce) that manage independent, asynchronous jobs, an ML Fleet operates under Synchronous Tight Coupling: all workers must reach the training-step barrier before any can advance, so near-perfect reliability is required to maintain throughput.
3. **Common pitfall:** A frequent misconception is that an ML Fleet is “just more servers.” In reality, it is a Warehouse-Scale Computer (WSC) where the network is the system bus and the orchestrator is the operating system.

3 | **Bisection Bandwidth** (from graph theory): The minimum aggregate bandwidth of all links that, if cut, would partition the network into two equal-sized sets of nodes. In distributed ML, this “worst-case” cut determines the cluster’s synchronization bottleneck: an AllReduce synchronization can move no faster than the bisection bandwidth, regardless of how many GPUs are added.

4 | **Hardware Failure Rates at Scale:** Individual GPUs fail at 1–2 percent annually under typical conditions, but rates exceed 9 percent under intensive training workloads. Multiply by fleet size and failure becomes routine: Meta reported 419 unexpected interruptions during Llama 3’s 54-day training on 16,384 H100s, roughly one every three hours, with GPU and HBM3 faults causing over half. Automated checkpointing and recovery maintained over 90 percent effective training time, illustrating that at fleet scale the engineering challenge shifts from preventing failure to minimizing recovery latency.

5 | **InfiniBand (IB):** Born in 1999 from the merger of Intel’s NGIO and the Compaq/IBM Future I/O initiatives, InfiniBand was originally designed to replace the PCI bus. Its defining feature for ML is RDMA (Remote Direct Memory Access), which bypasses the OS kernel to transfer data directly between application memory on different machines at microsecond-scale latency. HDR IB provides about 25 GB/s line-rate bandwidth per link; NDR reaches about 50 GB/s. This bandwidth gap compared with common Ethernet links determines whether large-model training is compute-bound or communication-bound.

As systems scale beyond a single node, a fundamental physical constraint emerges: the **bisection bandwidth wall**³, which limits how fast data can cross the network midpoint. At fleet scale, networking often determines model throughput more than compute does.

On a single GPU, training proceeds deterministically: the same code, data, and random seed produce identical results. At the scale of thousands of GPUs, new phenomena emerge. Network partitions can split clusters into groups that train independently, causing model divergence. Stragglers (workers that process data slower than peers due to hardware variation or thermal throttling) can bottleneck entire training runs. Hardware failures that occur once per machine-year become daily events when operating 10,000 machines⁴. Systems must checkpoint frequently enough that losing a day’s progress becomes acceptable rather than catastrophic.

These scale-induced challenges have driven infrastructure investment by large AI organizations. Meta’s Research SuperCluster (RSC), announced in 2022, contained 16,000 NVIDIA A100 GPUs connected by 200 Gb/s InfiniBand⁵ networking (AI 2022). Google’s TPU v4 pods contain 4,096 chips with 1.1 EFLOP/s of aggregate compute capacity (Zu et al. 2024). Microsoft’s Azure supercomputer for OpenAI reached more than 10,000 GPUs in 2020, and later Azure AI data center announcements describe tens-of-thousands-GPU training fabrics (Langston 2020; Microsoft 2025). The scale of the models dictates the scale of the infrastructure. Section D.1 catalogs these interconnect bandwidth constants and feeds them into the α - β communication model, which lets a reader turn a link’s bandwidth and latency into a predicted transfer cost.

The scale moment establishes the *why*: exponential growth in compute demand forces ML systems beyond any single machine, creating communication dominance, routine failure, and governance obligations. The next question is *how* to organize the engineering response. Distributed systems frameworks designed for independent tasks cannot satisfy the tight coupling that ML training demands; a different architectural hierarchy is needed.

1.2 The Fleet Stack: A Hierarchy of Architecture

Apache Spark (Zaharia et al. 2016) processes independent data partitions; a web microservice handles isolated requests. The Machine Learning Fleet does neither. Its workload requires synchronous state updates across thousands of accelerators every few hundred milliseconds, a coupling intensity that existing distributed frameworks were never designed to sustain. The workload characteristics of ML systems differ fundamentally from traditional distributed systems, even though the underlying hardware (network, compute, storage) is identical. To reason about these differences systematically, this book formalizes the engineering crux of scale as a four-layer stack, the fleet stack, which transforms raw cluster resources into global-scale AI applications.

Figure 1.3 visualizes the transition from single-node to fleet. The left side of the diagram summarizes the single-node regime: 1–8 accelerators connected by shared memory, where the binding constraint is the memory wall. The scaling arrow crosses into the distributed fleet regime, where thousands of nodes coordinate across a high-speed switch fabric and the bottleneck shifts to the bisection bandwidth wall: network congestion and message-passing latency dominate.

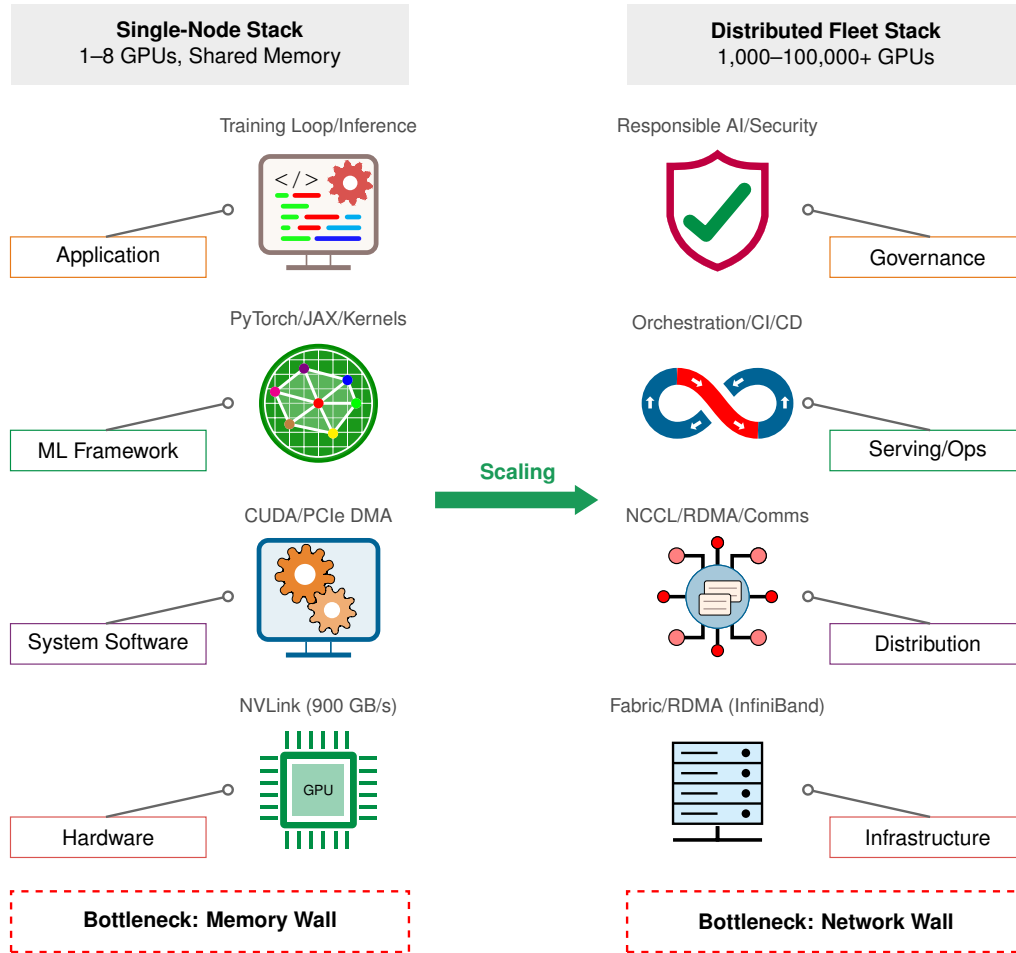

Figure 1.3: The Scaling Regimes of ML Systems: Machine learning engineering is partitioned into two distinct physical regimes. Single-node systems are limited by local memory bandwidth (memory wall), while distributed fleets are limited by network communication (bisection bandwidth wall). Mastery of intra-node data movement is the prerequisite for distributed scaling.

The stack architecture in figure 1.3 does not change when we scale: every ML system still has hardware, a system envelope, a workload, and a mission. *What* changes is the physics at each layer. Read the figure from bottom to top. At the bottom row, Hardware (NVLink at 900 GB/s within one node) becomes Infrastructure (InfiniBand RDMA fabric spanning racks at 400 Gb/s per link), and the bottleneck shifts from the memory wall to the bisection bandwidth wall. One row up, System Software (a single CUDA runtime managing PCIe DMA) becomes Distribution (NCCL and RDMA libraries coordinating thousands of processes across the fabric).

The upper two layers undergo an equally profound transformation. ML Framework (PyTorch or JAX executing a training loop on one node) becomes Serving/Ops (orchestration and continuous integration/continuous deployment (CI/CD) pipelines that schedule distributed jobs and manage rolling deployments). At the top, Application (a single training script or inference service) becomes Governance (responsible AI policy, security auditing, and multi-tenant access control), because fleet-scale deployment introduces organizational concerns absent from a single machine. Four layers compose the fleet stack:

1. **Infrastructure** (Hardware, the Engine): The physical foundation. This layer defines the fleet’s raw capabilities: per-node R_{peak} and BW, interconnected by InfiniBand RDMA fabric. The

recurring hardware anchor for this introduction is the NVIDIA H100, which serves as a concrete reference accelerator rather than an abstract placeholder.

2. **Distribution** (Systems, the Car): The communication substrate. This layer defines the cluster envelope: NCCL, the collective library that implements reductions and broadcasts on GPU fabrics; RDMA collectives that coordinate thousands of accelerators; bisection bandwidth; power usage effectiveness (PUE), the facility-energy overhead above IT load; and failure rates (MTBF).
3. **Serving/Ops** (Workloads, the Route): The orchestration layer. This layer manages the mathematical workload sharded across the cluster ($O, D_{\text{vol}}, \text{CI}$) through deployment pipelines and scheduling, where O is local operation count, D_{vol} is data volume, and CI previews the communication-intensity ratio: network bytes per local FLOP. We use Lighthouse Workloads like GPT-4 and DLRM.
4. **Governance** (Missions, the Destination): The mission context. This is the top of the stack, where responsible AI policy, security, and multi-tenant access control shape fleet-wide behavior. A mission (such as Frontier Model Training) introduces high-level requirements (for example, “99.99 percent service availability”) that dictate the configuration of every layer below.

This hierarchy ensures that every distributed engineering decision is grounded in its “Mission Context.” For example, the Frontier Training mission instantiates Archetype A (GPT-4/Llama-3) from the volume’s canonical roster (section 1.6.1), and operates on a cluster of H100 hardware. By standardizing these protagonists, we ensure that the “Physics of Scale” remains traceable across every chapter.

1.2.1 Traditional vs. ML fleet dynamics

Traditional systems (for example, a search engine or a banking database) optimize for independent, asynchronous tasks. A web server handles millions of requests, each isolated from the other. When one request fails, the others continue. This model, exemplified by systems like **MapReduce** (Dean and Ghemawat 2004), achieves scale by partitioning data into independent chunks that require minimal coordination.

The Machine Learning Fleet, by contrast, operates under **Synchronous Tight Coupling**. While the parameter server architecture (Li et al. 2014) introduced ways to manage distributed state, large synchronous models often require even tighter synchronization to maintain performance. Iterative statefulness makes ML training repeat the same math millions of times while updating a massive shared state, the model weights, rather than processing independent one-and-done jobs. Barrier synchronization means that 10,000 GPUs in a synchronous training step must wait for the slowest worker before any can proceed, so a 10 percent performance drop on one node can reduce the entire cluster’s throughput by 10 percent. Bisection bandwidth dominance makes ML training bandwidth-bound rather than user-latency-bound, because gigabytes of gradient data must cross the network every second and require non-blocking topologies that traditional data centers rarely implement.

Figure 1.4 illustrates this contrast directly: in MapReduce, workers write independently to shared storage and a straggler delays only its own partition, whereas in the ML Fleet, every worker must arrive at an AllReduce barrier before the training step can proceed.

The barrier synchronization pattern in figure 1.4 explains *why* ML fleets cannot borrow fault-tolerance strategies from MapReduce: in a barrier-coupled system, every worker’s progress depends on every other worker’s health.

Checkpoint 1.1: The fleet mindset

These questions check whether the fleet mindset is clear:

- ☐ **Straggler impact:** Explain why a single slow worker (straggler) has a disproportionate impact on a synchronous ML training job compared to a MapReduce job.
- ☐ **Bisection bottleneck:** Identify whether traditional web serving or ML training is more likely to make bisection bandwidth the primary performance bottleneck.

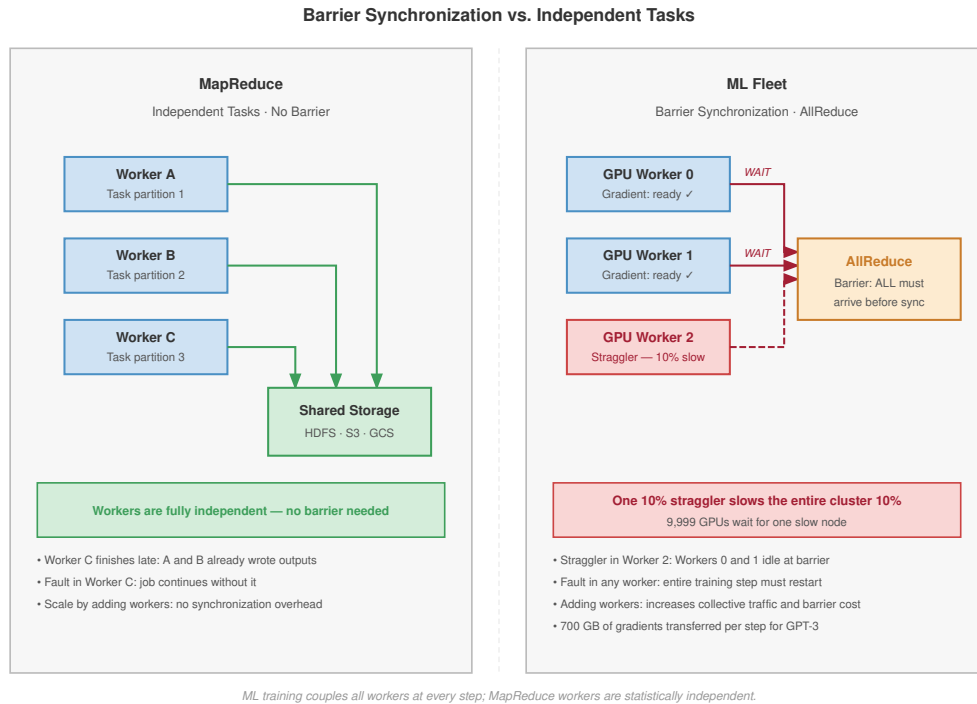

Figure 1.4: Barrier Synchronization vs. Independent Tasks: MapReduce workers (left) operate independently, writing results to shared storage without coordination. A straggler delays only its own output. ML Fleet workers (right) must synchronize gradients at an AllReduce barrier every training step, meaning a single 10% straggler slows the entire cluster by 10%.

- ☐ **Tight coupling:** Explain Synchronous Tight Coupling and connect it to the global barrier at the end of each training step.
- ☐ **Linear speedup myth:** Classify the claim as true or false: adding more GPUs to a training job always results in a linear speedup of the training process.

1.2.2 The shift to the warehouse-scale computer

The ML Fleet demands the **Warehouse-Scale Computer (WSC)**⁶ perspective. In traditional computing, the data center is a building that *houses* many computers. In the ML Fleet, the data center *is* the computer.

- **Network Fabric:** The system bus.
- **Distributed Storage:** The local disk.
- **Fleet Orchestrator:** The operating system.

Mastering this material requires making this mental shift: the engineer is no longer writing code for a CPU but writing logic for a 100-Megawatt computer spanning thousands of racks. The warehouse-scale computer is a common paradigm for large models, while alternative architectures like **wafer-scale engines** attempt to collapse this entire hierarchy back into a single piece of silicon, trading the modularity of a distributed cluster for the extreme bandwidth of on-chip communication.

1.2.3 Communication becomes dominant

These workload characteristics produce two further consequences at scale, both expressions of the canonical triad introduced at the scale moment: communication becomes the dominant cost (the network wall), and failure becomes routine (the reliability gap that accompanies it). At small scale,

⁶ | **Warehouse-Scale Computer (WSC):** Barroso and Hölzle, later with Clidaras, framed the data center itself as the computer. For ML fleets, power delivery, cooling topology, optical network layout, and bisection bandwidth become first-order constraints; a 100 MW facility can limit training throughput more than any single accelerator's TFLOP/s.

Gradient synchronization becomes the defining cost of distributed training.

computation dominates. Training a model on a single GPU spends most of its time performing matrix multiplications. Communication overhead is a small fraction of total time.

At large scale, *communication dominates*. Distributed training requires synchronizing gradients across workers after each batch. For a model with 175B parameters, FP32 gradients occupy about 700 GB before any collective algorithm is applied. In Ring All-Reduce, each worker sends and receives roughly $2(N-1)/N$ times the gradient tensor size, because each gradient byte makes about two trips around the ring, one to reduce and one to broadcast back; Chapter 6 derives this factor. Network traffic therefore depends on precision, worker count, and collective implementation, and on slower interconnects communication can consume a large fraction of each iteration rather than a negligible one.

This ratio explains *why* distributed training systems optimize communication so aggressively. **Horovod** uses Ring All-Reduce, NCCL integration, and Tensor Fusion to improve collective communication (Sergeev and Balso 2018); **Megatron-LM** applies model parallelism (Shoeybi et al. 2019); and **ZeRO** reduces memory redundancy (Rajbhandari et al. 2020). For the present argument, the important mapping is role-based: Horovod represents the collective runtime, NCCL the GPU communication backend, Tensor Fusion the gradient-fusion path, Megatron-LM model partitioning, and ZeRO optimizer-state sharding. At fleet scale, these techniques are requirements for viability, not optional performance improvements.

1.2.4 Failure becomes routine

The reliability arithmetic established at the scale moment already showed the second consequence: with thousands of GPUs, hardware fails every few hours, manual intervention becomes impossible, and the system must self-heal through frequent checkpointing, redundant workers, and automated recovery. The formal availability model and its architectural consequences follow in section 1.4.1.

Communication dominance and routine failure are consequences of the scale moment, but they do not explain *what* drives the relentless growth in fleet size. The answer lies in a set of empirical relationships that connect model quality to resource investment, relationships that have made warehouse-scale infrastructure an economic necessity rather than an engineering luxury.

1.3 AI Scaling Laws

Training GPT-3 consumed roughly 3×10^{23} floating-point operations (Brown et al. 2020). Public GPT-4-class training estimates are often on the order of 10^{25} FLOPs, although OpenAI did not disclose the actual training compute or hardware configuration (OpenAI et al. 2023; SemiAnalysis 2023). These estimates matter here because each order-of-magnitude increase in compute demanded a corresponding expansion of the Machine Learning Fleet.

This pattern is not coincidental. Rich Sutton’s “bitter lesson” articulated the underlying principle: performance in machine learning is primarily driven by applying general methods at massive scale rather than encoding human knowledge into algorithms (Sutton 2019). Scaling laws formalize this observation quantitatively: model loss improves sublinearly as a power-law function of compute, dataset size, and parameters, $\mathcal{L}(X) \propto X^{-\alpha_{\text{scale}}}$ (Kaplan et al. 2020; Hoffmann et al. 2022). Each equal-sized loss improvement therefore requires disproportionately more resources, a systems consequence this volume later names as the universal scaling law. Each scaling dimension (parameters, data, and compute) interacts with infrastructure constraints differently, making multi-dimensional efficiency optimization essential at production scale.

1.3.1 Empirical evidence for scaling laws

The rapid evolution in AI capabilities since the late 2010s exemplifies this scaling trajectory. GPT-1 (2018) contained 117 million parameters and performed basic sentence completion. GPT-2 (2019) scaled to 1.5 billion parameters and achieved coherent paragraph generation.

GPT-3 (2020) expanded to 175B parameters and achieved sophisticated text generation across diverse domains. Each increase in model size brought substantially improved capabilities at exponentially increasing costs.

The pattern extends beyond language models. In computer vision, parameter counts climbed roughly an order of magnitude from AlexNet (2012) to large vision transformers, and each generation

traded better accuracy for proportionally more compute and training data, the same coupling that forced vision training onto multi-accelerator infrastructure.

The scaling hypothesis underlies this progress: larger models capture more intricate data patterns, yielding improved accuracy and generalization. This trajectory, however, introduces critical resource constraints. Training GPT-3 required approximately 3.14×10^{23} floating-point operations, equivalent to running a consumer gaming PC continuously for hundreds of years, at substantial financial and environmental costs.

These resource demands reveal *why* scaling laws are necessary for efficient resource allocation. Figure 1.5 traces *how* computational demands of training large models have escalated at an unsustainable rate, growing faster than Moore’s Law improvements in hardware.

Figure 1.5: Model Training Compute Trends: Training compute has grown exponentially, accelerating dramatically in the deep learning era. The fitted trends shift from roughly $1.4\times$ per year before 2010 to roughly $4\times$ per year inside the deep learning era, both far steeper than Moore’s Law (~ 2 years). The fastest stretch was steeper still: within the 2012–2019 frontier subset, compute doubled approximately every 3.4 months. This trajectory explains *why* efficiency has become a strategic imperative rather than an optional optimization.

These scaling relationships provide a quantitative framework for navigating the trade-offs. Model performance follows power-law relationships where improvements are consistent but exhibit diminishing returns. Optimal resource allocation therefore requires coordinating model size, dataset size, and computational budget rather than scaling any single dimension in isolation. The computational characteristics that drive these workloads’ resource demands determine *how* they stress distributed infrastructure.

🔍 Systems Perspective 1.1: Transformer compute refresher

Transformers process sequences using self-attention mechanisms that compute relationships between all token pairs. This architecture’s computational cost scales quadratically with sequence length ($\mathcal{O}(S^2)$ where S is sequence length), making resource allocation particularly critical for language models. The term “FLOPs” (floating-point operations) quantifies total computational work, while “tokens” represent the individual text units (typically subwords) that models process during training.

1.3.2 Compute-optimal resource allocation

Empirical studies of large language models (LLMs) reveal a key insight. For any fixed computational budget, there exists an optimal balance between model size and dataset size (measured in tokens⁷)

⁷ | **Tokens:** Subword units produced by algorithms like Byte-Pair Encoding (BPE), which iteratively merges the most frequent character pairs in a corpus. Token vocabulary size creates a direct systems trade-off: larger vocabularies can reduce sequence length for some languages and domains, but they expand the embedding table roughly in proportion to vocabulary size. GPT-3 used a 50,257-token vocabulary; moving to 100K+ tokens in newer models therefore trades tokenization efficiency against additional embedding memory.

that minimizes training loss.

Figure 1.6 illustrates this principle through three related views. The left panel shows IsoFLOP curves where each curve corresponds to a constant number of floating-point operations (FLOPs⁸) during transformer training. The valleys in these curves identify the most efficient model size for each computational budget. The center and right panels reveal how the optimal number of parameters and tokens scales predictably as computational budgets increase, confirming that compute-optimal training requires coordinated scaling. The annotated markers extrapolate those fits to a frontier-scale budget near 10^{24} FLOPs, where the compute-optimal point lands at roughly 63 billion parameters trained on roughly 1.4 trillion tokens. That pairing is the roughly 20 tokens per parameter Chinchilla ratio in action: parameters and tokens grow together rather than either dimension racing ahead.

Figure 1.6: Optimal Compute Allocation: For fixed computational budgets, language model performance depends on balancing model size and training data size; the left panel maps training loss across parameter counts, identifying an efficiency sweet spot for each FLOP level. The center and right panels quantify how optimal parameter counts and token requirements scale predictably with increasing compute, demonstrating the need for coordinated scaling of both model and data to maximize resource utilization in large language models.

Kaplan et al. (2020) demonstrated that transformer-based language-model loss follows predictable power-law relationships with model parameters, dataset size (measured in tokens), and total computational budget. The result was not a license to increase every dimension blindly; it showed that model quality depends on coordinated allocation across those resources, a point later sharpened by Chinchilla’s compute-optimal scaling analysis (Hoffmann et al. 2022).

Figure 1.7 presents test loss curves for models spanning from 10^3 to 10^9 parameters, revealing two insights. Larger models achieve superior sample efficiency, reaching target performance levels with fewer training tokens. As computational resources increase, the optimal model size grows correspondingly, with loss decreasing predictably when compute is allocated efficiently.

Figure 1.7: Scaling Laws & Compute Optimality: Larger models consistently achieve better performance with increased training data and compute, but diminishing returns necessitate careful resource allocation during training. Optimal model size and training duration depend on the available compute budget, as evidenced by the convergence of loss curves at different parameter scales and training token counts.

Optimal compute allocation follows the Chinchilla result that model size *and* training tokens should scale approximately proportionally for compute-optimal training, with a ratio on the order

of 20 training tokens per parameter (Hoffmann et al. 2022). This corrected earlier guidance that favored making models larger while training them on comparatively fewer tokens.

These predictions assume perfect compute utilization, an assumption that breaks down in distributed training. Communication overhead scales unfavorably with system size, creating bandwidth bottlenecks that reduce effective utilization. At multi-thousand-GPU scale, utilization depends on partitioning and interconnect: Narayanan et al. (2021) report Megatron-LM runs on 3,072 A100 GPUs at 52 percent of peak device throughput and note that slower interconnects or communication-heavy partitions hinder scaling.

1.3.3 Mathematical foundations and operational regimes

Power-law relationships express scaling behavior mathematically, though the intuition behind these patterns matters more for system design than precise formulation. The equations in this section explain why the same fleet can enter different operational regimes governed by how compute and data are allocated, by where diminishing returns set in, and by how much computation a system spends before answering.

Theorem 1.1: Power-law scaling formulation

Scaling laws are expressed formally as power-law relationships. The general formulation is:

$$\mathcal{L}(X) = A_{\mathcal{L}} X^{-\alpha_{\text{scale}}} + C_{\mathcal{L}}$$

where loss $\mathcal{L}$ decreases as resource quantity X increases, following a power-law decay with rate α_{scale} , plus a baseline constant $C_{\mathcal{L}}$. Here, $\mathcal{L}(X)$ represents the loss achieved with a resource quantity such as parameters, tokens, or compute; $A_{\mathcal{L}}$ and $C_{\mathcal{L}}$ are task-dependent constants; and α_{scale} is the scaling exponent that characterizes the rate of performance improvement. A larger value of α_{scale} signifies more efficient performance improvements with respect to scaling.

These predictions find strong empirical support across multiple model configurations. Figure 1.8 shows *how* early-stopped test loss varies predictably with both dataset size and model size, confirming that learning curves across configurations align through appropriate parameterization.

1.3.3.1 Resource-constrained scaling regimes

Applying scaling laws in practice is a scarcity diagnosis: the useful question is which resource prevents balanced growth first. Compute budget, data availability, and model size create three regimes with different optimal responses.

Three regimes determine the appropriate scaling response:

- **Compute-limited regime:** Compute scarcity restricts scaling potential despite abundant training data, so academic institutions, startups, and time-constrained teams often train smaller models for longer periods to maximize utilization.
- **Data-limited regime:** Data scarcity appears when computational resources exceed what the available dataset can support, so teams in specialized, proprietary, or privacy-constrained domains often train larger models for fewer optimization steps to extract more information from limited examples.
- **Optimal regime:** Balanced compute and data follow compute-optimal scaling laws, as DeepMind’s Chinchilla model demonstrated by outperforming much larger models through proportional scaling of model size and training data (Hoffmann et al. 2022).

Recognizing which regime governs a given project prevents common inefficiencies: over-parameterized models with insufficient training data, or under-parameterized models that waste available compute.

Performance improvements follow predictable patterns, but the relevant design action changes with resource availability and with the point in the ML lifecycle where compute is spent. Two further distinctions matter for system design: how performance changes with dataset size, and when in the lifecycle additional compute is applied.

☒ compute scarce

☐ data scarce

☐ balanced

Scaling regimes are compute-scarce, data-scarce, or balanced.

Figure 1.8: Loss vs. Dataset Size Across Model Scales: Test loss curves showing how models of different sizes (393K to 708M parameters) benefit from increased training data. Larger models achieve lower loss but all curves exhibit diminishing returns at high token counts.

Dataset size passes through three phases of its own (figure 1.9). With few examples, generalization error is high and erratic; as data grows it falls predictably along a power law, the regime where additional data buys the most; eventually it saturates against a noise floor where more data yields negligible gain. The systems consequence is that finite high-quality data, not compute, becomes the binding constraint once a model enters the saturation regime, which is why data efficiency complements brute-force scaling. Chapter 5 develops where this saturation reshapes training-data pipelines and budgets.

Figure 1.9: Data Scaling Regimes: Generalization error as a function of dataset size exhibits three distinct phases. The Small Data regime shows high variance; the Power-Law regime demonstrates predictable error reduction; the Irreducible Error regime represents the fundamental noise floor.

The lifecycle distinction names three points where a fleet can invest compute, as figure 1.10 traces: pretraining, the long, failure-sensitive run that realizes the scaling law in wall-clock time; posttraining adaptation, where fine-tuning and preference optimization replace one massive run with many smaller, coordination-heavy jobs; and test-time computation, where extra reasoning steps per query trade serving latency and throughput for accuracy. Each shifts the binding constraint to a different part of the fleet, so the full treatments belong with their workloads: Chapter 5 for the pretraining and posttraining runs, and Chapter 10 for test-time compute at serving. For resource-constrained deployments, posttraining and test-time scaling often prove more practical than retraining a model from scratch.

Figure 1.10: The Three Scaling Phases: Intelligence (capability) improves through successive scaling regimes. Pretraining scales with compute and data. Posttraining (reinforcement learning from human feedback, instruction tuning) refines behavior. Test-time scaling (chain-of-thought, search) extracts additional capability at inference.

1.3.4 Practical applications in system design

When OpenAI sized GPT-3, it did not run an exhaustive architecture search; it extrapolated scaling curves from smaller experiments to pick a model size and token budget in advance. That decision is the clearest illustration of how scaling laws inform practical system design and resource planning. Within well-defined operational regimes, model performance depends predominantly on scale rather than idiosyncratic architectural innovations, though diminishing returns mean each additional improvement demands exponentially increased resources for progressively smaller benefits.

Concretely, the authors used scaling-law extrapolations to choose model size and training data under the guidance available at the time (Brown et al. 2020; Kaplan et al. 2020). They scaled an established transformer architecture to 175B parameters and approximately 300 billion tokens, enabling advance prediction of model performance and resource requirements; later Chinchilla results showed that this point was undertrained relative to compute-optimal token allocation (Hoffmann et al. 2022).

Scaling laws serve multiple practical functions. During resource budgeting, empirical scaling curves help estimate returns on investment across model size, dataset expansion, and training duration under fixed computational budgets. Scaling trends also reveal when architectural changes yield significant improvements relative to gains from scaling alone, reducing the need for exhaustive architecture search. When a model family exhibits favorable scaling behavior, scaling the existing architecture is often more effective than transitioning to unvalidated designs.

The same principles apply in reverse for resource-constrained settings. In edge and embedded environments, scaling laws enable designers to select smaller configurations that deliver acceptable accuracy within deployment constraints. By quantifying scale-performance trade-offs, these laws identify when brute-force scaling becomes inefficient and point toward model compression, knowledge transfer, and hardware-aware design.

Scaling laws also function as diagnostic instruments. A performance plateau despite increased resources may indicate dimensional saturation (inadequate data relative to model size) or inefficient compute utilization. This diagnostic capability makes scaling laws both predictive and prescriptive: they forecast what resources a target capability requires and reveal *why* a system underperforms its predicted trajectory.

1.3.5 Sustainability and cost implications

Scaling laws reveal performance pathways while exposing rapidly escalating resource demands. As models expand, training and deployment costs grow disproportionately, creating tension between performance gains and system efficiency. Training the largest models demands distributed infrastructures comprising hundreds or thousands of accelerators, consuming tens of thousands of GPU-days and millions of kilowatt-hours of electricity. Chapter 5 examines how distributed training introduces additional complexity around communication overhead, synchronization, and scaling efficiency.

Large models also require extensive, high-quality datasets to reach their potential. As models approach saturation of available high-quality data, particularly in natural language processing, performance gains from data scaling can become marginal. Data efficiency is therefore a necessary complement to brute-force scaling.

The sharpest of these costs is environmental, and it turns on a decision the fleet operator actually makes: where to site the cluster. The same training run can differ by roughly $40\times$ in CO₂ emissions depending on grid location, from Quebec hydropower at ~ 20 g CO₂/kWh to Poland coal at ~ 800 g CO₂/kWh.⁹ That single placement choice, together with job scheduling that shifts workloads to low-carbon hours, makes data-center siting a first-order infrastructure decision rather than an afterthought. Financial cost moves in parallel: training a large foundation model runs into the millions of dollars, which limits who can do large-scale research at all. Chapter 15 develops the full energy and carbon accounting that turns these pressures into design constraints.

Scaling laws do not guarantee unbounded improvement. Each incremental performance gain must be weighed against its resource cost. As systems approach practical scaling limits, the emphasis shifts from *scaling alone* to *efficient scaling*: balancing performance, cost, energy consumption, and environmental impact.¹⁰

1.3.6 Scaling law breakdown conditions

Scaling laws hold within specific operational regimes but break down at their boundaries. As systems expand, they encounter conditions where the assumptions of smooth, predictable scaling cease to apply. These breakdown points expose inefficiencies that demand refined design approaches.

Most of these breakdowns share one root cause: growth in one dimension that outpaces the others. Hoffmann et al. (2022) show that many large language models were undertrained because model size grew faster than training-token budgets, and that compute-optimal training requires scaling parameters and tokens together. The same imbalance appears in other guises. Schedules and learning rates that are not retuned to a larger model leave it short of its potential despite the infrastructure spent on it; finite high-quality data eventually yields diminishing marginal utility, so larger models begin to memorize rather than generalize; and hardware ceilings on memory bandwidth, interconnect capacity, and I/O throughput cap how far a trillion-parameter model can be distributed at all. At the extreme, even balanced scaling reaches the limits of what a training distribution can teach: benchmark numbers keep rising while generalization does not, and models grow brittle to adversarial or out-of-distribution inputs. Table 1.2 organizes these failure modes, mapping each breakdown type to its underlying cause and a representative scenario, so practitioners can anticipate the inefficiency before committing the budget.

Table 1.2: Scaling Breakdown Types: Unbalanced scaling across model size, training data size, and compute resources leads to specific failure modes, such as overfitting or diminishing returns, impacting system performance and efficiency. The table categorizes these breakdowns, identifies their root causes, and provides representative scenarios to guide more effective system design and resource allocation.

Dimension Scaled	Type of Breakdown	Underlying Cause	Example Scenario
Model Size	Overfitting	Model capacity exceeds available data	Billion-parameter model on limited dataset
Training Data Size	Diminishing Returns	Saturation of new or diverse information	Scaling web text beyond useful threshold
Compute Budget	Underutilized Resources	Insufficient training steps or inefficient use	Large model with truncated training duration
Imbalanced Scaling	Inefficiency	Uncoordinated increase in model/data/compute	Doubling model size without more data or time
All Dimensions	Semantic Saturation	Exhaustion of learnable patterns in the domain	No further gains despite scaling all inputs

⁹ | **Carbon Intensity of Training:** GPT-3 training emitted an estimated 552 tons of CO₂, and published estimates place large-language-model training in the 10² to 10³ ton range, though figures vary widely with hardware, utilization, and electricity mix (Patterson et al. 2021).

¹⁰ | **Scaling Law Saturation:** While power-law relationships suggest unbounded gain, empirical evidence identifies **Semantic Saturation** points where adding data or parameters yields negligible improvement in downstream utility. This “diminishing returns” regime forces systems engineers to pivot from brute-force scale to data efficiency and model compression to extract further value within fixed power budgets.

Checkpoint 1.2: Applying scaling laws

These questions check whether scaling laws are being used as resource-allocation tools:

- ☐ **Compute vs. data regime:** Choose between training a larger model for fewer steps and training a smaller model for more steps when a team has fixed compute but limited training data.
- ☐ **Scaling breakdown:** Identify the scaling breakdown that follows from doubling model parameters (P) while keeping dataset size (D) constant.
- ☐ **Chinchilla optimality:** Explain why Chinchilla optimality serves as a resource-allocation target and identify the minimized quantity.
- ☐ **Compute vs. capability:** Classify the claim as true or false: scaling laws predict that doubling compute always yields a doubling of model capability.

These breakdown points demonstrate that scaling laws describe empirical regularities under specific conditions, conditions that become difficult to maintain at scale. Discerning *where* and *why* scaling ceases to be effective drives the development of strategies that enhance performance without relying solely on scale.

1.3.7 Integrating efficiency with scaling

Scaling laws reveal the walls; efficiency engineering builds the paths around them. Data saturation, infrastructure bottlenecks, and diminishing returns set hard limits on what brute-force scaling can achieve. The same constraints, however, point toward solutions along three interconnected dimensions:

- **Algorithmic efficiency:** Techniques such as sparsity and distillation extract more capability per FLOP.
- **Data efficiency:** Curriculum learning and active selection extract more information per training example.
- **Systems efficiency:** Communication hiding and pipeline overlap extract more utilization per accelerator.

Each dimension addresses a different breakdown condition from table 1.2, and each receives detailed treatment in the chapters that follow.

Scaling laws and efficiency techniques determine *how much* computation large models require and *how well* the fleet uses it. They do not, however, address the physical and logical constraints that the fleet itself imposes. Hardware fails, bandwidth saturates, distributed systems face fundamental impossibility results, and societal impact at scale demands governance. These constraints *cannot* be optimized away; they must be engineered around.

1.4 Constraints of Scale

The three walls describe where performance binds; the constraints behind them are broader. The Machine Learning Fleet operates under three categories of irreducible constraint: physical (the memory, network, and energy walls themselves, plus the reliability gap that opens as fleet size grows), logical (distributed systems face impossibility results like the CAP theorem), and societal (scale amplifies the impact of every technical decision). Understanding these constraints is a prerequisite for the diagnostic framework that follows.

1.4.1 The reliability gap

In traditional software, we treat hardware as a reliable abstraction. A single server typically has an availability of “four nines” (99.99 percent), meaning it fails for roughly 53 minutes a year. The Machine Learning Fleet, however, operates at a scale where this abstraction collapses, opening the **reliability gap**: hardware that is reliable in isolation becomes unreliable as a fleet. When a fleet coordinates 25,000 GPUs, equation 1.1 multiplies the individual component probabilities to give the probability that the entire system is healthy ($R_{\text{system}}(t)$):

$$R_{\text{system}}(t) = (R_{\text{component}}(t))^N = e^{-N\lambda t} \quad (1.1)$$

Here, N is the number of independent components in the fleet, λ is the per-component failure rate per unit time, t is the time window, and $R_{\text{component}}(t)$ is the probability that one component survives that window. The engineering implication is the exponent: every added component multiplies the failure opportunity, so reliability engineering becomes a scaling problem rather than a cleanup task.

If each node in a cluster is 99.9 percent reliable, a 1,000-node cluster is healthy only 36.8 percent of the time. Scale that to a 10,000-node fleet, and the probability of the entire system being healthy at any given second drops to 0.0045 percent. Figure 1.11 traces this exponential decay for two per-node reliability levels across fleet sizes from 1 to 10,000 GPUs.

Figure 1.11: The Reliability Collapse: Fleet availability as a function of fleet size for two per-node reliability levels. At 99.9% per-node reliability (blue), a 1,000-GPU cluster retains only 36.8% fleet availability; at 10,000 GPUs, availability collapses to near zero. Even 99.99% per-node reliability (green) drops to 36.8% at 10,000-GPU scale.

The exponential decay in figure 1.11 makes the architectural consequence inescapable: no amount of per-node improvement can sustain fleet-wide availability at scale. Here we establish the idea with a single per-node reliability figure; section E.1 derives the full failure-probability cascade and the fleet-wide availability formula a reader needs to size checkpoint intervals and redundancy. The engineering lesson is that *failure is the common case*. At scale, resilience replaces prevention as the governing objective: the system trades absolute uptime for recovery speed, checkpoint quality, and automated repair. The defining challenge of Chapter 7 is this shift from keeping every component running to ensuring that the fleet self-heals when components fail.

1.4.2 Communication intensity (the CI ratio)

If the single-machine iron law governs *how* a system executes, **communication intensity (CI)** governs *where* it stalls. On a single accelerator, the roofline model determines whether a kernel is compute-bound or memory-bound. At fleet scale, this analysis elevates to the network.

Equation 1.2 defines communication intensity as the ratio of data moved across the network to the operations performed locally:

$$CI = \frac{\text{Bytes Transferred (Network)}}{\text{FLOPs Executed (Local)}} \quad (1.2)$$

Low communication intensity, $CI < 0.01$, describes compute-heavy workloads whose GPUs spend most of their time doing math, so scaling is relatively easy. High communication intensity, $CI > 0.1$, describes network-bound workloads limited by bisection bandwidth, where adding more GPUs can slow training rather than speed it up.

Communication and scaling optimizations, from gradient sparsification (sending fewer gradient bytes) to 3D parallelism (partitioning data, tensor, and pipeline dimensions across different fabric tiers), try to lower exposed communication intensity so that the Machine Learning Fleet acts as a single, massive computer rather than a collection of idling processors waiting for the wire. We

define the ratio here and apply it qualitatively; section C.3.3 works communication intensity through concrete regimes and shows the bandwidth-saturation point at which adding accelerators stops helping.

Checkpoint 1.3: The scale mandate

These questions check whether the scale mindset has shifted from local execution to distributed constraints:

- ☐ **Communication intensity:** Explain in CI-ratio terms why adding more nodes (N) to a high-CI workload can slow training rather than speed it up.
- ☐ **Reliability gap:** Explain the reliability gap that prevents a 10,000-GPU cluster from remaining “perfectly healthy.”
- ☐ **Arithmetic vs. communication:** Distinguish arithmetic intensity (local memory) from communication intensity (global network).

1.4.3 Why distribution is hard

Scale forces distribution: no single machine provides the compute required for the largest models, and no centralized system can collect every data source that global user bases generate. Coordinating computation across physically separated machines connected by finite-bandwidth networks, however, creates constraints that no engineering can eliminate.

The first stressor appears inside data centers, where synchronous training must choose how much consistency to preserve under partitions and failures. The second appears at the edge, where the devices themselves are unreliable, power-limited, and policy-constrained.

1.4.3.1 The CAP theorem reality

The **CAP Theorem**¹¹ establishes that distributed systems can provide at most two of three properties: **Consistency**, **Availability**, and **Partition Tolerance**. The ML fleet encounters all three constraints, forcing explicit trade-offs.

Distributed ML systems make different trade-offs depending on their requirements. Synchronous training chooses consistency: all workers see the same model state, but training halts if any worker becomes unreachable. Asynchronous training chooses availability: training continues even with stragglers, but workers may operate on stale model versions. Federated learning often chooses availability with eventual consistency, accepting temporary divergence for continuous operation on edge devices.

1.4.3.2 Edge distribution complexity

The coordination challenges discussed so far assume data-center distribution, where machines run in managed facilities. At the network edge, these challenges intensify along every dimension.

Billions of smartphones and IoT devices operate in uncontrolled environments with unreliable connectivity and limited power. Privacy, consent, or policy constraints may prevent raw data from leaving the device, making federated learning a natural architecture (McMahan et al. 2017). Intermittent connectivity forces the system to tolerate asynchronous updates spanning days. These constraints require architectural approaches (differential privacy, on-device inference, and model compression) that differ fundamentally from data-center ML.

When ML systems operate at the scale of billions of users, their societal impact demands consideration beyond technical excellence. Governance becomes an engineering requirement.

1.4.4 Why governance matters at scale

Scale and distribution amplify impact beyond engineering. When a system serves billions of users, a technical bug becomes a societal risk. This amplification creates governance requirements that small-scale systems can safely ignore. We frame governance as the **Control Plane** of the Machine Learning Fleet, not a set of external rules.

¹¹ | **CAP Theorem** (Brewer’s Theorem): Brewer formulated the conjecture (Brewer 2000), and Gilbert and Lynch gave the formal proof that in the face of a network partition (P), a system must choose between absolute Consistency (C) and high Availability (A) (Gilbert and Lynch 2002). For the ML Fleet, this manifests as a choice between **Synchronous Training** (Consistency prioritized; the job stalls if a node fails) and **Asynchronous Training** (Availability prioritized; training continues but with stale gradients).

At fleet scale, a technical bug becomes societal risk.

12 | **Differential Privacy (DP):** A mathematical framework for adding calibrated noise to computations to bound information leakage about individual data points. Chapter 13 examines how DP protects user privacy in large-scale ML systems.

That control plane first has to defend the fleet. ML systems face unique security threats that intensify at production scale. Model extraction attacks steal proprietary intellectual property through API queries. Data poisoning injects backdoors into models that remain dormant until triggered by a specific input. At fleet scale, these threats become economically attractive targets for sophisticated attackers. Defending the fleet requires systematic approaches: access controls, differential privacy¹², and continuous behavioral monitoring that go far beyond traditional perimeter security.

The same control plane must make the fleet auditable. Systems operating at scale attract regulatory attention. Regimes such as the **EU AI Act** and local privacy laws make **Auditability** an architectural requirement for many deployments. Proving that a model trained on 10,000 GPUs did not ingest prohibited data requires end-to-end data lineage tracking. Generating a human-interpretable explanation for a sub-millisecond recommendation demands techniques designed into the serving architecture. Meeting these requirements calls for technical capabilities (audit trails, bias testing, and consent management) built into the infrastructure from day one.

Beyond legal compliance, the Machine Learning Fleet carries ethical obligations. Recommendation algorithms shape public discourse; hiring algorithms affect livelihoods. These systems do not fail loudly with a crash log; they fail silently through bias and polarization. Responsible AI is the engineering practice of treating fairness, transparency, and accountability as invariants: hard constraints that, if violated, should trigger a system-wide halt.

1.5 The C³ Taxonomy: Foundations of Scale

The physical, logical, and societal constraints just surveyed all manifest as wasted wall-clock time, so navigating them demands a diagnostic that says where that time actually goes. The single-machine foundation for that analysis is the **Data · Algorithm · Machine (D·A·M) taxonomy**, which Appendix A develops as a complete diagnostic framework. Data is the information the system learns from, and performance becomes data-bound when the I/O pipeline cannot feed the processor fast enough. The algorithm is the mathematical logic being executed, and performance becomes compute-bound when arithmetic units are the limiting factor. The machine is the physical hardware substrate, and performance becomes memory-bound when memory bandwidth or capacity limits throughput.

Scaling from one machine to a fleet introduces three new fundamental resources that compete for wall-clock time. Where the canonical triad of walls names where the fleet binds, these three resources name where its time is spent. The **C³ Taxonomy** extends the D·A·M lens to the fleet, identifying the physical and logical boundaries of the Machine Learning Fleet. Compute (C_1 , the math) is the local execution of matrix operations on individual accelerators, where the goal is to keep the math engine running at peak utilization. Communication (C_2 , the wire) is the movement of data across the network fabric, governed by bisection bandwidth and the speed of light. Coordination (C_3 , the logic) is the synchronous management of state across thousands of nodes, where collective algorithms, fault tolerance, and distributed consensus determine how efficiently N independent nodes can act as a single computer.

These three dimensions form the **Triad of Distributed Efficiency**. If the fleet spends too much time on communication or coordination, the expensive compute capacity sits idle. The central challenge is engineering the fleet to minimize the C³ Gap: the difference between theoretical hardware peak and actual distributed throughput. We introduce the three dimensions here as a framing device; Appendix B develops the complete taxonomy and the diagnostic structure that lets a reader localize a bottleneck to one of the three C's.

1.5.1 The projection: From D·A·M to C³

The D·A·M taxonomy describes the *workload*: the nouns of our system (the data we have, the algorithm we want to run, the machine we bought). The C³ taxonomy describes the *execution tax*: the verbs of the fleet (computing the math, communicating the results, coordinating the state). Appendix A reviews the single-node D·A·M lens; the C³ taxonomy projects that workload onto a distributed fleet. Stretching an algorithm across nodes creates communication, such as AllReduce operations to synchronize gradients. Stretching data across nodes requires coordination through distributed samplers and checkpointing. Machine failures in a fleet require coordination through fault tolerance and straggler mitigation.

The intersection of these two taxonomies defines the entire design space of fleet-scale ML systems engineering. We do not solve D-A-M or C³ *in isolation*; we solve their *cross-products*.

1.5.2 The fleet law

The C³ taxonomy yields a diagnostic equation for every distributed training step. To reason about performance at scale, we must distinguish the efficiency of a single component from the efficiency of the entire system. On a single machine, execution time is often governed by the iron law of performance, $T \approx D_{\text{vol}}/\text{BW} + O/(R_{\text{peak}}\eta_{\text{hw}}) + L_{\text{lat}}$, decomposing into data movement, computation, and overhead. At fleet scale, that single-machine view no longer suffices: we care about the efficiency of the fleet across time and energy, and a parallel decomposition emerges. Equation 1.3 states the **Fleet Law** (the distributed step time law), which decomposes distributed execution into its canonical distributed-step components:

$$T_{\text{step}}(N) = \frac{T_{\text{compute}}}{N} + T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}} \quad (1.3)$$

where T_{compute}/N is the idealized local arithmetic time after distributing work across N devices, $T_{\text{comm}}(N)$ is the time moving data across the network (gradient synchronization, parameter broadcasts), $T_{\text{sync}}(N)$ is time consumed by synchronization logic (barriers, scheduling decisions, fault recovery), and T_{overlap} is the communication hidden behind useful compute. Equation 1.4 rewrites this decomposition as the compute-time fraction, defined as the fraction of wall-clock time spent on useful math:

$$f_{\text{compute}} = \frac{T_{\text{compute}}/N}{T_{\text{step}}(N)} \quad (1.4)$$

This decomposition is a diagnostic instrument. When f_{compute} drops below 0.5, more than half the fleet’s expensive silicon sits idle. The C³ taxonomy identifies *where* the time goes: if $T_{\text{comm}}(N)$ dominates, upgrade interconnects or overlap communication with computation; if $T_{\text{sync}}(N)$ dominates, consider asynchronous methods or reduce barrier frequency; if T_{compute}/N dominates, the fleet is doing its job. Crucially, the **Displacement of Overhead** dictates that overhead *cannot* be eliminated, only relocated among the three C’s. Asynchronous training eliminates coordination barriers but introduces gradient staleness; pipeline parallelism reduces communication volume but adds bubble time. There is no free lunch in distributed systems.

Google’s **ML Productivity Goodput** metric provides the production-scale instantiation of this framework. Goodput decomposes end-to-end training productivity into three multiplicative factors: **Program Goodput** (η_{program}), measuring how efficiently code uses hardware (Compute); **Runtime Goodput** (η_{runtime}), capturing losses from communication stalls and failures (Communication); and **Scheduling Goodput** ($\eta_{\text{scheduling}}$), capturing wasted time from preemptions and reconfigurations (Coordination). The C³ taxonomy is the theoretical framework; Goodput is how production teams measure it.

Figure 1.12 visualizes the C³ framework as a three-column layout, with Compute, Communication, and Coordination each occupying their own column of subtopics and the inter-column gaps highlighting the bottlenecks that arise where the dimensions meet. The same framework can be drawn as a triangle in which the vertices are the three resources, the edges are the trade-offs, and the center embodies the displacement of overhead—the unavoidable consequence of distributing computation across independent machines.

The fleet law is the time-side diagnostic of fleet efficiency across time and energy: it asks how much of each distributed step remains useful compute after communication, synchronization, and overlap are accounted for. Section B.3 develops the full derivation and attributes each term to a physical cause.

1.5.3 The energy-scale invariant

While the fleet law governs time, the **Energy-Scale Invariant** governs the sustainability and economic viability of the fleet. At scale, every training step is a thermodynamic event. Equation 1.5 defines the

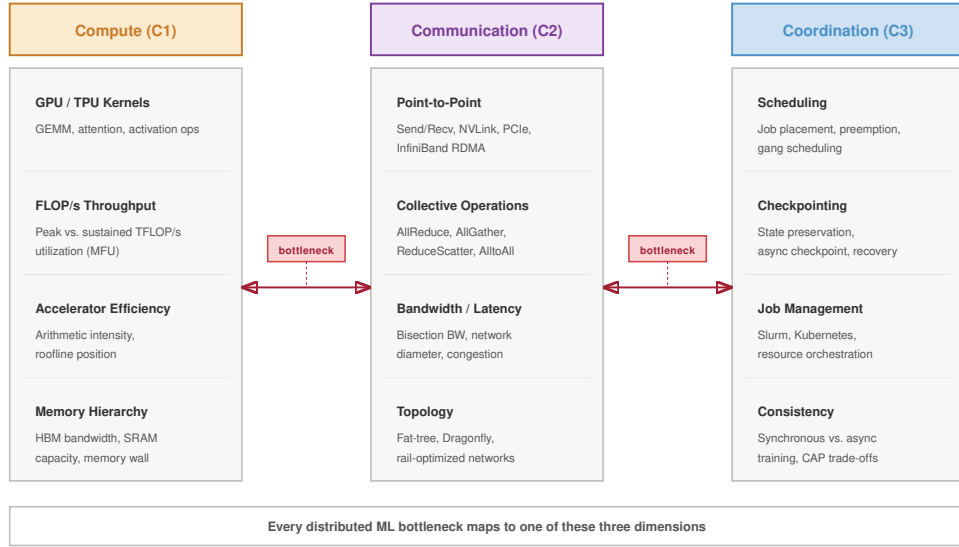

Figure 1.12: The C³ Taxonomy: Every distributed ML system partitions wall-clock time among three irreducible dimensions: Compute (the useful math), Communication (data movement across the network), and Coordination (synchronization logic). The figure lays out each dimension as a column of subtopics, with the bottlenecks that arise between adjacent dimensions called out in the inter-column gaps. The framework’s underlying claim—displacement of overhead—asserts that overhead cannot be eliminated, only relocated; this is the diagnostic lens for every performance analysis in this book.

fleet energy productivity (ρ_{energy}), measured in FLOP/J, as the ratio of useful work to total energy consumed:

$$\rho_{\text{energy}} = \frac{O_{\text{useful}}}{E_{\text{compute}} + E_{\text{cooling}} + E_{\text{network}}} \quad (1.5)$$

where O_{useful} is useful work in FLOPs and E_{network} often becomes a nonnegligible fraction of the total budget as we move terabytes across optical fabrics. Mastery of scale requires optimizing for the Pareto frontier of both laws: minimizing T_{step} while maximizing ρ_{energy} . We introduce the invariant here; section C.4.2 details the energy hierarchy at scale and the thermodynamic constraints that bound how far ρ_{energy} can be pushed.

The energy-side metric is only half of the scaling diagnosis. A production team also needs a time-side efficiency scalar that says whether extra devices are shortening the training step or merely increasing coordination overhead.

The scaling efficiency (η_{scaling}) of the fleet is the ratio of ideal parallel step time to actual step time:

$$\eta_{\text{scaling}} = \frac{T_1}{N \times T_N}$$

where T_1 is the single-device time for the same work and $T_N = T_{\text{step}}(N)$ is the step time on N devices. Section B.3.1 provides the component-decomposition technique and worked examples for splitting $T_{\text{step}}(N)$ into its terms, equipping a reader to compute η_{scaling} numerically.

🔍 Systems Perspective 1.2: Amdahl’s distributed pitfall

The fleet law is a specialized form of Amdahl’s Law. The maximum speedup of a distributed system is limited by its most tightly coupled component, usually the network synchronization. If a model spends 20 percent of its time waiting for the network ($T_{\text{comm}}(N)$), no amount of

faster GPUs can make it more than $5\times$ faster, regardless of how many are added. Scale is limited by coordination, not compute alone.

Applying both laws to a GPT-3-class synchronization estimate makes the coordination tax and its thermodynamic counterpart visible in the same terms as the scaling equation: the same Ring AllReduce that starves the accelerators of time also burns energy on every step.

Napkin Math 1.2: The coordination and energy tax

Problem: What scaling efficiency and energy cost result when training GPT-3 (175B params) on a cluster connected by 100 Gb/s Ethernet versus 200 Gb/s InfiniBand?

Physics: To synchronize 175B parameters (FP16), a Ring AllReduce must move approximately 700 GB of data through each participating accelerator endpoint per iteration.

Analysis: The fleet law exposes the communication tax.

- **InfiniBand** (200 Gb/s): High bandwidth and low latency yield a scaling efficiency of only 4.1 percent, meaning the accelerators compute for just 4.1 seconds out of every 100 seconds while the rest is consumed by synchronization.
- **Ethernet** (100 Gb/s): Lower bandwidth and higher overhead collapse the scaling efficiency further to 2.1 percent, leaving the accelerators productive for roughly 2.1 seconds out of every 100 seconds.

Energy: The energy wall is the thermodynamic cost of the same synchronization. Each endpoint's gradient synchronization consumes approximately 84 J across the network fabric (at 15 pJ/bit). In a training run of 1,000,000 steps, the endpoint network movement alone accounts for about 84 MJ of energy before multiplying by the number of participating accelerators.

Systems insight: Scale makes the network the primary “processor.” If the network is inefficient, the GPUs sit idle, wasting millions of dollars in compute capacity. Furthermore, the thermodynamic cost of data movement (the energy wall) means that “more GPUs” is not a sustainable scaling strategy without communication-hiding and compression.

sync 96%
compute 4%

At scale only about 4 percent of step time is compute; sync dominates.

1.6 Foundational Concepts

The fleet stack is the organizing spine for this book. The C^3 taxonomy introduced earlier (figure 1.12) gives the local diagnostic lens for one distributed step: *where* wall-clock time goes among compute, communication, and coordination. Scaling laws predict *how much* computation a target capability level demands, and governance constraints define *what* the fleet must never do. Those lenses support the stack rather than competing with it. When a chapter needs to trace how a change propagates, we will use the AI Triad at Scale; when it needs to assign ownership, we will use the Five-Pillar map. The dependency order comes from the fleet stack. Figure 1.13 organizes the complexity of this book into **The Fleet Stack**, a four-layer framework where engineering decisions at the bottom constrain possibilities at the top.

This layered progression structures the textbook's four parts: the physical substrate, the logic of distribution, deployment at scale, and the responsible fleet. The detailed chapter map appears in section 1.7; here the stack establishes the dependency order.

The **AI Triad at Scale** is the dependency reminder inside that stack. Every machine learning system comprises three interdependent components: data that guides behavior, algorithms that learn patterns, and computational infrastructure that enables both training and inference. At production scale, these interdependencies intensify. A GPT-4-class scenario at roughly 10^{25} FLOPs would demand infrastructure capable of efficient gradient synchronization across tens of thousands of GPUs. Training data at this scale requires distributed storage systems with access patterns optimized for ML workloads. Figure 1.14 visualizes these dependencies between data, algorithms, and infrastructure, revealing the optimization landscape that ML systems engineers must address.

The **Five-Pillar Framework** turns those layer-level constraints into ownership domains. Data engineering defines what the fleet must ingest, transform, and serve; model development defines the

Figure 1.13: The Fleet Stack: The organizing framework for this book. We build from the Infrastructure Layer (compute, network, data) up through the Distribution Layer (parallelism, communication, fault tolerance) and Serving Layer (inference, performance, edge, operations) to the Governance Layer (security, robustness, sustainability, responsible engineering). Engineering decisions at the bottom constrain possibilities at the top.

architectures and training procedures that consume that data at scale. Optimization then bridges the model to its deployment constraints, compressing or accelerating the workload when latency, memory, or power budgets become binding. Deployment infrastructure supplies the cloud platforms, network fabrics, and storage hierarchies that make the fleet runnable. Operations (MLOps) closes the loop by measuring whether the deployed system remains reliable, secure, and effective as production data and hardware conditions change.

Production frameworks matter because each implements the same abstract primitives with different names and ownership boundaries. Table 1.3 provides a cross-framework mapping as a translation aid for the primitives developed across the fleet stack, not as a tool ranking.

Table 1.3: The Framework Rosetta Stone: A mapping of abstract distributed ML primitives to their implementations across major frameworks. The primitives are developed where they become binding constraints, including distributed training (Chapter 5), collective communication (Chapter 6), inference (Chapter 10), and operations (Chapter 12).

Abstract Primitive	PyTorch (Native)	DeepSpeed	Megatron-LM	JAX/XLA	Ray
Data Parallel	DDP	DeepSpeedEngine	DistributedDataParallel	pmmap/jit(sharded)	Ray Train
Sharded DP	FSDP	ZeRO-1/2/3	FullyShardedDataParallel	sharding.Mesh	FSDP Strategy
Tensor Parallel	DTensor	InferenceTP	Column/RowParallel	xmap/spmd	Ray Train TP
Pipeline Parallel	PiPPy	PipelineModule	PipelineParallel	GSPMD	Ray Train PP
Grad Accumulation	backward(accumulate)	grad_accum_steps	grad_acc_steps	lax.scan	Ray Train Config
Checkpointing	torch.save/DCP	save_checkpoint	save_checkpoint	orbox	ray.checkpoint
Orchestration	torchrun	deepspeed CLI	megatron_main.py	jax.distributed	Ray Core

These primitives recur throughout the book; the table is a reference to return to as each one is introduced, not a syllabus to memorize now. The **Six Systems Engineering Principles** provide the standard for individual design decisions: instrument first, design for $10\times$ headroom, expect

Figure 1.14: The AI Triad at Scale: The three interdependent components of every ML system. At production scale, each component's requirements intensify: data pipelines must handle petabytes with consistent quality; algorithms can demand 10^{25} FLOPs for large-model training; and infrastructure must coordinate thousands of accelerators while maintaining fault tolerance. Changes to any vertex cascade through the others, creating the multi-dimensional optimization challenge that defines ML systems engineering.

bottlenecks to migrate, treat failure as steady state, compound small efficiency gains across the fleet, and co-design hardware with algorithms. At fleet scale, a claim about performance or reliability is only useful when it is instrumented, because the cause may sit in the model, the scheduler, the network, the storage tier, or the serving path. That measurement discipline supports $10\times$ design: a prototype is not yet an architecture until it shows where headroom remains. As scale rises, bottlenecks move from local compute toward communication and coordination, hardware failures become routine, and small efficiency gains become material because they repeat across the fleet. Hardware co-design follows from the same logic, since network topology, storage hierarchy, and accelerator choice shape which algorithms remain practical. These are the practices a fleet engineer applies; the volume closes by distilling what they ultimately serve into the durable principles of distributed ML systems.

Together, these frameworks assume familiarity with single-machine ML systems: *how* models are trained, optimized, and deployed on individual devices. This book teaches engineers to scale, distribute, and govern them across the global Machine Learning Fleet.

1.6.1 Three systems archetypes

Abstract frameworks become concrete through specific workloads. This book traces three **Light-houses at Scale** through every chapter. Each archetype occupies a distinct corner of the C^3 taxonomy, stressing communication, coordination, or compute in fundamentally different ways, ensuring that every principle is tested against the diversity of real-world fleet engineering.

1.6.1.1 Archetype A (GPT-4/Llama-3)

GPT-4 and Llama-3 are autoregressive transformer architectures that generate text one token at a time. At single-accelerator scale, autoregressive language models are memory-bandwidth probes; at the scale of hundreds of billions of parameters, and in some proprietary systems potentially more, these models define the *throughput-bound* regime: training demands ExaFLOP/s of sustained compute distributed across thousands to tens of thousands of accelerators, while serving requires memory bandwidth sufficient to load billions of weights for every generated token. The fleet

challenge is partitioning very large models across accelerator fleets using 3D Parallelism (data, tensor, and pipeline) without the network fabric becoming the binding bottleneck. In the C^3 taxonomy, Archetype A is dominated by communication—gradient synchronization and activation transfers across the cluster consume more wall-clock time than the arithmetic itself.

1.6.1.2 Archetype B (DLRM at scale)

DLRM is Meta’s production architecture for personalized content ranking. Unlike LLMs, which are dominated by dense matrix multiplications, recommendation models derive their capacity from massive embedding tables—sparse lookup structures that map billions of user and item features into dense vectors. A single production DLRM instance may contain 10 TB or more of embedding parameters, far exceeding any single accelerator’s memory. The fleet challenge is sharding these embedding tables across hundreds of nodes while processing millions of queries per second (QPS) with <100 ms tail latency, all while managing $\mathcal{O}(N^2)$ all-to-all communication contention between embedding shards and dense layers. In the C^3 taxonomy, Archetype B stresses coordination: sparse feature routing, shard placement, request scheduling, and embedding-update consistency determine whether the all-to-all traffic can be served within tail-latency limits.

1.6.1.3 Archetype C (federated MobileNet)

MobileNet is a family of efficient convolutional neural networks designed for on-device inference under tight power and memory budgets. In a federated learning setting, MobileNet instances train locally on millions of heterogeneous edge devices (smartphones, IoT sensors, medical wearables) without raw data ever leaving the device. The constraint regime is qualitatively different from the data-center archetypes: compute budgets are measured in *milliwatts* rather than *megawatts*, and privacy or policy constraints can prohibit centralized data aggregation. In the C^3 taxonomy, Archetype C is dominated by compute at the per-device level: each local training step is bound by the milliwatt-scale silicon envelope of the edge device, not by fleet-level network bandwidth or coordination protocols. The fleet challenge is coordinating model updates across millions of such compute-constrained, unreliable devices using Federated Averaging, which periodically averages device updates at a coordinator, while maintaining convergence guarantees despite data distributions that are not independent and identically distributed (i.i.d.) and intermittent connectivity.

Read the three archetypes as constraint probes, not as a catalog of model families. The LLM case asks whether dense synchronization can keep thousands of accelerators useful, the DLRM case asks whether sparse feature routing can meet tail-latency budgets, and the federated MobileNet case asks whether local device constraints can be coordinated into a statistically coherent update. Table 1.4 summarizes the three canonical workloads tracked throughout this book.

Table 1.4: Lighthouse Archetypes at Scale: The three canonical workloads tracked throughout this book, with their dominant constraint and the fleet-scale challenge each raises.

Archetype	C^3 Dominant Constraint	Fleet Challenge
Archetype A (GPT-4/Llama-3)	Communication (fleet-wide)	Partition hundreds of billions of parameters, and potentially larger proprietary models, across thousands to tens of thousands of GPUs using 3D Parallelism without the network becoming the bottleneck.
Archetype B (DLRM at Scale)	Coordination (routing and placement)	Shard 10 TB+ embedding tables across hundreds of nodes; process millions of QPS with <100 ms tail latency while managing sparse feature routing, shard placement, and $\mathcal{O}(N^2)$ all-to-all contention.
Archetype C (Federated MobileNet)	Compute (per-device envelope)	Coordinate learning across millions of compute-constrained, unreliable edge devices using Federated updates; raw data cannot leave the device.

1.7 The Structure of This Textbook

This textbook organizes around the fleet stack, progressing from the physical substrate through the logic of distribution to societal governance. The chapter sequence is a dependency map rather than a topic inventory: the physical constraints of silicon and cooling dictate how we wire the network; the network limits dictate how we partition training algorithms; partitioned algorithms dictate how we

handle fault tolerance and orchestration; and fleet orchestration dictates how we operate, secure, and govern systems in production. Each part addresses a fundamental scale impediment that prevents a single-machine solution from working at production scale.

The infrastructure arc begins with the impediment no algorithm can ignore: no single server has enough memory, power, cooling, or I/O to train the largest models. Chapter 2 therefore starts with high-density silicon and facility physics, Chapter 3 turns isolated machines into a cluster-scale “Gradient Bus,” and Chapter 4 completes the substrate by keeping accelerators fed without letting storage become the hidden bottleneck.

The distribution arc begins once the physical fleet exists and the coordination tax becomes unavoidable. Splitting math across machines creates two new problems: replicas must exchange state fast enough to behave like one optimizer, and failures become routine rather than exceptional. Chapter 5 develops partitioning strategies for models with hundreds of billions to trillions of parameters, Chapter 6 explains the communication primitives that bind independent nodes into a coherent computer, Chapter 7 treats recovery speed as more important than individual-node uptime, and Chapter 8 manages the multi-tenant cluster where those jobs must be placed, isolated, and rescheduled.

The deployment arc shifts from training a model to serving it economically. Once a model reaches production, the binding question is no longer only time-to-train; it is whether latency, utilization, and lifetime serving cost stay inside the operating envelope. Chapter 9 closes the gap between hardware peak and actual throughput through kernel fusion and compilation, Chapter 10 turns those local optimizations into serving systems for millions of users, Chapter 11 moves intelligence toward devices with milliwatt power budgets, and Chapter 12 develops the control plane for monitoring health, drift, and performance across global deployments.

The governance arc treats responsibility as an engineering layer rather than an afterword. At global scale, technical bugs become societal hazards: adversaries can poison data or extract weights, open-world inputs can break brittle models, energy use becomes a fleet constraint, and governance failures can turn technical capability into social harm. Chapter 13, Chapter 14, Chapter 15, and Chapter 16 develop those obligations as system properties that must be designed, measured, and operated.

1.8 Fallacies and Pitfalls

The following fallacies and pitfalls capture architectural mistakes that waste development resources, miss performance targets, or deploy systems critically mismatched to their operating constraints. Each represents a pattern we have seen repeatedly in the transition from single-machine ML to the Machine Learning Fleet.

Fallacy: *Focusing on algorithmic efficiency while ignoring hardware-system alignment.*

Engineers often optimize FLOPs and parameter counts assuming these metrics predict deployment performance. Real efficiency depends on *how* well the math aligns with the underlying hardware. For example, unstructured pruning achieves 80 percent sparsity but delivers no speedup on dense hardware (like NVIDIA Tensor Cores), while structured pruning at 50 percent sparsity can enable up to 2× sparse-math throughput on supported hardware and kernels, but does not guarantee end-to-end speedup. A model reduced from 10B to 3B parameters (70 percent FLOPs reduction) might achieve only 20 percent latency improvement because memory bandwidth bottlenecks dominate and the pruning pattern lacks hardware-friendly structure.

Pitfall: *Optimizing one metric without checking system-wide trade-offs.*

The **Universal Efficiency Fallacy** assumes that optimizations like quantization or distillation are “free wins.” In production, each optimization introduces specific trade-offs. INT8 quantization achieves 4× memory reduction but typically incurs 1–2 percent accuracy loss. Knowledge distillation enables 2–4× compression but demands expensive teacher model training. The optimal architecture requires balancing accuracy, latency, and power, not merely minimizing resource consumption.

Fallacy: *Edge deployment efficiency requirements are simply scaled-down versions of cloud requirements.*

This “**Cloud-Lite**” Fallacy treats edge systems as resource-constrained cloud systems. Edge devices face qualitatively different constraints. For example, autonomous vehicles at 120 km/h convert every 100 ms of processing delay into 3.33 m of positional uncertainty. While cloud deployments scale to kilowatts, edge systems operate under 5–15 W power budgets. A cloud-optimized model

Cutting FLOPs alone leaves latency memory-bound.

with 95 percent accuracy and 50 ms latency might be unusable on an edge device where thermal throttling increases latency to 200 ms and drains the battery in under an hour.

Pitfall: *Assuming scaling laws predict efficiency requirements linearly across all scales.*

The **Linear Scaling Fallacy** occurs when teams extrapolate resource requirements using power-law relationships without accounting for coordination overhead. $\mathcal{L}(X) = A_{\mathcal{L}}X^{-\alpha_{\text{scale}}} + C_{\mathcal{L}}$ works within validated ranges but fails at the boundaries. A team training 100B-parameter models by extrapolating from 10B-parameter experiments might predict a 3× improvement but achieve only 1.8× if coordination and communication overhead consumes 40 percent of the scaled step time. Production systems designed assuming linear scaling have experienced 2–3× cost overruns when empirical performance deviated from power-law predictions beyond validated thresholds.

1.9 Summary

This volume opens with a fundamental challenge: the principles that enable success on single machines become the obstacles that prevent success at scale. We have moved from the laboratory to the Machine Learning Fleet, where communication costs dominate computation, failures are a statistical certainty, and societal impact demands rigorous governance.

The transition from building systems that *work* to building systems that *scale* represents the next regime of engineering. The core principles of machine learning systems (measure everything, optimize the bottleneck, design for failure) remain essential, but their application changes fundamentally when the system spans thousands of nodes. Network topology becomes as important as memory hierarchy, and fleet coordination replaces local synchronization: updates, failures, and shared state must be managed across many machines.

These principles collectively reshape *how* engineers reason about system design. When failure is routine rather than exceptional, and when communication cost eclipses computation, the diagnostic instincts developed on single machines must be recalibrated. The engineer who internalizes these constraints moves from local speedup questions to fleet-governance questions: where coordination overhead appears, what fails when a node disappears, and which consistency guarantee can be relaxed. That shift, from optimizing a component to governing a fleet, is what separates practitioners who can architect at scale from those who can only prototype on one machine.

Key Takeaways: Scale makes a new machine

- **More GPUs change the problem:** Techniques that work on one node stop being merely slower at fleet scale; they can become wrong. Bisection bandwidth, power delivery, reliability, and governance create constraints that do not appear in single-accelerator experiments.
- **The network spends every speedup:** Adding accelerators divides local compute but adds synchronization, gradient traffic, and tail-latency exposure. A 175B-parameter model can move hundreds of gigabytes of gradients per step, so useful FLOPs depend on communication, not peak arithmetic alone.
- **Failure becomes steady state:** A 25,000-GPU training run with per-GPU MTBF measured in tens of thousands of hours still sees cluster-level failures every few hours. Checkpointing, recovery, and observability are baseline design requirements, not cleanup work.
- **C³ replaces local intuition:** The single-machine Data, Algorithm, Machine lens projects to Compute, Communication, and Coordination at fleet scale. The fleet law makes this shift explicit: scaling depends on synchronization, overlap, and consistency as much as hardware count.
- **Impact needs a control plane:** Foundation-scale systems amplify security, privacy, fairness, and policy failures across large user populations. Governance is not an appendix to infrastructure; it is the mechanism that decides what the fleet is permitted to optimize and deploy.

Everything this introduction has argued converges on one reversal. At scale, the techniques that made a single machine fast become the very things that hold a fleet back, because the binding constraint moves outside the box. On one accelerator, computation is the cost and the memory hierarchy sets the limit; across ten thousand, computation is the easy part, and the limit is everything between the machines, the communication that carries every gradient and the coordination that keeps thousands of nodes agreeing on one state. That is the physics of distribution, and it answers to its own three-letter law: where a single node is governed by Data, Algorithm, and Machine, the fleet is governed by Compute, Communication, and Coordination. The rest of this book works out that shift, from the silicon upward to the governance that decides what the fleet is permitted to do.

What's Next: From requirements to silicon

The requirements of scale are established: we know *why* we must distribute, *what* physical costs arise, and which principles govern the Machine Learning Fleet. Requirements alone, however, do not compute gradients. The fleet needs a physical foundation (silicon, power, and cooling) capable of sustaining the workloads we have described. Chapter 2 begins building that foundation, examining the accelerator architectures, memory hierarchies, and power delivery systems that form the Infrastructure Layer of the fleet stack.

Research Questions: For further inquiry

- How should the single-machine D·A·M lens change when a workload crosses into the fleet-scale C^3 regime?
- When can adding accelerators reduce useful training progress rather than improve it?
- How should engineers use scaling laws as planning tools without mistaking them for infrastructure guarantees?
- Why should governance be treated as a control plane of the fleet rather than an external policy layer?

I

THE FLEET

Part I

Fleet Principles

The Machine Learning Fleet is the warehouse-scale computer where the network is the bus, power density is the speed limit, and failure is a statistical certainty. Continuing the curriculum's focus on the physics of AI engineering, Part I builds the physics of scale: the silicon, the wires, the cooling systems, and the storage hierarchies that make distributed ML possible. We shift from the single accelerator to the data-center-scale machine, where the engineering question is no longer how to compute on one device but how to move energy and information at a scale that challenges the limits of the physical infrastructure.

This transition requires a fundamental shift in perspective. At scale, the individual GPU is merely a component in a larger, tightly coupled system. The principles of the Fleet are not best practices for cluster management; they are the physical invariants that dictate what kind of models can be trained and how they can be served. From the thermodynamic limits of heat dissipation to the bisection bandwidth of the network fabric, these constraints define the boundaries of the fleet stack. The governing pattern parallels the single node: where the node is bound by the conservation of complexity across Data, Algorithm, and Machine, the Fleet is bound by the displacement of overhead across Compute, Communication, and Coordination (the C³ taxonomy). The execution tax of scale cannot be eliminated, only relocated.

Those boundaries appear first in the facility itself: every operation eventually becomes heat that must be removed.

III Principle 1: The Thermodynamic Limit

Invariant: Irreversible computation and data movement dissipate electrical energy as heat; at data-center scale, the practical limit is the rate at which that heat can be removed.

$$\dot{Q}_{\text{limit}} = \frac{\Delta Q}{\Delta t}$$

where $\dot{Q}_{\text{limit}}$ is the maximum heat-removal rate, ΔQ is heat energy, and Δt is the removal time window.

Implication: The bottleneck of the modern AI data center is not FLOP/s, but watts per square foot. When a rack generates 100 kW of heat, air cooling fails. The physical design of the fleet is dictated by the ability to move heat away from silicon.

At the rack level, the same heat budget becomes a density constraint.

III Principle 2: The Power Density Wall

Invariant: Cluster scaling is constrained by thermal dissipation limits (watts per rack) and cooling capacity, not just silicon area or floor space.

Implication: Modern AI accelerators generate heat densities that exceed air cooling capabilities. **Liquid cooling** becomes a facility requirement, not an option, for large-scale training clusters.

Thermal capacity sets the outer envelope; inside it, memory capacity determines how frontier models must be divided.

III Principle 3: The Memory Capacity Gap

Invariant: Frontier model memory requirements have grown faster and more irregularly than single-accelerator HBM capacity.

Implication: Models no longer fit on single devices. Architectures must embrace 3D parallelism (splitting the model itself via tensor and pipeline parallelism) as the default state, breaking the abstraction of the “single device.”

Once a model is divided across devices, the network becomes part of the execution path.

III Principle 4: The Bisection Bandwidth Theorem

Invariant: The performance of a distributed application is limited by the minimum bisection bandwidth of the network topology.

Implication: A cluster with 10,000 GPUs cannot support synchronized distributed training if the accelerators are connected by a 1 Gbps Ethernet tree. **Non-blocking topologies** (fat-tree, Dragonfly) are required to ensure that the network does not become the bottleneck for collective operations like AllReduce.

The fleet also fixes where efficiency comes from: the choice between general-purpose flexibility and hardware specialization.

III Principle 5: The Generality Tax

Invariant: For workloads with stable computation patterns, specialization can improve performance per watt by reducing general-purpose overhead, while also reducing programmability and workload flexibility.

$$\rho_{\text{energy,specific}} \gg \rho_{\text{energy,general}} \quad \text{for a fixed power budget}$$

Implication: The trajectory from CPU to GPU to Tensor Processing Unit (TPU) to fixed-function ASIC is a workload-dependent architecture trade-off, not a universal physical law. Each step can trade programmability for efficiency, and the fleet architect must choose the right point on this curve for each workload.

Compute efficiency helps only if the training pipeline can keep the accelerators fed.

III Principle 6: The I/O Wall

Invariant: When storage throughput cannot deliver training data as fast as accelerators consume it, GPUs idle regardless of their computational power.

$$\text{Utilization} = \min \left(1, \frac{\text{BW}_{\text{storage}}}{N_{\text{GPU}} \times R_{\text{consumption}}} \right)$$

where $\text{BW}_{\text{storage}}$ is aggregate storage bandwidth, N_{GPU} is the number of accelerators, and $R_{\text{consumption}}$ is each accelerator’s data-consumption rate.

Implication: A storage system that was adequate for 8 GPUs becomes the bottleneck at 64. The I/O wall scales with the number of accelerators: every GPU added to the cluster raises the throughput floor that storage must sustain, making the data pipeline, rather than the model, the limiting factor.

Meeting that demand requires a hierarchy rather than a single undifferentiated storage pool.

Principle 7: The Storage Hierarchy Principle

Invariant: Storage performance decreases and capacity increases as data moves further from the accelerator.

Implication: The systems engineer’s task is to ensure that the *right data* is on the *right tier* at the *right time*. Data format choices, caching strategies, prefetch buffer sizing, and tiering policies all exist to manage movement upward through the hierarchy so that accelerators do not starve.

Even after data reaches the right tier, coordination limits how efficiently more nodes translate into more throughput.

Principle 8: The Scaling Efficiency Bound

Invariant: Adding nodes to a distributed training job yields diminishing returns because communication overhead grows with cluster size while per-node computation remains constant.

$$\eta_{\text{scaling}} = \frac{T_1}{N \times T_N} \leq 1$$

Implication: Perfect linear scaling ($\eta_{\text{scaling}} = 1.0$) is a theoretical limit, not a practical target. Well-tuned dense-training jobs commonly reach $\eta_{\text{scaling}} \approx 0.85\text{--}0.95$ at moderate scale on modern fabrics, and degrade further as N grows. The gap between $\eta_{\text{scaling}} = 1.0$ and the achieved efficiency is the **Communication Tax**—the price of coordination.

These invariants establish the Fleet as a first-class engineering object. Part I builds this machine from the ground up: from the landscape of distributed ML systems and why single machines no longer suffice, through the silicon, power, and cooling systems of the AI data center, the network fabrics that connect the fleet, and the storage hierarchy that feeds the training pipeline. Together, these chapters form the foundation for the lighthouse archetypes (section 1.6.1) that we will track throughout this volume.

Purpose

Why does infrastructure, not algorithms alone, determine who can participate in advancing machine learning at scale?

Machine learning systems have a physical reality that transcends code. While the algorithms for training large models may be public, the ability to execute them at scale is gated by the physics of infrastructure. Every training run is a race against thermal limits, power delivery stability, and the cost of data movement. When algorithms are the primary bottleneck, progress can happen anywhere. At large scale, the constraint shifts toward who can build and operate the physical systems that make scale possible. Building an ML fleet requires engineering across four physical levels: the accelerator (silicon physics), the node (interconnect density), the rack (thermal management), and the pod (warehouse-scale networking). At each level, the goal is the same: to minimize the time data spends in transit and maximize the time it spends in computation. The economics are equally unforgiving: a large accelerator cluster represents major capital expenditure and megawatts of continuous power. Infrastructure becomes a participation boundary for organizations working at the largest scales. This chapter maps that physical stack, from the stacking of memory dies to the stabilization of grid-scale power ramps. In C³ terms, this substrate is where the fleet's limits originate: every bound on compute and communication in the chapters that follow traces back to it.

Learning Objectives

- Compare GPU, TPU, and ASIC dataflows to explain specialization across the accelerator spectrum
- Apply roofline analysis to identify compute-, memory-, or bandwidth-bound limits for training and inference
- Calculate token latency or memory budgets from HBM capacity, bandwidth, precision, and model state size
- Map tensor, pipeline, and data parallelism onto NVLink, rack, and pod bandwidth tiers
- Evaluate rack and pod designs using power density, cooling limits, topology, and facility reliability constraints
- Select accelerator infrastructure using sustained throughput, utilization threshold, energy cost, and fleet ownership cost

2.1 The Infrastructure Walls

SCALE forces distribution: Compute, Communication, and Coordination replace the single-machine instincts of Data, Algorithm, and Machine. Those fleet-level limits now have to be paid for in hardware. Four physical constraints recur as the system grows from one accelerator to a warehouse-scale pod: memory bandwidth, power delivery, communication bandwidth, and reliability. Figure 2.1 shows where each wall becomes dominant along that path.

The physical stack begins at the silicon die and expands outward through four levels. At each level, the same engineering pattern appears: a constraint becomes intolerable, and the solution creates the next layer of infrastructure. Nodes aggregate accelerators to overcome memory capacity limits. Racks concentrate nodes and confront power delivery and cooling. Pods wire racks into a warehouse-scale computer and face the communication wall at full force. The path from transistor to data center is anchored by the 175B model, which serves as the thread connecting each level.

2.2 Accelerator Spectrum

The foundation starts with the silicon, where a specialized chip earns its place by doing one thing a general-purpose processor cannot do efficiently: run the same dense arithmetic, over and over, at maximum throughput. Consider what happens when a CPU executes a matrix multiplication. The processor fetches an instruction, decodes it, checks for data hazards, routes operands through a deep pipeline, and writes the result back to a register file. For each multiply-accumulate operation, the chip expends energy on branch prediction, speculative execution, out-of-order scheduling, and cache coherence.

These mechanisms exist because a CPU must handle any instruction sequence efficiently, from pointer-chasing linked-list traversals to system calls. For neural network workloads, however, the operation is almost always the same: multiply two matrices of known dimensions, add a bias, and apply a nonlinear function. The CPU's elaborate control logic represents a tax on every operation, one that buys flexibility the workload does not need. This concept mirrors the classic reduced instruction set computer (RISC) vs. complex instruction set computer (CISC) debate in computer architecture: just as RISC processors achieved higher throughput by simplifying the instruction set, ML accelerators achieve higher throughput by simplifying the computational model to match the dominant workload pattern.

Systems Perspective 2.1: The generality tax

A modern server CPU devotes roughly 30–40 percent of its die area to caches, 20–30 percent to control logic (branch predictors, reorder buffers, instruction decoders), and only 5–10 percent to arithmetic units. This allocation makes sense for general-purpose code, where branches are unpredictable and data access patterns are irregular. For matrix multiplication, however, the access pattern is perfectly regular and the control flow is trivially predictable. Every transistor

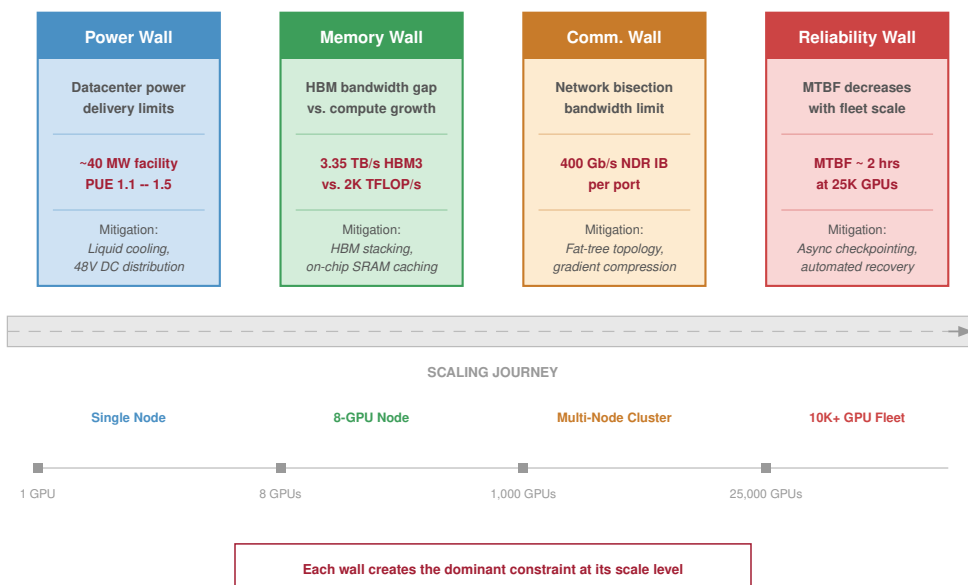

Figure 2.1: The Four Infrastructure Walls: Four dominant constraints arranged across a Scaling Journey: Power wall (data center delivery limits, ~40 MW facility), memory wall (HBM bandwidth gap, 3.35 TB/s HBM3 vs. ~2K TFLOP/s), communication wall (network bisection limit, 400 Gb/s NDR IB per port), and reliability wall (MTBF ~2 hours at 25K GPUs). Each wall becomes the dominant constraint at a different scale, from a single GPU through 8-GPU nodes and 1K-GPU clusters to 25K+ GPU fleets.

spent on branch prediction or speculative execution is a transistor that could have been a multiplier. This is the **generality tax** (principle 5): the silicon area that a processor wastes on capabilities irrelevant to the dominant workload.

The accelerator revolution is, at its core, an exercise in eliminating this tax. Each step along the spectrum from CPU to custom ASIC reclaims more die area for arithmetic by removing another layer of general-purpose control logic. The progression is quantifiable: a CPU devotes roughly 5–10 percent of its die to arithmetic, a GPU devotes roughly 50–60 percent, a Tensor Processing Unit (TPU) devotes roughly 70–80 percent, and a purpose-built ASIC can devote over 90 percent of its die to the target computation.

The transition from general-purpose to specialized silicon follows a logical progression. At one end of the spectrum, GPUs retain substantial programmability while providing 10–100× the matrix throughput of CPUs. At the other end, custom ASICs hardwire a specific dataflow for maximum efficiency at the cost of flexibility.

Understanding *where* each architecture falls on this spectrum, and *why*, is essential for selecting hardware that matches a given workload. The spectrum is not a ranking from “bad” (general-purpose CPU) to “good” (custom ASIC), but a continuum of trade-offs where each position offers the best match for a different combination of workload characteristics and deployment constraints.

GPUs represent the first major step away from general-purpose computing toward massive parallelism while retaining programmability. An NVIDIA H100, for example, contains 16,896 CUDA cores organized into 132 Streaming Multiprocessors (SMs). Each SM can execute thousands of threads simultaneously using the **Single Instruction, Multiple Threads (SIMT)**¹ execution model. Unlike a CPU, which optimizes for single-thread latency, a GPU hides memory latency

¹ | **SIMT (Single Instruction, Multiple Thread):** Coined by NVIDIA to distinguish their GPU model from classical single instruction, multiple data (SIMD). In SIMT, 32 threads form a *warp* that shares an instruction stream but can diverge at branches; divergence forces serial execution of both paths, halving throughput per branch. For ML workloads, where matrix operations have uniform control flow, warp divergence is rare, which is why GPUs achieve near-peak utilization on general matrix multiply (GEMM) operations but degrade on irregular operations like sparse attention or dynamic routing.

by maintaining thousands of threads in flight and switching between them when one stalls on a memory access.

The programmer writes a single function (a *kernel*), and the hardware maps it across a massive grid of threads. This model is flexible enough to run any mathematical kernel, from convolutions to attention mechanisms to custom loss functions, while providing orders of magnitude more throughput than a CPU for data-parallel computation.

The trade-off is that irregular, branch-heavy code runs poorly because divergent threads within a warp (a group of 32 threads that execute in lockstep) must execute serially. When threads in the same warp take different branches of an if-else statement, the hardware must execute both branches sequentially, disabling the threads that took the other path during each branch. For ML workloads, this divergence penalty is usually small because neural network operations have highly uniform control flow: every element in a matrix multiplication follows the same computation path.

TPUs go a step further, sacrificing some programmability for maximum efficiency on a single operation type by hardwiring the dataflow itself. Google's Tensor Processing Units use a **systolic array**² architecture: a fixed grid of multiply-accumulate (MAC) units where data flows between neighboring cells in a regular, wave-like pattern. Instead of fetching and decoding instructions for each operation, the systolic array receives a matrix at one edge and pulses it through the grid, with each cell performing one MAC and passing the result to its neighbor. This eliminates the instruction fetch and decode overhead entirely, and it avoids writing intermediate results to memory because each partial sum flows directly to the next computation.

The cost of this efficiency is reduced programmability. Models must be compiled through Accelerated Linear Algebra (XLA), which maps high-level operations onto the fixed dataflow. Workloads with irregular control flow or dynamic shapes may not map well to this architecture, and the compilation process itself can be time-consuming (minutes to hours for complex models), which slows the iteration cycle during model development.

The programming model distinction between GPUs and TPUs has practical implications for organizational decisions. Research teams that frequently modify model architectures (adding custom attention patterns, experimenting with new activation functions, prototyping novel training algorithms) generally prefer the GPU's CUDA ecosystem because new operations can be implemented as custom kernels without waiting for compiler support. Teams running established architectures at scale (standard Transformer training, large-scale fine-tuning) may prefer TPUs because the XLA compiler can optimize the entire computation graph, often achieving better hardware utilization than hand-written CUDA kernels for standard operations.

2 | **Systolic Array:** From Greek *systole* (contraction), the systolic-array model was introduced by H. T. Kung and Charles E. Leiserson's VLSI work and later framed by Kung as a class of architectures where data pulses through a grid of processing elements in a heart-like rhythm (Kung and Leiserson 1979; Kung 1982). The metaphor explains the design: each cell performs one MAC and passes the result to its neighbor, eliminating register-file round-trips. Google's TPU v1 deployed a 256×256 array (65,536 MACs), achieving 92 TOPS within 75 W by hardwiring this dataflow – the architectural bet that made data center-scale inference economically viable (Jouppi et al. 2017).

Example 2.1: The TPU origin story

Context: In 2013, Google engineers projected that if users spoke to their Android phones for just three minutes per day using voice search, the company would need to double its data center compute capacity to handle the inference load (Jouppi et al. 2017). The cost was prohibitive.

Insight: Google's TPU analysis framed production neural-network inference as a dense-linear-algebra workload large enough that voice-search growth alone could have doubled serving capacity needs. This finding led directly to the TPU v1, a purpose-built inference accelerator with a 256×256 systolic array that could deliver 92 TOPS (INT8) within a 75 W power envelope. The first TPUs were deployed in 2015 and served production inference workloads including RankBrain and portions of Google Neural Machine Translation (Jouppi et al. 2017); the AlphaGo match-play system is documented separately (Silver et al. 2016).

Systems lesson: Specialization became economically justified because the workload was stable, massive, and dominated by one operation class. The TPU story is a generality-tax case, not merely a faster-chip story.

Custom ASICs represent the extreme end of the spectrum, where the economics of silicon justify abandoning general-purpose programmability entirely. When an organization runs a single model architecture at enormous scale, designing a chip specifically for that workload becomes economically rational. By stripping away every feature not required by the target computation, custom ASICs

achieve the lowest energy per operation and the highest sustained utilization of any architecture on the spectrum.

Tesla's Dojo D1 chip, for example, is optimized for the spatial and temporal structure of video-based vision models. Its hundreds of tightly coupled processing nodes are designed around the dataflow needs of Tesla's vision pipeline, with on-chip SRAM sized to keep spatial tiles close to the compute units. This reduces the repeated round-trips to off-chip memory that a general-purpose GPU would require for the same computation.

AWS Trainium takes a different approach, targeting the broad category of Transformer training rather than a single model. Trainium systems combine compiler-managed memory scheduling with hardware-assisted collective communication, so common training patterns such as tensor-parallel synchronization and data-parallel reductions can be optimized in the accelerator fabric rather than handled entirely by host software.

The risk of custom silicon is equally clear: if the dominant model architecture shifts, as it did from convolutional neural networks (CNNs) to Transformers between 2017 and 2020, a custom ASIC designed for the old architecture becomes a stranded asset. The design cycle for a new ASIC is 2–3 years from conception to deployment, which means the architecture decision must anticipate workload trends several years into the future. This prediction challenge is nontrivial: in 2015, few would have predicted that attention-based Transformers would replace CNNs as the dominant architecture within five years, and organizations that committed to CNN-optimized ASICs during that period found their hardware stranded by the architectural shift.

Custom silicon is therefore a bet on workload stability, and the organizations that make this bet are typically those with enough scale to justify the \$50–\$200 million development cost and enough workload volume to amortize the per-chip NRE (nonrecurring engineering) cost across millions of chips. Google can justify the TPU's development cost because high-volume services such as Search, YouTube recommendations, and Gmail spam filtering can amortize a shared accelerator platform. A research lab running a few hundred GPUs cannot justify the same investment.

The bet pays off handsomely when workloads are stable: a purpose-built ASIC can deliver 5–10× the energy efficiency of a general-purpose GPU for its target operation. However, the consequences of a wrong bet are severe, as the chip's fixed dataflow cannot be reprogrammed to accommodate a fundamentally new computational pattern. Pushing the locality argument further leads to a deeper question of physical scale: whether a single die can be expanded to the size of the entire wafer.

2.2.1 Wafer-scale engines

Wafer-Scale Engines (WSE) represent the ultimate pursuit of data locality. While every other architecture on the spectrum relies on chiplets or discrete dies connected by relatively slow PCB-level or package-level interconnects, a wafer-scale engine (like the Cerebras WSE-3) is a single, continuous piece of silicon the size of a dinner plate. By avoiding the need to “dice” the wafer into individual chips, a WSE can maintain a single, massive on-chip interconnect across its entire surface.

The WSE-3 contains 900,000 AI-optimized cores and 44 GB of on-chip SRAM, all connected by a silicon fabric that delivers 21 PB/s of memory bandwidth. To put this in perspective, a single WSE-3 has compute comparable to a large multi-H100 cluster and on-chip memory bandwidth comparable to thousands of H100 HBM links, but because the entire system resides on a single piece of silicon, the communication latency between any two cores is measured in nanoseconds rather than microseconds.

As figure 2.2 shows, the challenge of wafer-scale integration is physical: manufacturing yield, power delivery, and thermal expansion. A single defect on a standard chip might render it useless, but on a wafer-scale engine, the software must be “defect-aware,” routing around local manufacturing flaws in the silicon fabric. Delivering 23 kW of power to a single piece of silicon and cooling it requires specialized manifold-level liquid cooling that is closer to industrial plumbing than traditional computer engineering.

Wafer-scale engines sit at a unique point on the spectrum: they are highly specialized in their *physical* architecture but flexible in their *computational* model, as the underlying cores are often general-purpose enough to execute diverse ML kernels. They represent a “Scale Up” philosophy that attempts to eliminate the communication wall by making the cluster the chip.

Figure 2.2: Wafer-Scale Engine (WSE) Architecture: Unlike traditional processors, a WSE uses the entire 300 mm silicon wafer as a single continuous compute fabric. This eliminates the ‘Dicing’ process and replaces PCB-level interconnects with a high-bandwidth on-chip mesh. The software must be defect-aware, routing data through a unified fabric that treats the entire wafer as a single logical processor with uniform memory access (UMA) characteristics across 900,000 cores.

The key wafer-scale trade-off is manufacturing complexity and defect-aware routing in exchange for eliminating the inter-chip communication bottleneck entirely, keeping all 900,000 cores within nanoseconds of each other on a single silicon fabric. Figure 2.3 places these architectures on a continuum, revealing the fundamental trade-off between programmability and efficiency that governs every accelerator design choice. Table 2.1 turns the same continuum into the architectural features an engineer must compare.

Table 2.1: The Accelerator Spectrum: As we move from left to right, we trade general-purpose programmability for compute density and power efficiency. Wafer-scale engines occupy a distinct niche, providing cluster-scale performance on a single piece of silicon.

Feature	CPU	GPU (H100)	TPU (v5p)	Wafer-Scale	Custom ASIC
Arithmetic Core	Scalar/Vector	Tensor Core	systolic array	RISC-style Core	Fixed Dataflow
Execution	Instruction	SIMT	Data-Driven	Dataflow	Hardwired
Memory Control	Cache	L1/L2 + HBM	Scratchpad	On-Chip SRAM	Explicit Mesh
Flexibility	Extreme	High	Moderate	High	Low
Efficiency	Low	High	Very High	High	Extreme

As table 2.1 summarizes, for our 175B model, the choice is not purely about peak FLOP/s. If we are a research lab experimenting with novel architectures weekly, the GPU’s flexibility justifies its generality tax. If we are deploying a fixed Transformer at scale for years, the TPU’s dataflow efficiency or a custom ASIC’s power advantage may dominate total cost. The accelerator spectrum is ultimately an economic question of *how much flexibility can be surrendered, given the stability of the workload*.

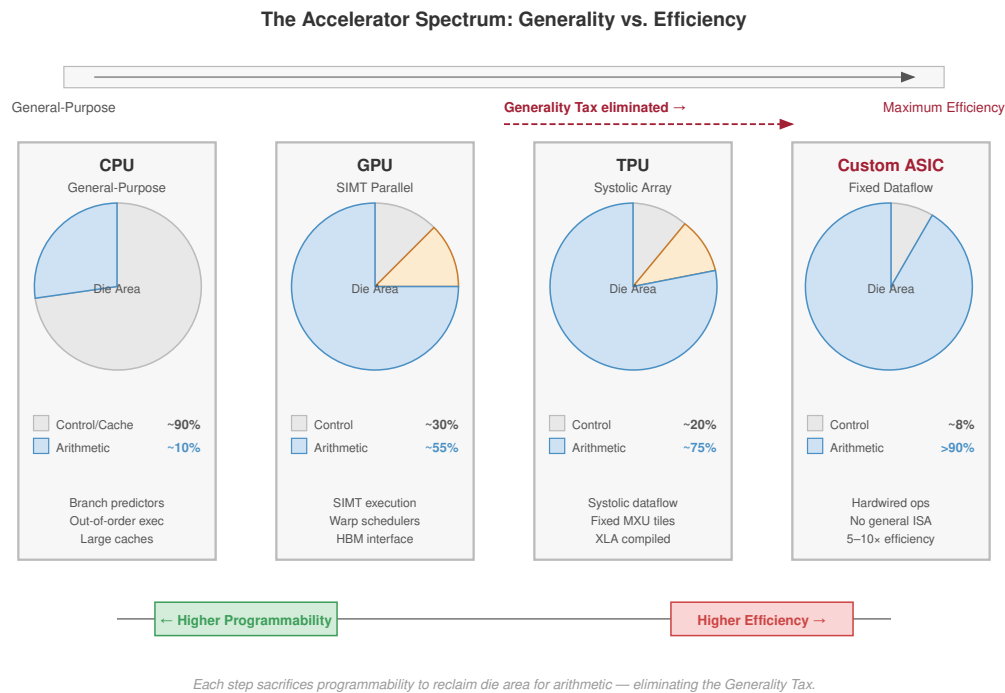

Figure 2.3: The Accelerator Spectrum: The landscape of ML hardware involves a fundamental trade-off between programmability and efficiency. General-purpose CPUs provide maximum flexibility but low compute density. Moving toward custom ASICs and systolic arrays increases throughput per watt by hardwiring common dataflows, at the cost of supporting a narrower range of model architectures.

2.2.2 Chiplet-based accelerators

A major accelerator design pattern is the **chiplet** architecture, exemplified by NVIDIA’s Blackwell and AMD’s Instinct MI300 series. Rather than fabricating a single monolithic die, chiplet-based designs partition the processor into multiple smaller dies connected by a high-bandwidth die-to-die interconnect on a common package substrate. This approach addresses two physical limitations that constrain monolithic designs.

First, the maximum die size is capped by the photolithographic reticle limit (the 858 mm² single-exposure ceiling examined in section 2.2.3), which limits the number of Tensor Cores, SMs, and HBM stacks a monolithic GPU can integrate. Chiplet designs bypass this limit by placing multiple dies on a single package, with the B200’s dual-die design effectively creating a 1,600 mm² equivalent processor.

Second, manufacturing yield decreases exponentially with die area because a single defect anywhere on the die renders the entire chip unusable. Smaller chiplets have higher individual yield, and the package-level integration allows partial yields (a defective chiplet can be replaced with a good one). This yield advantage translates directly to lower manufacturing cost per unit of compute, which is particularly important as transistor densities continue to increase and process nodes become more expensive.

The trade-off is the die-to-die interconnect. Communication between chiplets within a package is faster than communication between packages (NVLink) but slower than communication within a single monolithic die (the on-die mesh network). Workloads that generate frequent, fine-grained communication between processing elements (such as operations that share data between nonadjacent SMs) may experience a latency penalty when those SMs reside on different chiplets. GPU vendors mitigate this by making the die-to-die link transparent to the programmer, so the software sees a single logical GPU regardless of the underlying chiplet topology.

2.2.3 Evolution of GPU architectures

The rapid evolution of NVIDIA's GPU architectures over the past decade illustrates how accelerator design has adapted to the changing demands of ML workloads. Each generation has introduced architectural innovations targeted at the specific bottlenecks revealed by production ML workloads, rather than simply increasing transistor counts.

The Volta architecture (2017) introduced the first-generation Tensor Core, recognizing that neural network training spends the majority of its time in matrix multiplications. By adding dedicated matrix-multiply-accumulate (MMA) hardware alongside the existing CUDA cores, Volta could accelerate the dominant workload pattern without sacrificing the general-purpose programmability that made GPUs attractive for research. The V100, Volta's flagship, delivered 125 TFLOP/s of FP16 Tensor Core throughput at 300 W.

The Ampere architecture (2020) expanded Tensor Core support to additional data types (TF32, BF16, INT8, INT4), reflecting the growing importance of mixed-precision training and quantized inference. The A100 also introduced Multi-Instance GPU (MIG), which partitions a single GPU into up to seven isolated instances, enabling efficient sharing of expensive hardware across multiple inference workloads. The most consequential change for infrastructure was Ampere's third-generation NVLink, which doubled bidirectional bandwidth to 600 GB/s per GPU from Volta's 300 GB/s, directly addressing the communication wall for tensor parallelism, which splits each layer's matrices across GPUs.

The Hopper architecture (2022) added the Transformer Engine, which dynamically selects between FP8 and FP16 precision on a per-layer basis, doubling the effective throughput for Transformer models without requiring manual precision tuning. Hopper also introduced NVLink 4.0 at 900 GB/s per GPU and the NVLink Switch, enabling NVLink connectivity beyond the 8-GPU boundary.

The H100's 1979 TFLOP/s of FP8 Tensor Core throughput at 700 W represents a $6.8\times$ efficiency improvement over V100, achieved through a combination of process technology (TSMC 4N), architectural innovation (Transformer Engine), and precision engineering (FP8 support).

The Blackwell architecture (2024) continued this trajectory with the B200, which pairs two GPU dies in a single package via a high-bandwidth chip-to-chip link, effectively creating a "dual-die GPU" that delivers about 4,500 TFLOP/s of dense FP8 Tensor Core throughput at 1000 W. FP16/BF16 comparisons should use the lower precision-specific vendor figure rather than the FP8 peak.

The dual-die approach acknowledges that single-die GPU sizes are approaching the reticle limit of lithographic equipment, and further scaling requires chiplet-based designs. The reticle limit is a fundamental constraint of photolithography: the lens system in the EUV scanner can only project a pattern onto an area of approximately 26×33 mm (858 mm²) in a single exposure. A die larger than this area would require multiple exposures with stitching, which is technically possible but dramatically increases cost and reduces yield.

Blackwell also introduced fifth-generation NVLink at 1800 GB/s per GPU, doubling the intra-node bandwidth again. The die-to-die link within the B200 package operates at 10 TB/s, fast enough that the two dies can appear as a single logical GPU to the software for many operations.

The progression reveals a consistent pattern: each generation addresses a bottleneck exposed by the previous generation. Volta added dedicated matrix hardware for the compute bottleneck. Ampere expanded mixed-precision support. Hopper targeted Transformer-specific precision with FP8. Blackwell pushed against the die-size limit with multi-die packaging.

At each step, the accelerator's design reflects an important workload of its era, illustrating *how* the physics of the workload drives the physics of the silicon. This co-evolution between workloads and hardware is not accidental: accelerator architects profile ML workloads to identify bottlenecks, and then design subsequent generations to address them. The result is a hardware evolution that is tightly coupled to model architecture evolution, which is *why* Transformer workloads have strongly shaped accelerator design since 2017.

The evolution also reveals a sobering procurement pattern for infrastructure planners: high-end accelerator generations can turn over faster than the facility that houses them. The V100 remained the flagship training GPU for approximately three years (2017–2020). The A100 held that position for roughly two years (2020–2022). Hopper and Blackwell continued that short-cadence pattern in the mid-2020s.

The planning implication is that a data center built for accelerators must anticipate refresh cycles before the first rack arrives. Hardware refresh planning is therefore an integral part of the initial procurement decision, not an afterthought. Table 2.2 compresses that cadence into the major NVIDIA GPU generations and the interconnect and power changes that arrived with them.

A subtlety that affects fleet consistency is the **silicon lottery** – the manufacturing reality where microscopic variance in 4nm lithography produces a distribution of chip quality across each wafer. NVIDIA manages this yield curve through aggressive binning: dies capable of sustaining high clock frequencies at strictly controlled voltages under the full TDP are designated as premium H100 SXM modules, while those with higher leakage currents or minor defects become H100 PCIe cards or are fused down to lower-tier products. Even within the top-tier SXM bin, the achievable boost clock varies based on silicon characteristics. In a synchronous training cluster, the collective communication primitives are blocked by the slowest participant. A single chip running 50 MHz below the fleet average can degrade the effective throughput of the entire cluster by 5–10 percent, which is *why* sophisticated fleet management systems track per-GPU performance metrics and quarantine underperforming silicon to inference pools where the impact of individual chip variance is less pronounced.

Table 2.2: NVIDIA GPU Architecture Evolution: Each generation introduces architectural features targeted at the dominant ML workload pattern of its era. Efficiency rises substantially but unevenly across generations, while NVLink bandwidth increases from 300 GB/s on V100 to 1,800 GB/s on B200, with a smaller 1.5× A100-to-H100 step between the larger doubling jumps.

Architecture	Year	Key Innovation	Peak Tensor	TDP	NVLink BW
Volta (V100)	2017	First Tensor Core	125 TFLOP/s	300 W	300 GB/s
Ampere (A100)	2020	Multi-precision, MIG	312 TFLOP/s	400 W	600 GB/s
Hopper (H100)	2022	Transformer Engine, FP8	1979 TFLOP/s	700 W	900 GB/s
Blackwell (B200)	2024	Dual-die, NVLink 5	4,500 TFLOP/s FP8	1000 W	1,800 GB/s

Table 2.2 compresses four hardware generations into a few columns. Figure 2.4 unpacks two of those columns, raw throughput and power efficiency, to reveal a divergence that shapes fleet-scale infrastructure decisions.

Figure 2.4 quantifies a critical asymmetry: while each GPU generation delivers dramatically more raw throughput, the power required to sustain that throughput grows nearly as fast. The advertised low-precision Tensor Core peak from P100 to B200 has grown by more than 200×, while TFLOP/s per watt has grown far less. The precision modes differ across generations, but that is itself part of the hardware trend: each generation gains compute density partly by introducing lower-precision formats. This divergence is the physical root of the power wall discussed in the next sections and explains *why* liquid cooling, megawatt-scale power delivery, and thermal management dominate dense accelerator facility design.

2.2.4 Evolution of TPU architectures

Google’s TPU trajectory follows a different path, focusing on distributed efficiency and XLA compiler integration. While GPUs emphasize peak per-chip throughput and software flexibility (CUDA), the TPU is designed from the beginning as a “Pod-scale” resource. Every TPU chip is born as part of a larger cluster, with dedicated inter-chip interconnect (ICI) links that bypass the host CPU entirely.

The generation sequence shows how that pod-first design moved from inference to training. The TPU v1 (2015) was a dedicated inference chip with a 256×256 systolic array, delivering 92 TOPS (INT8) for the matrix operations that dominated Google’s production inference workloads. TPU v2 (2017) and TPU v3 (2018) then shifted the architecture toward training by adding bfloat16 (BF16), avoiding the dynamic range problems of standard FP16, and scaling the pod concept to 1,024 chips

Figure 2.4: The Accelerator Efficiency Wall: Peak Tensor Core throughput (blue, left axis) and power efficiency (green, right axis) for six generations of NVIDIA data center GPUs, both on logarithmic scales. The series follows the advertised low-precision Tensor Core mode for each generation, so precision changes are part of the hardware trend rather than an apples-to-apples FP16 comparison. Raw throughput has grown over $200\times$ from the P100 to the B200, but efficiency (TFLOP/s per watt) has grown far less. The shaded region highlights the widening gap that the power grid, cooling systems, and data center infrastructure must absorb.

and 100+ PFLOP/s of aggregate compute. TPU v4 (2021) extended the same logic into the network itself, adding an optical circuit switch (OCS) so the physical topology could be reconfigured for different workloads while raising per-chip BF16 throughput to 275 TFLOP/s.

The TPU v5p (2023) continued this pod-scale design for high-end training. It features 459 TFLOP/s of BF16 compute, 95 GB of HBM2e with 2,760 GB/s memory bandwidth, and 1,200 GB/s bidirectional ICI bandwidth per chip, optimized for the massive AllReduce operations required by billion-parameter models. Table 2.3 shows how that pod-first design evolved across TPU generations. Section D.2.1 develops the collective communication complexity model and the algorithm choices behind AllReduce, which explain why inter-chip bandwidth, not per-chip arithmetic, sets the ceiling on training throughput as model size grows.

Table 2.3: Google TPU Architecture Evolution: The TPU’s development highlights a “Pod-first” design philosophy where inter-chip interconnect bandwidth and compiler-level optimization (XLA) are as important as peak per-chip arithmetic. Note: TPU v1 was INT8 only.

Generation	Year	Key Innovation	Peak BF16	HBM	ICI BW
TPU v1	2015	systolic array (Inference)	92 TOPS*	—	—
TPU v2	2017	High-Bandwidth Memory	45 TFLOP/s	16 GB	600 GB/s
TPU v3	2018	Liquid Cooling, Pod Scale	105 TFLOP/s	32 GB	650 GB/s
TPU v4	2021	Optical Circuit Switching	275 TFLOP/s	32 GB	1,200 GB/s
TPU v5p	2023	SparseCore, HBM2e	459 TFLOP/s	95 GB	1,200 GB/s

As table 2.3 illustrates, this comparison reveals a divergence in philosophy. GPU evolution is a race to pack more arithmetic and higher-precision Tensor Cores onto a single package, using chiplets (Blackwell) to overcome physical die-size limits. TPU evolution is a race to build more efficient warehouse-scale computers, where the individual chip's performance is secondary to the pod's collective bandwidth and reconfigurability (Barroso et al. 2019).

The accelerator's arithmetic engine performs nearly 2,000 TFLOP/s on the H100. Yet raw arithmetic throughput is meaningless if the data cannot reach the compute units fast enough. The fundamental bottleneck that limits every accelerator's effective performance is the memory wall.

2.3 The Memory Wall

With the accelerator's arithmetic engine selected, we confront a paradox: the faster we make our logic, the more it idles waiting for data. This diverging trajectory between processor throughput and data access speed is formally known as the **Memory Wall** (Wulf and McKee 1995). While transistor scaling has driven logic performance up by orders of magnitude, the physical interconnects that feed data to these cores have failed to keep pace. This bottleneck is existential for machine learning: unlike traditional software that benefits heavily from caching and data reuse, neural networks must stream billions of weights from memory for every inference pass, often making bandwidth – not compute – the governing constraint on performance. Section B.2 develops the diagnostic framework that classifies this memory-bound condition alongside the other bottleneck patterns a fleet encounters, so that a measured symptom maps to a named constraint rather than a guess.

The implications are concrete and perceptible in our running example. Our 175B model's weights occupy 350 GB in FP16. During autoregressive decoding, this entire 350 GB tensor must be streamed from off-chip memory into the processor's registers for every single token generated. A single H100 cannot hold that tensor, so this is a bandwidth-floor calculation after sharding or quantization has solved the capacity problem. At H100-class HBM bandwidths (~3.35 TB/s per accelerator), the data movement alone dictates a latency floor of over 100 ms per token if one accelerator-equivalent bandwidth path must stream the weights. The memory wall is not an abstract architectural concept: it is the physical reason a chatbot takes a perceptible pause between words. Three engineering responses address this constraint: high bandwidth memory (HBM) widens the data pipe, the roofline model rigorously diagnoses whether a workload is starving for data or for compute, and Tensor Cores maximize the arithmetic value of every byte fetched. As figure 2.5 shows, memory bandwidth is also a placement trade-off: moving the working set closer to compute raises bandwidth, but it usually reduces the amount of state that can stay there.

Figure 2.5 is not a ranking of accelerators; it is a map of where each design chooses to place bytes. Edge devices keep memory cheap and compact, but bandwidth stays low. HBM moves memory onto the accelerator package, buying enough capacity and enough bandwidth for active model state. Local-SRAM designs push the working set still closer to arithmetic, buying extraordinary bandwidth at the cost of much smaller resident capacity. That tier map explains why HBM is the next engineering response: it is not the fastest memory in the system, but it is the highest-bandwidth tier that can hold tens to hundreds of gigabytes next to the compute die.

2.3.1 HBM: Breaking the memory wall

An H100 can execute nearly 2,000 TFLOP/s of low-precision matrix arithmetic, yet during autoregressive decoding of our 175B model, its Tensor Cores would sit idle for over 99 percent of each cycle in a bandwidth-floor model. The bottleneck is not the speed of *multiplication* but the speed of *delivery*: once the model has been sharded or compressed so the weights fit, the serving path must still stream the active weight shards through the arithmetic units for every output token. No amount of additional Tensor Cores can help when the existing ones are already starved for data. The accelerator response to this fundamental limitation is High Bandwidth Memory³.

The memory hierarchy within a single accelerator spans orders of magnitude in both capacity and bandwidth. At the top sits the **register file**⁴ – approximately 20–30 MB distributed across all SMs – with effectively infinite bandwidth (hundreds of TB/s) but minuscule capacity. Below this lies the L1 cache and **shared memory** (SRAM)⁵, offering roughly 256 KB per SM (approximately 33 MB total) with an aggregate bandwidth of ~19 TB/s. Further down sits the 50 MB L2 cache (~12 TB/s), and finally the 80 GB of HBM3 at 3.35 TB/s.

³ | **HBM (High Bandwidth Memory)**: Standardized by JEDEC in 2013 as a joint development between AMD and SK Hynix, originally for graphics cards. ML accelerators adopted HBM because neural networks exhibit the same bandwidth-hungry, capacity-moderate access pattern as high-end rendering. Each HBM generation has roughly doubled bandwidth (128 GB/s in HBM1 to 1.2 TB/s per stack in HBM3e), yet the gap between memory bandwidth and arithmetic throughput continues to widen – making HBM a necessary but never sufficient response to the memory wall.

⁴ | **Register File Bandwidth**: In an H100 GPU, the register file provides over 300 TB/s of aggregate bandwidth to the CUDA cores. This is ~100× higher than HBM3 bandwidth, explaining why tiling is mandatory: any operand not in a register during execution forces the arithmetic units to wait 100+ clock cycles for data, collapsing utilization.

⁵ | **SRAM Energy (pJ/bit)**: Accessing a bit in SRAM (shared memory) consumes approximately 0.1–0.5 pJ, while fetching from HBM consumes 2–5 pJ. This 10× energy difference is the physical driver behind kernel fusion: every intermediate result kept in SRAM instead of written to HBM saves both time and significant power and thermal headroom.

Figure 2.5: Accelerator Memory Tiers: Peak memory bandwidth and capacity separate local-SRAM designs, HBM accelerators, and edge/shared-LPDDR devices. The dotted arrow marks the design trade-off: moving data closer to compute raises bandwidth but reduces capacity.

Lighthouse 2.1: Archetype B (DLRM at Scale): The capacity wall

While Archetype A (GPT-4) is primarily throughput-bound (demanding more TFLOP/s), Archetype B (DLRM at Scale), the DLRM workload, is primarily capacity-bound. A 10 TB embedding table cannot fit into the 80 GB HBM of a single H100, nor can it fit into the aggregate HBM of a single 8-GPU node (640 GB). Capacity alone requires at least 16 such nodes before accounting for replication, hot-table headroom, and bandwidth balance; production-scale recommenders often grow to much larger multi-node shards, transforming a memory-access problem into a massive **All-to-All** network coordination problem.

The bandwidth gap between registers and HBM is approximately 100×. If an operand must be fetched from HBM for a single operation, the arithmetic unit spends about 99 percent of its time stalling. High Model FLOPs Utilization (MFU), the fraction of peak hardware FLOP/s spent on useful model computation, is only possible through aggressive **tiling**: breaking the massive weight matrices into small tiles that fit entirely within shared memory and registers, then performing as many multiply-accumulate operations on each tile as possible before evicting it. As figure 2.6 illustrates, this strategy loads data once into the SM's fast SRAM and reuses it across multiple Tensor Core operations, effectively multiplying the arithmetic value of every byte fetched from HBM.

Despite the 175B model's massive total memory footprint, the active working set at any given microsecond must be meticulously managed to reside in that top 30 MB of register space, or the chip's theoretical performance becomes a mirage. HBM supplies the bulk capacity, but tiling decides whether that capacity feeds the arithmetic units fast enough to matter.

Definition 2.1: High bandwidth memory (HBM)

High Bandwidth Memory (HBM) is the 3D-stacked DRAM architecture used by ML accelerators, in which multiple memory dies are vertically bonded and connected to the processor through thousands of Through-Silicon Vias (TSVs) on a shared silicon interposer, eliminating the

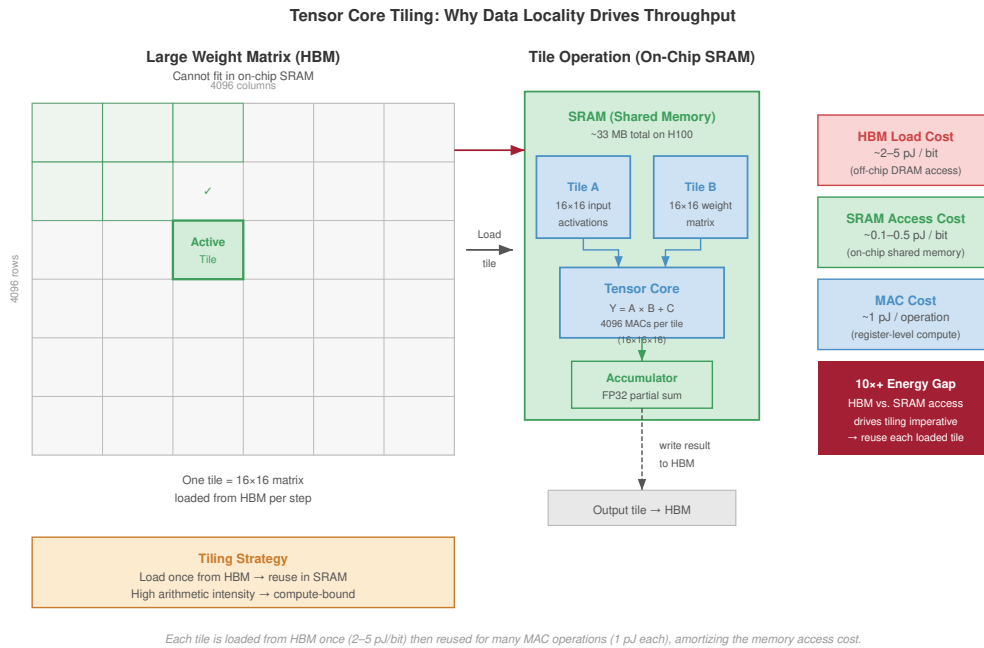

Figure 2.6: Tensor Core Tiling Strategy: To overcome the HBM bandwidth bottleneck, GPUs decompose large matrix operations into small tiles that fit within the Streaming Multiprocessor's (SM) fast SRAM. Data is loaded once into SRAM and reused across multiple Tensor Core operations, effectively multiplying the arithmetic value of every byte fetched from HBM.

centimeter-scale PCB traces of conventional DRAM and replacing them with micrometer-scale vertical paths.

1. **Significance:** HBM3 in the H100 delivers approximately 3.35 TB/s of memory bandwidth—roughly $16\times$ DDR5's ~200 GB/s—at 2 pJ/bit vs. DDR5's ~20 pJ/bit. This bandwidth sets the BW ceiling in the iron law: the H100's FP16 ridge point is approximately 989 TFLOP/s/ $3.35\text{ TB/s} \approx 295\text{ FLOP/byte}$, so any operator with arithmetic intensity below 295 FLOP/byte (for example, attention at 5–20 FLOP/byte) remains memory-bound even with HBM.
2. **Distinction:** Unlike DDR memory, which connects through centimeters of PCB trace (introducing capacitance, attenuation, and high driving current), HBM uses 1,024-bit-wide TSV buses with path lengths measured in micrometers, a $1,000\times$ reduction in signal distance that enables the wider bus without proportionally higher power.
3. **Common pitfall:** A frequent misconception is that HBM solves the memory wall. HBM moves the wall rather than eliminates it: Tensor Core throughput (R_{peak}) has scaled faster than HBM bandwidth across generations (from 900 GB/s with 125 TFLOP/s FP16 in V100 to 3.35 TB/s with 989 TFLOP/s FP16 in H100), so the ridge point continues rising and more operations remain memory-bound despite HBM improvements.

Traditional DDR memory connects to the processor through pins on the edge of a printed circuit board (PCB). Each DIMM communicates over a 64-bit bus, and even with multiple channels (8 channels is typical for a high-end server CPU), a modern server tops out at roughly 200 GB/s of aggregate memory bandwidth.

The physical distance from the DIMM slot to the processor die is measured in centimeters, and every centimeter of copper trace introduces capacitance, signal attenuation, and energy loss. At DDR5 data rates (4,800–6,400 MT/s per pin), the signal conditioning circuits must compensate for

significant channel impairment, consuming substantial power per bit transferred. Increasing the data rate on these long traces requires progressively more power for signal conditioning, creating a diminishing-returns curve that DDR5 is already approaching.

HBM solves this problem by changing the physical topology entirely, as figure 2.7 shows. Instead of routing signals *horizontally* across a PCB, HBM stacks multiple DRAM dies *vertically*, one on top of another, and connects them with **Through-Silicon Vias (TSVs)**⁶: microscopic copper pillars etched through the silicon substrate itself.

⁶ | **TSV (Through-Silicon Via)**: A vertical copper pillar, 5–10 micrometers in diameter, etched through a silicon die to connect stacked layers. Originally developed for CMOS image sensors in smartphone cameras, TSVs enabled HBM by replacing centimeters of PCB trace with tens of micrometers of vertical silicon—a 1,000× reduction in signal path that drops energy per bit from ~20 pJ (DDR5) to ~2 pJ (HBM), making terabyte-per-second bandwidth economically feasible within an accelerator’s power budget.

Figure 2.7: HBM 3D-Stacked Architecture: High Bandwidth Memory achieves its performance by vertically stacking DRAM dies and connecting them via Through-Silicon Vias (TSVs). The entire stack sits on a silicon interposer alongside the GPU die, enabling a 1024-bit-wide bus and reducing signal travel distance from centimeters to micrometers. This physical proximity is the key to breaking the memory wall.

The vertical stacking represents a fundamental change in memory architecture: rather than increasing bandwidth by pushing signals faster through long copper traces (the DDR approach, which has diminishing returns), HBM increases bandwidth by multiplying the number of parallel signal paths through extremely short vertical connections. A single HBM stack bonds 8–12 DRAM dies vertically, threading thousands of TSVs through each die to form a 1024-bit-wide interface per stack, compared to 64 bits for a DDR5 channel. This 16× wider interface, combined with higher per-pin signaling rates, is the source of HBM’s bandwidth advantage. Because the vias travel *through* the silicon rather than *across* a PCB, the signal path shrinks from centimeters to tens of micrometers, roughly a 1000× reduction, and the whole stack sits on the same silicon interposer as the processor die so data travels from DRAM cell to arithmetic unit in nanoseconds rather than the tens of nanoseconds required by off-package DDR.

The shortened distance has three direct physical benefits:

- **Energy per bit:** The transfer cost drops by an order of magnitude, from approximately 20 pJ/bit for DDR5 to approximately 2 pJ/bit for HBM, because shorter traces have lower capacitance and require less driving current.
- **Latency:** Electrical signals propagate through silicon at roughly two thirds the speed of light, so the shorter path reduces propagation time.

- **Signaling rate:** Lower capacitance allows higher signaling frequencies without the sophisticated equalization circuits required by long PCB traces, enabling the high per-pin data rates that complement the wide bus width.

Together, these effects explain why HBM widens the interface and shortens the path instead of simply driving off-package pins faster.

Checkpoint 2.1: HBM and the memory wall

These questions check whether the physical benefits of 3D-stacked memory are clear:

- ☐ **HBM vs. DDR5:** Explain why HBM achieves higher bandwidth than DDR5 despite having a lower clock frequency.
- ☐ **Off-package signaling cost:** Explain why off-package DDR memory has higher energy per bit and how vertical stacking (TSVs) reduces that cost.
- ☐ **Capacity overflow:** Locate where the remaining 60 GB must reside when an H100 has 80 GB of HBM and a 70B parameter model requires 140 GB for FP16 weights.
- ☐ **Bandwidth not capacity:** Classify the claim as true or false: HBM's primary benefit is increasing the total memory capacity available to the GPU.

Table 2.4 summarizes the physical trade-off: HBM wins bandwidth by moving memory onto the package and widening the interface, not by making each off-package signal faster.

Table 2.4: HBM vs. Standard DRAM Comparison: HBM achieves its bandwidth advantage through three simultaneous innovations: 3D die stacking (more bits per package), TSV interconnects (shorter signal paths), and on-package placement (proximity to the processor).

Metric	Host DRAM (DDR5)	Accelerator HBM (HBM3e)	Scaling Factor
Mechanism	2D PCB Traces	3D Die Stacking	-
Placement	Socketed DIMMs	On-package (Substrate)	Physical Proximity
Bandwidth	~200 GB/s	~3.35 TB/s	~17× Faster
Interface Width	64-bit	1024-bit per stack	16× Wider
Energy	~20 pJ/bit	~2–5 pJ/bit	4–10× Efficiency

As table 2.4 shows, this bandwidth advantage comes at a price. HBM costs approximately \$10–15 per GB, compared to roughly \$3 per GB for DDR5 server memory. For an H100 with 80 GB of HBM3, the memory alone represents approximately \$800–1,200 of the accelerator's manufacturing cost. For a B200 with 192 GB of HBM3e, the memory cost rises to \$1,920–2,880 per accelerator, making HBM one of the most expensive components in the system.

The advanced packaging process, which requires precise alignment of thousands of TSVs across multiple die layers, has lower manufacturing yields and higher complexity. Each step in the stacking process (die thinning, alignment, bonding, and TSV etching) can introduce defects. The cumulative yield across 12 stacking steps means that the overall yield for a complete HBM3e stack is substantially lower than the yield for a single DRAM die. The silicon interposer itself must be large enough to accommodate both the processor die and multiple HBM stacks (often exceeding 1,000 mm² in total area), and any defect in a TSV can render an entire stack unusable.

The supply chain dynamics of HBM production further affect its cost and availability. The HBM supply chain is highly concentrated among a small number of manufacturers, and the production processes (die thinning, TSV etching, die-to-die bonding) require specialized capital equipment that is fundamentally different from standard DRAM manufacturing. Expanding HBM production capacity requires 12–18 months of equipment procurement and qualification, which means that production cannot rapidly scale in response to demand surges. When demand outpaces supply, as it

did following the explosion of interest in large language models in 2023, lead times stretch to 12–18 months and prices can double.

For infrastructure planners, this supply chain concentration means that HBM availability, not just its specifications, can determine the timeline for building a training cluster. Organizations planning large deployments must secure HBM allocations 12–18 months in advance, committing capital before the rest of the system is designed. This procurement lead time is longer than for any other component in the stack, making HBM the pacing element for fleet expansion.

For our 175B model, the HBM alone in a cluster of 1,000 accelerators represents roughly \$0.8–1.2 million at 80 GB/accelerator (or \$2–3 million at 192 GB/accelerator) under the \$10–15/GB cost model above. This cost-capacity trade-off explains *why* accelerators typically offer 80–192 GB of HBM while the host server provides 512 GB to 2 TB of DDR: the *fast* memory holds the active computation (weights, activations, gradients that are accessed every cycle), and the *cheap* memory holds everything else (optimizer states, checkpoint buffers, data loading queues).

The boundary between what resides in HBM and what resides in DDR is a critical design parameter for training frameworks, and managing this boundary efficiently is one of the key challenges addressed by ZeRO (Zero Redundancy Optimizer) sharding and offloading strategies described in section 5.3.3. Sharding divides optimizer, gradient, and parameter state across workers; offloading places colder state in host DRAM or NVMe when HBM capacity is the binding limit. Getting this boundary wrong in either direction is costly: placing too much data in HBM wastes expensive capacity, while placing too much in DDR creates bandwidth stalls that idle the arithmetic units.

2.3.1.1 HBM generations and the scaling boundary

The evolution of HBM tracks the growth of model sizes with close correspondence. Each generation increases the number of stacked dies, the signaling rate per pin, and the total capacity per stack, driven by the relentless growth in model parameters. Table 2.5 shows the scaling boundary: HBM4 must widen the interface because pin-rate increases alone are no longer enough.

Table 2.5: Evolution of High Bandwidth Memory: Each generation increases aggregate accelerator memory bandwidth, tracking the growth of large model sizes. The jump to HBM4 doubles the interface width for the first time since HBM’s introduction, signaling that pin-rate increases alone can no longer sustain the required bandwidth growth.

Metric	HBM2e (A100)	HBM3 (H100)	HBM3e (B200)	HBM4 (Future)
Peak Bandwidth	~2.0 TB/s	~3.3 TB/s	~8.0 TB/s	12–16 TB/s (projected)
Typical Capacity	40–80 GB	80–96 GB	192 GB	288 GB+
Interface Width	1024-bit	1024-bit	1024-bit	2048-bit
Stack Height	8 dies	8–12 dies	12 dies	16 dies

As table 2.5 shows, the transition from HBM3 to HBM3e is particularly significant for our running example. An A100 with 80 GB of HBM2e can hold only 23 percent of our 175B model’s weights (at FP16). An H100 with 80 GB of HBM3 can hold the same fraction but deliver the data 65 percent faster. A B200 with 192 GB of HBM3e can hold 55 percent of the weights and deliver them at about 8 TB/s. Neither can hold the full model, which is precisely *why* we need multiple accelerators in a node, a topic we address in section 2.4.

However, the capacity story changes significantly when quantization is applied. The same 175B model quantized to INT8 requires only 175 GB, fitting in 3 H100 GPUs or a single B200. Quantized to INT4, it requires only 87.5 GB, fitting in two H100 GPUs. The capacity constraints that drive the need for multi-accelerator nodes for training (where FP16 or BF16 precision is typically required) are substantially relaxed for inference (where INT8 or INT4 quantization is often acceptable). This is another reason *why* training and inference infrastructure have different optimal configurations.

The bandwidth improvement matters independently of capacity. Each generation of HBM produces a nearly proportional reduction in per-token latency during autoregressive inference once the capacity problem has been handled by sharding or quantization.

A 70.6B FP16 model has 141 GB of weights, so a bandwidth-floor calculation gives roughly 141 GB/2.04 TB/s = 69.2 ms per token at A100-class bandwidth, 141 GB/3.35 TB/s = 42.1 ms at H100-class bandwidth, and 141 GB/8 TB/s = 17.7 ms at B200-class bandwidth. The A100 and H100 cases do not

imply that the full FP16 model fits on one device; they isolate the latency floor imposed by a single accelerator-equivalent HBM path. For interactive applications (chatbots, code assistants, real-time translation), where users perceive delays above 50 ms as “slow,” these bandwidth improvements translate directly into better user experience and into the ability to serve larger models within latency budgets.

The projected jump to HBM4 doubles the interface width from 1024 bits to 2048 bits for the first time since HBM’s introduction. This signals that per-pin signaling rate increases alone cannot sustain bandwidth growth indefinitely, and the bus must widen. The doubling of interface width requires a correspondingly larger interposer area for routing, which is one reason accelerator packages have tended to grow as bandwidth targets rise.

HBM4-class packages projected in the 12–16 TB/s aggregate range illustrate the planning pressure created by trillion-parameter-scale models. A 1T-parameter model requires roughly 2 TB of weight storage in FP16. At B200-class HBM3e bandwidths (about 8 TB/s), serving such a model at batch size 1 would produce tokens at $2000 \text{ GB} / 8 \text{ TB/s} = 250 \text{ ms}$ per token, far too slow for interactive applications. Even at 16 TB/s, the bandwidth floor remains roughly 125 ms per token before batching, quantization, or tensor-parallel sharding. This calculation suggests that trillion-parameter models require aggressive quantization and multi-accelerator tensor parallelism even for single-request inference. The co-evolution of model scale and memory technology continues to drive infrastructure requirements.

An important architectural consideration is the number of HBM stacks per accelerator and how they connect to the processor. The H100 has 5 HBM3 stacks, each providing approximately 670 GB/s, for a total of 3.35 TB/s aggregate bandwidth. A B200-class Blackwell GPU package uses 8 HBM3e stacks for an aggregate of about 8 TB/s. The number of stacks is constrained by the interposer area available for HBM placement: each HBM stack occupies approximately 100 mm² of interposer area, and the total interposer must accommodate both the processor die(s) and all HBM stacks. Larger interposers allow more HBM stacks (and therefore higher bandwidth and capacity) but are more expensive and harder to manufacture.

The interposer area constraint creates a concrete design tension. Making the processor die larger (more Tensor Cores, more SMs) leaves less interposer area for HBM stacks, potentially reducing bandwidth. Making the processor die smaller (fewer Tensor Cores) frees interposer area for more HBM but reduces peak compute throughput. The optimal balance depends on the target workload’s position on the Roofline plot: compute-bound workloads benefit from a larger processor die (more Tensor Cores), while bandwidth-bound workloads benefit from more HBM stacks. Section C.3.1 derives the ridge point that separates these two regimes, expressing it through equation C.2 and equation C.4 so that a workload’s arithmetic intensity predicts which side of the balance it falls on before any silicon is committed.

2.3.1.2 Memory bandwidth and token latency

The distinction between memory *capacity* (how many gigabytes the HBM can store) and memory *bandwidth* (how many terabytes per second it can deliver) is one of the most practically important concepts in ML infrastructure. Capacity determines whether a model’s weights *fit*. Bandwidth determines how fast the model can *run*. For autoregressive text generation, where each token requires a full pass through the model’s weights, bandwidth is almost always the binding constraint. Section D.1 formalizes the same latency-versus-bandwidth decomposition for data movement across the network, giving the reader a single algebraic model that applies equally to the memory system here and to inter-node transfers later.

Napkin Math 2.1: The physics of token latency

Problem: Generating one token from Llama-3 70B (141.2 GB of FP16 weights) requires both arithmetic and a full weight load from HBM. Assuming capacity has been solved (by sharding, a higher-capacity device, or quantization), which dominates the per-token time on an H100: compute or memory transfer?

1. **Compute Time:** Each token requires $2 \times 70 \times 10^9 = 1.4 \times 10^{11}$ floating-point operations. At 989 TFLOP/s of FP16/BF16 Tensor Core peak throughput, the arithmetic takes $T_{\text{compute}} \approx 0.14$ ms.

2. **Memory Time:**

Loading 141.2 GB of weights from HBM at 3.35 TB/s takes $T_{\text{mem}} \approx 42.1$ ms.

Systems insight: The processor spends 99.7 percent of its time waiting for data from memory. The arithmetic units are idle for almost the entire token generation. Even a hypothetical processor with infinite compute throughput would generate tokens only negligibly faster, because the memory transfer time dominates completely. This is *why* HBM bandwidth improvements deliver nearly linear speedups for inference workloads.

That bandwidth floor also gives us a clean way to compare adjacent hardware generations: if compute stays fixed while HBM capacity and bandwidth improve, decode latency should move with the memory system rather than the arithmetic units.

Napkin Math 2.2: The memory wall: H100 vs. H200

To understand *why* the “memory wall” is the primary constraint for modern large language models (LLMs), we compare the NVIDIA H100 against its successor, the H200. While both chips share the same compute cores (same peak TFLOP/s), the H200 provides 1.4× higher memory bandwidth and 1.6× more HBM capacity.

This LEGO comparison uses a Llama 3 model with 70.6B parameters, sequence length 2,048, and batch size 1; the reported speedup is the serving solver’s inter-token latency estimate, not a raw bandwidth ratio alone. A napkin estimate brackets that solver number: decode spends 99.7 percent of its per-token time on the weight load, so the expected gain is the HBM bandwidth ratio, $4.8 \text{ TB/s} \div 3.35 \text{ TB/s} \approx 1.4\times$.

Systems insight: For LLM decoding, the H200 is 1.4× faster than the H100 despite having identical compute power; the solver’s estimate lands almost exactly on the bandwidth ratio because decode is bandwidth-bound. This proves that for large-scale autoregressive models, the “Wall” is the memory interface, not the arithmetic logic.

The napkin math reveals a profound asymmetry at the heart of modern ML infrastructure. The accelerator vendors invest billions of dollars in designing faster arithmetic units (more Tensor Cores, higher clock speeds, wider datapaths), yet for single-request inference, the arithmetic completes in a fraction of a millisecond while the memory transfer takes tens of milliseconds. The arithmetic units are about 300× faster than the memory system for this workload, meaning that over 99 percent of the silicon dedicated to computation is idle during inference. That compute-memory asymmetry is the single most important physical fact about ML inference, and it shapes every architectural and economic decision about serving infrastructure.

The fraction of token time spent waiting on memory, 99.7 percent in this example, is called the **memory-boundedness** of the workload. A workload that is 99 percent memory-bound will see almost no benefit from a faster processor (more TFLOP/s) but will see nearly linear speedup from faster memory (more TB/s bandwidth).

Memory-boundedness is a quantitative expression of the memory wall: the gap between processing speed and memory speed has widened for decades and is particularly acute for ML inference workloads. The memory wall was first identified by Wulf and McKee in 1995, who observed that processor speed was improving at 60 percent per year while DRAM speed improved at only 7 percent per year. The growing disparity meant that processors would increasingly spend their time waiting for data rather than computing on it. Thirty years later, their prediction has proven accurate, and the ML inference workload is the most extreme manifestation of the memory wall in modern computing.

The practical implication is that accelerator selection for inference workloads should prioritize bandwidth-per-dollar over FLOP/s-per-dollar. An older-generation GPU with high memory band-

width but moderate compute throughput may deliver better inference performance per dollar than a latest-generation GPU with extreme compute but insufficient bandwidth improvement.

Figure 2.8 makes this divergence visible across four GPU generations. While peak Tensor throughput has grown $36\times$ from V100 to B200 when following each generation’s advertised low-precision mode, memory bandwidth has grown only $9\times$ over the same period. *The widening gap between compute growth and bandwidth growth is the memory wall: each generation of accelerator becomes more powerful in arithmetic but proportionally more starved for data.*

Figure 2.8: The Compute-Memory Divergence: GPU peak Tensor throughput has grown approximately $36\times$ from V100 to B200 when following each generation’s advertised low-precision Tensor Core mode, while HBM bandwidth has grown only $9\times$ over the same period. The widening gap between these curves is the memory wall: each generation of accelerator becomes proportionally more starved for data.

For training workloads, where large batch sizes increase arithmetic intensity, the calculus shifts toward compute: peak TFLOP/s per dollar becomes the relevant metric because the weight data loaded from HBM is amortized across many tokens in the batch. The Roofline Model, which we examine next, provides the formal framework for making this trade-off precise and for determining which metric matters for any given workload.

2.3.2 Roofline model

The token latency calculation above demonstrated that a 70B model on an H100 is overwhelmingly memory-bound. The question is how to determine this systematically for any workload on any hardware. The **Roofline Model**⁷, introduced by Williams, Waterman, and Patterson (Williams et al. 2009), provides a visual and analytical framework that answers this question with a single number: the arithmetic intensity of the workload.

For an H100 (989 TFLOP/s FP16, 3.35 TB/s HBM), the ridge point is ~ 295 FLOP/byte; most LLM inference operators fall well below this threshold, which is *why* the Roofline remains the first diagnostic tool for identifying whether more compute or more bandwidth will improve performance. The quantity that places a workload on this plot is its **arithmetic intensity** (I), defined as $I = \text{FLOP/byte}$: the ratio of computation to memory traffic that determines whether a workload is bandwidth-bound or compute-bound. The same quantity carries forward to fleet-scale performance analysis at section 9.1.5.

The Roofline Model expresses the maximum achievable performance of a workload as the lesser of two ceilings:

⁷ | **Roofline Model:** Introduced by Williams, Waterman, and Patterson at UC Berkeley in 2009, the model plots attainable FLOP/s against arithmetic intensity on a log-log scale, producing two intersecting lines whose crossover point – the *ridge point* – separates memory-bound from compute-bound regimes.

Decode sits deep in the memory-bound regime, far below the ridge.

$$\text{Achievable FLOP/s} = \min(R_{\text{peak}}, \text{BW} \times I) \quad (2.1)$$

Equation 2.1 has a direct physical interpretation. If the workload’s arithmetic intensity is low (it needs many bytes per operation), then performance is limited by how fast memory can deliver those bytes. The achievable FLOP/s grows linearly with I , tracing a sloped line on a log-log plot. If the arithmetic intensity is high (each byte fuels many operations), then performance plateaus at the hardware’s peak compute rate, regardless of further increases in I . This plateau is the flat “roof” of the model.

Definition 2.2: Ridge point

Ridge Point is the ML accelerator arithmetic intensity where the memory bandwidth ceiling meets the compute ceiling ($I_{\text{ridge}} = \frac{R_{\text{peak}}}{\text{BW}}$).

1. **Significance:** It defines the Hardware Efficiency Threshold. Workloads with an intensity below the ridge point are bandwidth-bound (BW), while those above are compute-bound (R_{peak}).
2. **Distinction:** Unlike Peak FLOP/s (which only describes the horizontal ceiling), the ridge point describes the Balance of the architecture. A rising ridge point over hardware generations indicates that compute is growing faster than bandwidth, making utilization harder.
3. **Common pitfall:** A frequent misconception is that all GPUs have the same ridge point. In reality, it varies by Precision: because R_{peak} is higher for INT8 than FP32 while BW is constant, the ridge point for INT8 is much higher, requiring more data reuse to saturate the hardware.

Specific ML workloads occupy different regions of this plot depending on the operation and the batch size:

- **LLM decode (batch size 1):** Each token requires loading the full weight tensor (~2 bytes per parameter) for just 2 FLOPs per parameter, yielding $I \approx 1$ FLOP/byte. This is deep in the memory-bound region, well below the ridge point of 295.2 FLOP/byte. Our token latency calculation confirmed this: the arithmetic finished in microseconds while the memory transfer took milliseconds.
- **LLM prefill (large context):** Processing a long input sequence in parallel increases the FLOPs (matrix-matrix multiply instead of matrix-vector) without proportionally increasing memory traffic, pushing I to 100–500 FLOP/byte. This range straddles the H100 ridge point: the lower end remains memory-bound or near the ridge, while the upper end crosses into the compute-bound region.
- **CNN training (large batch):** Convolution with large spatial dimensions and batch sizes achieves I of 50–200 FLOP/byte, placing it near or above the ridge point for most accelerators.
- **Attention (long sequences):** The self-attention mechanism scales quadratically with sequence length in FLOPs but linearly in memory traffic for the KV cache, making its arithmetic intensity sequence-length-dependent. Short sequences are memory-bound; long sequences are compute-bound.

The point is to classify each phase and batch shape on the roofline, not to assign one permanent region to an entire model family.

Reading a Roofline plot requires understanding what each axis represents. The horizontal axis is arithmetic intensity (FLOP/byte), plotted on a log scale. The vertical axis is achievable performance (FLOP/s), also on a log scale. Two lines define the “roofline” shape: a diagonal line with slope 1 (on the log-log plot) representing the memory bandwidth limit, and a horizontal line representing the peak compute limit. These two lines meet at the ridge point.

Any workload can be plotted as a single point on this chart by computing its arithmetic intensity and measuring its achieved performance. If the point lies on the diagonal line, the workload is

memory-bound and would benefit from faster memory. If it lies on the horizontal line, the workload is compute bound and would benefit from more arithmetic units.

If the point lies below either line, the workload is not fully using the available resource. This gap indicates an optimization opportunity in the software: kernel inefficiency, poor memory access patterns, or excessive synchronization. Closing this gap is the province of kernel engineering and communication optimization, topics examined in Chapter 9.

The Roofline’s diagnostic power extends beyond individual kernels to entire training runs. For our 175B model, the computation graph contains thousands of distinct operations with different arithmetic intensities. The dense Feed-Forward Network (FFN) layers are dominated by large GEMMs with high arithmetic intensity, placing them firmly in the compute-bound regime where Tensor Core utilization is the bottleneck. Conversely, operations like layer normalization and element-wise activations possess low arithmetic intensity, sitting deep in the memory-bound region where the compute units idle while waiting for data. The self-attention mechanism fluctuates between regimes depending on sequence length: while the quadratic complexity of attention scores suggests a compute bound, the loading of Key and Value matrices creates memory pressure at shorter sequences. This diagnostic distinction dictates the optimization strategy: memory-bound layers benefit from kernel fusion (reducing HBM round-trips), while compute-bound layers benefit from precision reduction (moving from FP16 to FP8, which effectively raises the hardware’s compute ceiling).

Figure 2.9 makes these relationships visible for the H100. Notice how LLM decode at batch size 1 sits deep in the memory-bound region, achieving less than 1 percent of peak compute, while LLM training at large batch sizes crosses the ridge point into the compute-bound regime. Under the batch-size 2048 simplification used in the running example, the 2,048 $\times$ gap between these two workloads’ arithmetic intensities (~ 1 FLOP/byte for decode vs. $\sim 2,048$ FLOP/byte for training) explains why the same hardware that delivers excellent training throughput can appear woefully underutilized during inference.

Figure 2.9: The Roofline Landscape: NVIDIA H100 (FP16): H100 roofline showing the memory-bandwidth and peak-compute ceilings, with representative ML workloads spanning memory-bound and compute-bound regions.

The roofline in figure 2.9 is defined by two ceilings: memory bandwidth (diagonal) and peak compute (horizontal), meeting at the FP16 ridge point (~ 295.2 FLOP/byte for 989 TFLOP/s over 3.35 TB/s). ML workloads span the full range: LLM decode at batch size 1 is deeply memory bound,

while LLM training at large batch sizes is compute bound. The position of each workload determines whether faster memory or faster compute would improve performance.

The Roofline Model also reveals a subtle but important insight about the interaction between batch size and hardware utilization. Increasing the batch size for a given model raises the arithmetic intensity because the weight matrix is loaded once but multiplied against a larger activation matrix (more FLOPs for the same bytes transferred). This shifts the workload point rightward on the plot, potentially crossing the ridge point from memory-bound to compute-bound territory. The arithmetic intensity grows linearly with batch size (doubling the batch size doubles the FLOPs while keeping the weight loading unchanged), creating a simple and predictable relationship between batch size and hardware utilization.

For inference serving, batching multiple requests together dramatically increases hardware utilization and throughput. A model that achieves 1 percent of peak FLOP/s at batch size 1 might achieve 50 percent of peak FLOP/s at batch size 64, simply because the weight data loaded from HBM is reused across 64 independent requests rather than one. This $50\times$ improvement in hardware utilization comes at a cost: the 64 requests must wait until a full batch is assembled before processing begins, introducing queuing latency. Serving systems must carefully balance this trade-off between throughput (larger batches, higher utilization) and latency (smaller batches, faster response per request).

For training, the batch size is a hyperparameter that affects both statistical convergence and hardware efficiency, creating a trade-off that practitioners must navigate carefully. Larger batch sizes improve hardware utilization (pushing the workload into the compute-bound regime) but may require learning rate adjustments and warmup schedules to maintain training quality. The optimal batch size depends on both the model architecture and the hardware's Roofline characteristics, creating a cross-disciplinary optimization problem that spans ML theory and systems engineering.

The practical value of the Roofline Model is that it tells us which resource to optimize. If a workload is memory-bound, buying a faster accelerator (more TFLOP/s) yields no benefit; only higher memory bandwidth will help. Conversely, if a workload is compute bound, upgrading HBM generations is wasted money. This diagnostic power is the reason that experienced infrastructure engineers always begin a hardware selection process by computing the arithmetic intensity of their target workload and plotting it against the candidate hardware's Roofline: the plot immediately reveals which hardware characteristic matters and which is irrelevant.

For our 175B model, training with large batch sizes is compute bound (optimize for TFLOP/s), while serving individual requests is memory bound (optimize for bandwidth). This duality explains why some organizations use different hardware generations for training and inference. An A100, with its lower cost and adequate memory bandwidth, may be more cost-effective for inference than an H100, despite the H100's higher peak FLOP/s.

The Roofline Model also provides a quantitative framework for evaluating the return on investment of different optimizations. If a workload is $10\times$ below the compute ceiling but already touching the bandwidth ceiling, spending engineering effort on kernel optimization (moving toward the compute ceiling) yields no benefit. The effort should instead be directed toward reducing memory traffic (shifting the workload rightward on the plot) through techniques like batching, kernel fusion, or quantization.

The Roofline's diagnostic power makes it one of the most practically useful analytical tools in the infrastructure engineer's toolkit. Before committing to any hardware purchase or optimization effort, plotting the workload on the Roofline reveals immediately whether the investment will produce returns. Teams that skip this analysis risk spending months optimizing the wrong resource, an expensive mistake when GPU-hours cost thousands of dollars per day.

The same arithmetic-intensity calculation separates the running model's inference and training regimes.

Example 2.2: Roofline analysis: Training vs. inference

Consider our 175B model on an H100 with 989 TFLOP/s peak compute and 3.35 TB/s memory bandwidth. The ridge point is 295.2 FLOP/byte.

Inference (decode, batch size 1): Each token loads 350 GB of FP16 weights and performs $2 \times 175 \times 10^9$ FLOPs. Arithmetic intensity: $I = \frac{2 \times 175 \times 10^9}{350 \times 10^9} = 1$ FLOP/byte. Since 1 FLOP/byte $\ll$ 295.2 FLOP/byte (the ridge point), the workload is deeply memory bound. The achievable throughput is $3.35 \times 1 = 3.35$ TFLOP/s, which is about 0.34 percent of the H100's peak 989 TFLOP/s. No amount of additional compute will help; only more memory bandwidth improves throughput.

Training forward pass (batch size 2048): The same weight tensor is multiplied by a batch of 2048 activation vectors simultaneously, turning matrix-vector operations into matrix-matrix operations. The FLOPs increase by 2048 $\times$ while the weight loading remains constant: $I = 2048 \times 1 = 2,048$ FLOP/byte. Since 2,048 FLOP/byte $\gg$ 295.2 FLOP/byte, the workload is compute bound. The achievable throughput is now limited by the peak compute ceiling of 989 TFLOP/s, and the memory bandwidth is irrelevant. Adding more TFLOP/s (through a newer GPU generation) directly improves performance.

Systems insight: The contrast explains why organizations sometimes use different hardware for training and inference: *training* benefits from peak FLOP/s, while *inference* benefits from memory bandwidth per dollar.

That same diagnostic becomes most valuable when a proposed upgrade changes the wrong ceiling.

Checkpoint 2.2: Roofline diagnosis

A team is serving a 13B-parameter model at batch size 1 on an H100 and observing 25 ms per token. The profile shows low tensor-core utilization during decode.

- ☐ **Arithmetic intensity:** Estimate the arithmetic intensity of the workload.
- ☐ **Peak-throughput upgrade:** Decide whether a higher peak-TFLOP/s accelerator changes the binding term.
- ☐ **Binding constraint:** Identify the measurement or hardware capability that should improve first.

2.3.3 Tensor Cores and matrix units

The Roofline Model tells us whether a workload can reach peak compute. The next question is what determines that peak in the first place. The answer lies in the specialized arithmetic units that occupy the majority of a modern accelerator's die area: **Tensor Cores**⁸ on NVIDIA GPUs and **Matrix Multiply Units (MXUs)** on Google TPUs.

A standard CPU floating-point unit performs one multiply-accumulate per cycle per lane. Even with wide SIMD units (AVX-512 provides 16 FP32 lanes), a CPU core performs at most 16 MACs per cycle. With 32 cores, a high-end server CPU achieves approximately 512 MACs per cycle, a respectable number for general-purpose computation but wholly inadequate for the demands of matrix multiplication at neural network scale.

A Tensor Core, by contrast, executes matrix-multiply-accumulate (MMA) instructions of the form $\mathbf{Y} = \mathbf{A} \times \mathbf{B} + \mathbf{C}$ on small tile matrices in specialized hardware. On the H100, these tile operations are distributed across the Tensor Core array in each SM, producing hundreds of accumulated results per instruction while keeping operands in registers and shared memory. This concentrates the dominant neural-network operation in hardware that occupies a small fraction of the chip area.

With 528 Tensor Cores across the chip (4 per SM, 132 SMs), the H100 reaches the 989 TFLOP/s FP16/BF16 peak used in the roofline analysis. The important systems point is not the exact per-cycle instruction accounting, but the architectural specialization: the die dedicates a large fraction of its arithmetic area to dense tiled matrix operations rather than general-purpose scalar execution.

Google's MXUs take the same concept further by organizing the multipliers into a systolic array. In a systolic MXU, one matrix is loaded into the array's weight registers while the other matrix streams through the array one row at a time. Each cell multiplies the incoming activation by its stored

⁸ | **Tensor Core:** Introduced with NVIDIA Volta (2017) as 4 $\times$ 4 $\times$ 4 FP16 fused matrix-multiply-accumulate units. Each generation widened the tile: Turing (2018) added INT8, Ampere (2020) added TF32/BF16, and Hopper (2022) reached 16 $\times$ 16 $\times$ 16 with FP8 support. This precision cascade tracks ML's own shift toward lower-precision training and inference—each new format unlocks a 2 $\times$ throughput gain on the same silicon, making Tensor Core generations a proxy for how quickly the hardware-software co-design loop can widen the Roofline's compute ceiling.

weight, adds the result to the partial sum flowing from the cell above, and passes both the activation rightward and the partial sum downward. This pipelined flow means the array is performing useful computation on every cycle, with no idle cells once the pipeline is full. The TPU v5p contains two 128×128 MXUs per chip, providing 459 TFLOP/s of BF16 throughput. The systolic dataflow eliminates the register file accesses between operations that a Tensor Core still requires, achieving marginally higher energy efficiency at the cost of the flexibility to run nonmatrix workloads.

For our 175B model, the choice between Tensor Cores and MXUs manifests in the compiler stack. CUDA kernels can intermix Tensor Core operations with arbitrary thread-level code, enabling fused kernels that combine matrix multiplies with activation functions, dropout, and layer normalization in a single launch. This fusion is critical for performance because it eliminates the intermediate memory reads and writes that would otherwise occur between operations, keeping data in registers and shared memory where access is fastest.

XLA compilation for TPUs must decompose the computation into sequences of matrix operations that map onto the systolic dataflow, which can be more efficient for standard Transformer architectures but less flexible for custom operations. The XLA compiler performs whole-program optimization, analyzing the entire computation graph to find the optimal tiling, memory layout, and execution schedule for the systolic array. For standard Transformer layers, this whole-program optimization can achieve higher hardware utilization than hand-tuned CUDA kernels, because the compiler can reason about the entire computation rather than optimizing individual operations in isolation.

The hardware dictates the software abstraction, which in turn shapes what architectures are practical to experiment with. This coupling between hardware and software is a defining characteristic of ML infrastructure and explains why hardware selection has downstream effects on research velocity and model design flexibility.

Definition 2.3: Tensor core

Tensor Core is a specialized ML accelerator hardware unit that performs a fused matrix-multiply-accumulate (MMA) operation $\mathbf{Y} = \mathbf{A} \times \mathbf{B} + \mathbf{C}$ on small tiles (for example, $16 \times 8 \times 16$ in BF16) as a single hardware instruction, delivering dramatically higher throughput than general-purpose CUDA cores by trading programmability for fixed-function matrix arithmetic.

1. **Significance:** Tensor Cores provide the bulk of the H100's 989 TFLOP/s FP16/BF16 peak (and ~1,979 TFLOP/s at FP8)—roughly 14.8× the ~67 TFLOP/s delivered by CUDA (vector) cores alone. However, this peak is only achievable for operations that decompose into tiled matrix multiplications. Layer normalization and softmax, which involve reductions and element-wise operations rather than matrix multiplications, run at approximately 3–8 percent of peak throughput on the same hardware.
2. **Distinction:** Unlike general-purpose CUDA cores (which execute one floating-point operation per clock per lane in a SIMT pipeline), Tensor Cores execute 512 multiply-accumulate operations per clock per warp on matrix tiles—trading the arbitrary per-element programmability of CUDA cores for the specific throughput of matrix arithmetic.
3. **Common pitfall:** A frequent misconception is that all GPU operations benefit from Tensor Cores. Only operations that map to the $\mathbf{Y} = \mathbf{A} \times \mathbf{B} + \mathbf{C}$ tile computation (dense linear layers, attention score computation, convolutions) engage Tensor Cores; element-wise activations, layer norm, and embedding lookups fall back to CUDA cores and can run 10–30× slower per FLOP than Tensor Core operations.

The precision support of Tensor Cores has expanded with each generation, driven by the discovery that neural network training and inference can tolerate lower numerical precision than was previously assumed. The Volta generation supported only FP16 accumulation. Ampere added BF16, TF32, and INT8. Hopper added FP8 (both E4M3 and E5M2 formats) with dynamic per-tensor scaling through the Transformer Engine.

The Transformer Engine automatically monitors the magnitude distribution of each tensor and selects FP8 when precision is adequate or FP16 when higher precision is needed, doubling the

effective throughput for layers where FP8 suffices. This hardware-assisted precision management represents a convergence of arithmetic design and model-level insight: the hardware is no longer a passive executor of the programmer's precision choices but an active participant in the precision decision.

Understanding the distinction between the two FP8 formats clarifies why this matters for practitioners. The E4M3 format (4 exponent bits, 3 mantissa bits) can represent values up to approximately 4.48×10^2 , with 3 bits of mantissa providing about 1 part in 8 relative precision. This range and precision are adequate for many neural network weights and activations after per-tensor scaling brings their observed range into the FP8 window.

The E5M2 format (5 exponent bits, 2 mantissa bits) provides a wider dynamic range, with maximum finite values around 5.73×10^4 , at the cost of reduced precision (only 2 mantissa bits, or about 1 part in 4 relative precision). This wider range is important for gradients during the backward pass, which can span more orders of magnitude than forward-pass activations, particularly in the early and late layers of deep networks.

The Transformer Engine selects between these formats on a per-layer basis, and the per-tensor scaling factors are maintained in a small metadata buffer that adds negligible memory overhead. The scaling factors are updated every few iterations based on the observed tensor value distributions, ensuring that the limited precision of FP8 is focused on the range of values that actually appear in each tensor.

The practical implication for fleet design is that peak TFLOP/s specifications are precision-dependent. The H100 delivers 989 TFLOP/s in FP16 but twice that (1,979 TFLOP/s) in FP8. A fleet designed for FP8 training effectively has twice the compute density of the same fleet running FP16, with no additional hardware. This makes precision engineering a first-class optimization lever for infrastructure planners, not just a model accuracy concern.

To achieve this peak throughput in practice, the entire accelerator must be viewed as a rigid pipeline where data flows from HBM through a deepening hierarchy of caches before reaching the Tensor Cores. The fundamental constraint is **pipeline balance**: the rate at which data is staged into registers must match or exceed the rate at which the arithmetic units consume it. When the arithmetic intensity of an operation falls below the ridge point, the pipeline stalls, leaving teraflops of compute potential idle while waiting for data. This makes **kernel fusion** the single most critical software optimization for large-scale training. By fusing multiple operations (matrix multiplication, bias addition, activation function) into a single kernel, the system eliminates the round-trips to HBM that would occur if each operation were executed sequentially. Consider the attention mechanism: a naive, unfused implementation writes the $S \times S$ attention matrix to HBM only to read it back for the softmax operation, creating a round trip capped by the 3.35 TB/s memory bandwidth. A fused implementation like FlashAttention keeps these intermediate matrices entirely in on-chip SRAM, bypassing HBM and allowing the Tensor Cores to run near their theoretical peak. For our 175B model, where each training step involves thousands of matrix operations across 96 Transformer layers, the difference between fused and unfused kernels can be a 2–3 $\times$ throughput improvement, separating a 2-week training run from a 6-week one.

2.3.3.1 Peak vs. sustained throughput

A critical distinction for infrastructure planning is the difference between *peak* throughput (the maximum the hardware can achieve on a synthetic benchmark) and *sustained* throughput (what the hardware actually delivers during real training runs). Peak TFLOP/s assumes that the Tensor Cores are fed with data on every cycle, which requires perfect scheduling, zero memory stalls, and no communication overhead. In practice, sustained throughput during Transformer training is typically 30–50 percent of peak for compute-bound operations and less than 5 percent of peak for memory-bound operations. The gap between peak and sustained throughput arises from several sources, each of which represents a different physical or software limitation.

Memory stalls occur when the Tensor Cores complete their current tile multiplication before the next tile has been loaded from HBM. Even with the H100's 3.35 TB/s HBM bandwidth, the Tensor Cores can consume data faster than HBM can deliver it for certain matrix dimensions, creating idle cycles while the arithmetic units wait for data.

Pipeline bubbles arise when one operation must complete before the next can begin, leaving some processing elements idle. In a Transformer layer, the attention computation must complete before the

feed-forward network can begin, and the feed-forward computation must complete before the next layer's attention can start. These sequential dependencies create brief periods where some hardware resources are unused. The local mechanism is simple: a bubble is an idle slot between dependent stages, and microbatching reduces the waste by feeding later microbatches into stages that would otherwise wait. At the infrastructure level, the lesson is that peak throughput assumes a perfectly filled pipeline, while real training includes dependency gaps that lower sustained utilization.

Communication overhead from AllReduce operations (for tensor parallelism) or gradient synchronization (for data parallelism) pauses computation entirely while data is exchanged between accelerators. Even when communication is overlapped with computation (using separate communication and compute streams), there are typically operations that cannot be overlapped because they depend on the result of the communication.

Software overhead from kernel launch latency, memory allocation, and Python-level control flow contributes an additional 5–10 percent overhead. Each CUDA kernel launch incurs approximately 5–10 microseconds of latency on the host side, and a single Transformer layer may involve 20–30 kernel launches. For small microbatches where each kernel completes in microseconds, the launch overhead can become a meaningful fraction of total execution time.

Kernel fusion partially addresses this gap by combining multiple operations (matrix multiply, bias add, activation function, dropout) into a single GPU kernel, eliminating the intermediate memory reads and writes that would otherwise stall the Tensor Cores between operations. The art of achieving high sustained utilization is largely the art of minimizing the time Tensor Cores spend idle, which is why specialized kernel libraries like FlashAttention and the Transformer Engine exist.

For capacity planning, the sustained throughput rate, not the peak rate, should be used. A training run estimated at 1,000 GPU-hours using peak FLOP/s will actually require 2,000–3,000 GPU-hours when accounting for real-world utilization. Experienced infrastructure teams track their **Model FLOPs Utilization (MFU)**, defined as the ratio of the model's useful FLOP count to the product of hardware peak FLOP/s and wall-clock time, as the primary metric for infrastructure efficiency. MFU values of 40–50 percent are considered good for large-scale transformer training; values above 50 percent indicate excellent software optimization. Section 9.9.1 formalizes MFU and develops its fleet-scale application.

2.3.4 Power wall and thermal constraints

The memory wall constrains how fast data reaches the compute units; the Roofline Model diagnoses whether compute or memory is the binding constraint; and Tensor Cores maximize the arithmetic value of every byte fetched. A third physical constraint also limits the accelerator's performance: the heat generated by all this computation. Every FLOP dissipates energy, and the faster we compute, the more heat we must remove. This is the power wall. Figure 2.10 traces the journey of energy from grid to transistor.

The cascade shown in figure 2.10 reveals why power delivery is an infrastructure problem, not merely an electrical one: these conversion losses, combined with the overhead of removing heat, determine the facility's total power draw, and the 10–40 kW concentrated at the rack PDU-to-VRM transition dictates the cooling architecture for the entire facility. Equation 2.2 captures that cooling overhead through a single facility ratio, Power Usage Effectiveness (PUE):

$$\text{PUE} = \frac{P_{\text{facility}}}{P_{\text{IT}}} \quad (2.2)$$

Here P_{facility} is total power drawn by the data center and P_{IT} is the power consumed by servers, accelerators, storage, and networking equipment. A PUE of 1.5 means the facility draws 1.5 watts from the grid for every 1 watt delivered to IT equipment; the extra 0.5 watts powers cooling, power conversion, lighting, and other overhead.

Every floating-point operation dissipates energy as heat. Dense Tensor Core activity during large matrix multiplications drives heat proportional to the switching activity of billions of transistors. The Thermal Design Power (TDP)⁹ of an accelerator is the maximum sustained heat dissipation that the cooling system must handle, and it has become the single most consequential specification in fleet design. At dense fleet scale, this creates the power wall: the point where facility power delivery

⁹ | **TDP (Thermal Design Power)**: Often misunderstood as “power consumption,” TDP specifies the maximum sustained thermal load (in watts) that the cooling solution must remove. Accelerators can briefly exceed their sustained power target during transient workloads before firmware throttles back toward the configured limit, which forces rack-level VRM and cooling designs to provision for worst-case, not average, power draw.

Figure 2.10: The Power Delivery Path: The journey of energy from the high-voltage grid to the low-voltage transistor involves multiple conversion stages, each with its own efficiency loss. The cumulative delivery loss, combined with overhead for cooling (measured by PUE), dictates how much power a facility must draw from the grid. The critical engineering challenge is the rack PDU to VRM transition, where 10–40 kW of power must be delivered within a single cabinet.

and heat removal, not available arithmetic units, determine how much compute can be installed and sustained.

This is the thermodynamic limit (principle 1) in action: the bottleneck of the modern AI data center is not FLOP/s, but Watts per square foot. When a rack generates 100 kW of heat, air cooling fails. The physical design of the fleet is dictated by the ability to move heat away from silicon. The closely related power density wall (principle 2) makes the consequence concrete: liquid cooling becomes a facility requirement, not an option, for large-scale training clusters.

 Definition 2.4: Thermal design power (TDP)

Thermal Design Power (TDP) is the maximum sustained thermal load in watts that an ML accelerator’s cooling system must continuously remove for the processor to operate at its rated clock frequency—defining both the cooling infrastructure requirement and the performance ceiling for the accelerator.

1. **Significance:** The H100 SXM5 operates at 700 W TDP. When a liquid cooling system can only sustain 500 W of heat removal (inadequate cooling), the GPU firmware reduces clock frequency via thermal throttling, dropping R_{peak} from 989 TFLOP/s to roughly 712 TFLOP/s FP16, a 28 percent reduction in training throughput that propagates directly into longer wall-clock training time and higher cost per model.
2. **Distinction:** Unlike peak power consumption (the instantaneous maximum during a single-instruction burst), TDP specifies the steady-state thermal budget: the long-term average that determines whether training can run continuously at rated performance or must throttle.
3. **Common pitfall:** A frequent misconception is that TDP is a power limit for the software. TDP is a cooling requirement: the processor exceeds its rated speed only if the cooling system removes heat at least as fast as the chip generates it; insufficient cooling causes

hardware throttling silently—no error is raised, training simply slows down and MFU drops without obvious cause.

10 | **Dennard Scaling:** Named after Dennard et al. (1974) at IBM, who showed how MOSFET dimensions, voltage, and current could scale so that power density stayed roughly constant. Later voltage-scaling limits and leakage effects ended that constant-power-density regime; Hennessy and Patterson describe the resulting post-Dennard power wall as one reason modern architecture turned toward parallelism and specialization (Hennessy and Patterson 2019). For ML infrastructure, the V100-to-B200 TDP trajectory (300 W to 1,000 W) is an illustration of the post-Dennard planning problem: cooling and power delivery are now co-equal design constraints with the silicon itself.

11 | **Liquid Cooling Flow Rate:** A rack of GB200 NVL72 nodes (120 kW) requires approximately 150–200 liters per minute (LPM) of coolant flow. At these rates, the primary risk shift is from thermal throttling to mechanical failure (leaks, pump cavitation), necessitating the industrial-grade manifolds and quick-disconnect fittings common in chemical processing plants.

The trajectory of TDP tells the story of a scaling regime reaching its limits. For three decades, **Dennard scaling**¹⁰ allowed chip designers to shrink transistors while maintaining approximately constant power density: smaller transistors required lower voltage, so packing more transistors into the same area did not increase heat output per unit area. As voltage scaling and leakage limits ended that regime, architects had to treat energy, cooling, and parallelism as first-order constraints rather than free byproducts of process shrinks (Dennard et al. 1974; Hennessy and Patterson 2019). Since then, each generation of accelerator has had to trade performance against power and heat. The era of “free” performance improvements through process shrinks is over; every gain in throughput now has to be paid for in watts, cooling capacity, or specialization.

The numbers are stark: the V100 (2017) operated at 300 W TDP, the A100 (2020) increased to 400 W, the H100 (2022) reached 700 W, and the B200 (2024) draws 1000 W. In seven years, TDP has more than tripled, growing at approximately 18 percent per year.

If this growth rate continued as a planning scenario, a generation after Blackwell would approach 1,200–1,400 W per accelerator, and another step could reach 1,500–2,000 W. At 2,000 W per accelerator, a single 8-GPU node would consume 16 kW of GPU power alone, requiring liquid cooling¹¹ infrastructure that can remove heat at rates approaching those of industrial process cooling equipment.

Systems Perspective 2.2: The end of Dennard scaling

For three decades, Dennard scaling allowed architects to increase transistor count without increasing power density, as smaller transistors required proportionally less voltage. That free lunch ended around 2006 when process nodes dropped below 28nm, where quantum effects like subthreshold leakage and gate oxide tunneling prevent further voltage reduction. The result is that power density rises with transistor density when voltage no longer scales proportionally: accelerators that deliver more TFLOP/s often demand more watts. The transition from the V100 (12nm) to the H100 (4nm) illustrates this physics: while transistor density tripled, the inability to scale voltage meant TDP grew from 300 W to 700 W. The “free” efficiency gains of the silicon era are over; higher performance per watt increasingly comes from architectural specialization – Tensor Cores, systolic arrays, precision engineering – or from accepting higher power and cooling requirements. For ML infrastructure planners, power and cooling capacity must be sized against compute demand, and facility designs cannot assume that later hardware automatically lowers power density.

TDP is not merely a specification on a data sheet; it is a physical constraint that propagates through every level of the infrastructure stack. The power delivery chain, cooling system, rack design, and facility electrical infrastructure must all be designed to accommodate deployed accelerators and the plausible TDP range of future refresh cycles.

Accelerators implement sophisticated power management to operate within their TDP envelope. When the workload does not fully use all SMs (for example, during the communication phase of a training step when the GPUs are waiting for AllReduce to complete), the GPU firmware can disable the clock signal to idle circuitry through **clock gating**, eliminating dynamic switching power and freeing thermal headroom for the active SMs. A separate mechanism, **dynamic voltage and frequency scaling (DVFS)**, adjusts the chip’s clock frequency and supply voltage to stay within power and thermal limits; during a large matrix multiplication that activates all SMs simultaneously, DVFS reduces the clock frequency to keep total power within TDP. When some SMs are idle, the active SMs can boost frequency because total chip power is below TDP, so the actual clock, and therefore the actual throughput, varies throughout a training step.

Dynamic power management means that the actual power draw of a GPU varies continuously during training. A typical training step might see power swing from 400 W (during communication phases when most SMs are idle) to 700 W (during the forward and backward pass when all Tensor

Cores are active) and back, with each transition occurring in microseconds. The VRMs on the baseboard must respond to these transitions fast enough to maintain a stable supply voltage despite the rapidly changing current draw.

To appreciate the physical challenge, consider what 700 W means in terms of heat flux. An H100 die measures approximately 814 mm² (roughly 29×28 mm). Dissipating 700 W from this area produces a heat flux of approximately 86 W/cm². For comparison, the surface of an electric stovetop burner at high heat produces approximately 10 W/cm². An H100 die generates 8.6× the heat flux of a stove burner, concentrated on an area the size of a large postage stamp.

The B200 pushes even further: at 1,000 W across a dual-die package, the average heat flux remains comparable, but the total energy that must be removed per package increases by 43 percent. Removing this heat without allowing the junction temperature to exceed 83 degrees Celsius (the typical operating maximum for HBM reliability) requires thermal solutions with extremely low thermal resistance from die to coolant.

The critical component in this thermal path is the **Thermal Interface Material (TIM)** – the microscopic layer of phase-change material or liquid metal between the silicon die and the cold plate (for liquid cooling) or heatsink (for air cooling). Under the extreme thermal cycling of deep learning workloads, where die temperatures spike from 40 degrees C to 80 degrees C in milliseconds during matrix multiplications and drop back during communication phases, inferior TIM can pump out (migrate away from the contact surface) or crack. A mere 5 percent degradation in TIM thermal conductivity forces the GPU to thermally throttle, reducing clock frequency by hundreds of MHz to protect the silicon. This degradation is a *gray failure*, a fault that degrades rather than halts: the GPU continues to function, but at reduced performance that silently degrades the entire cluster's throughput, a failure class we return to in fleet monitoring. Fleet management systems that track per-GPU junction temperatures over time can detect TIM degradation as a gradual upward trend in temperature at constant workload, enabling proactive replacement before the performance impact becomes severe.

At rack scale, four nodes of eight such chips require 33.5 kW of facility-relevant power, enough to heat several homes in winter. To put this in more tangible terms, a single ML rack at full power could run about 33 household space heaters simultaneously, concentrated in a volume roughly the size of a large refrigerator.

At pod scale, the power demand reaches megawatts, requiring dedicated electrical substations and industrial cooling plants. A 10,000-GPU cluster consumes 7–10 MW, comparable to the electrical demand of a large factory or a small town of several thousand residents.

The physical volume of a 10,000-GPU pod operating at this power density is surprisingly compact: the compute hardware (excluding networking and storage) fits in approximately 300 racks, occupying a data center floor area of roughly 1,500 square meters (about one third of an American football field). The density is the point: keeping the accelerators physically close minimizes cable lengths, which reduces signal propagation delay and enables higher interconnect bandwidth.

Physical density, however, makes power delivery and cooling exponentially harder, creating the engineering challenges that define the rack and pod levels of the hierarchy. The paradox of modern ML infrastructure is that computational efficiency demands *physical proximity*, while thermal management demands *physical separation*. Every rack design is a negotiation between these opposing forces.

This frequency variability creates a subtle interaction with software optimization. A kernel that achieves high SM occupancy (many active warps per SM) draws more power, potentially triggering a frequency reduction that partially offsets the occupancy benefit. Conversely, a kernel with moderate occupancy may run at a higher clock frequency, achieving comparable throughput at lower power. Power-normalized throughput (TFLOP/s per watt) is therefore a more robust comparison metric than raw TFLOP/s, and it explains why the same GPU can show different sustained clock frequencies depending on the workload and the cooling solution.

At fleet scale, DVFS also affects power planning. The data center's power delivery must be designed for the *worst-case* power draw (all GPUs at TDP simultaneously), but the *average* power draw is typically 70–85 percent of TDP because DVFS reduces frequency during communication phases and because not all SMs are fully occupied at all times. Some operators deliberately set lower power caps on their GPUs (for example, capping an H100 at 600 W instead of 700 W), accepting a 10–15 percent

reduction in peak performance in exchange for 15 percent lower power consumption and the ability to fit more GPUs within a fixed power budget. Power capping is a form of the compute-efficiency trade-off at the operational level.

The power efficiency trajectory provides a partial counterweight to rising TDP. While absolute power has increased, the advertised low-precision TFLOP/s delivered per watt has improved dramatically: from 0.42 TFLOPs/s/W (V100 FP16) to 2.83 TFLOPs/s/W (H100 FP8) to 4.50 TFLOPs/s/W (B200 FP8). These are not apples-to-apples FP16 numbers; the precision mode is part of the hardware trend. For a fixed compute budget that can use the newer precision modes, each generation requires fewer chips and therefore less total power. Large-model capability targets, however, can grow faster than efficiency improves, so the absolute power demand of training the next larger model may still increase. This is the treadmill of infrastructure: efficiency gains buy time, but scale growth consumes it.

The implications of TDP for fleet design are profound and will recur throughout this chapter. At the node level, TDP determines how many accelerators can share a single chassis (we examine this in section 2.4). At the rack level, TDP dictates the transition from air cooling to liquid cooling (section 2.5). At the pod level, TDP drives the megawatt-scale power delivery systems that connect the fleet to the electrical grid (section 2.6). The accelerator is the engine, but TDP is the exhaust, and every level of infrastructure above the die exists, in part, to manage that exhaust.

2.3.5 Accelerator selection for ML workloads

An accelerator's compute throughput, memory bandwidth, memory capacity, and power consumption are meaningful only in relation to a specific workload. The same H100 that delivers near-peak utilization during large-batch training may achieve less than 5 percent utilization during single-request inference, because the binding constraint shifts from arithmetic to memory bandwidth. Selecting the right accelerator therefore requires mapping each workload archetype to its position on the Roofline plot and identifying which physical resource dominates its performance.

Start with the 175B running example. During training, large batches push the forward and backward passes above the Roofline ridge point, so the immediate constraint is arithmetic throughput. Peak low-precision TFLOP/s matters, but only after memory capacity is sufficient to hold the sharded model state and after the interconnect can keep tensor and data parallel groups synchronized. H100, B200, and TPU v5p pods are all plausible answers to this training problem; the final choice depends on the software stack as much as the silicon. A PyTorch-first research team values the GPU ecosystem, while a JAX/XLA-centered organization may accept tighter compilation constraints for TPU cost efficiency.

Serving the same language model changes the answer. During autoregressive decode, every generated token streams weights through memory, so the key metric becomes memory bandwidth per dollar rather than peak TFLOP/s. At batch size 1, the H100's 3.35 TB/s bandwidth determines throughput while much of the arithmetic silicon waits. Batching raises arithmetic intensity by reusing the same weight movement across more requests, which is why serving systems work so hard to batch without violating tail-latency SLOs. The workload did not change names, but the binding term in the iron law changed, and the accelerator choice changes with it.

Recommendation models split the decision again. Embedding table lookup is dominated by random access and memory capacity, because each request retrieves small vectors from TB-scale tables with poor locality. The dense tower that consumes those embeddings is compute bound. A hybrid CPU-GPU design follows from that split: CPU and DRAM capacity handle the sparse lookup path, while GPUs accelerate the dense neural network layers. A single headline TFLOP/s number cannot describe this workload because it has two different bottlenecks inside one request.

Vision and diffusion workloads move back toward arithmetic throughput because convolutions, attention blocks, and denoising networks reuse data heavily. Diffusion inference makes this especially clear: the Stable Diffusion v1.5 profile in MLSysIM uses 50 denoising steps, so the service pays for a sequence of full model evaluations rather than one decode step per token. For these workloads, TFLOP/s per dollar often dominates bandwidth per dollar once model state fits in memory.

Mixture-of-Experts (MoE) adds a routing constraint: the sparsely gated layer activates only part of a much larger parameter set for each token (Shazeer et al. 2017). Mixtral-8x7B (A. Q. Jiang et al. 2024), for example, has 46.7B total parameters but only 12.9B active parameters per token because

the router chooses 2 experts from 8 experts. That compute saving introduces a many-to-many token exchange pattern, the AllToAll collective examined in Chapter 6, and load-balance risk because tokens must be routed to different expert placements. High-bisection fabrics and load-balancing mechanisms such as auxiliary losses, which penalize overloaded experts, or capacity factors, which cap how many tokens each expert accepts, determine whether the theoretical saving appears in the training trace (Fedus et al. 2022; Lepikhin et al. 2021).

Multi-modal models add heterogeneity rather than only routing. They combine text decode, vision processing, audio features, and sometimes video, each with different arithmetic intensity and batching behavior. These workloads favor platforms with flexible scheduling and strong bisection bandwidth rather than accelerators optimized for one regular dataflow.

Systems Perspective 2.3: Matching hardware to workload

The fundamental insight from the Roofline Model is that no single accelerator is optimal for all workloads. An H100 that delivers outstanding training throughput for a 175B LLM can sit mostly idle when serving that same model at batch size 1. A TPU pod that provides exceptional cost efficiency for Transformer training may be poorly suited for a recommendation model with irregular memory access patterns.

A mature fleet is therefore heterogeneous by design because each workload makes a different resource decisive. Training clusters spend on arithmetic throughput and fast accelerator-to-accelerator links because synchronization sits in the critical path. Serving clusters spend on memory bandwidth per dollar and latency control because decode streams weights under tail-latency SLOs. Embedding systems spend on DRAM capacity and locality management because sparse lookups dominate the request. Fine-tuning clusters sit between those regimes, balancing memory headroom with enough compute to keep iteration fast. The accelerator spectrum is a design space that must be navigated for each workload independently. Organizations that deploy a single hardware configuration for all workloads inevitably overpay: either the hardware is overprovisioned for simple workloads or underprovisioned for demanding workloads.

2.3.5.1 Precision and throughput trade-offs

The relationship between numerical precision and hardware throughput is one of the most important considerations for infrastructure planning, because it directly affects how much useful work each accelerator can perform per second. Lower precision representations use fewer bits per number, which has two compounding benefits: more numbers fit in the same HBM capacity (reducing memory pressure), and the arithmetic units can process more operations per cycle (increasing throughput).

The precision landscape for ML has evolved rapidly. Table 2.6 summarizes representative precision formats on H100-class accelerators and their common use cases.

Table 2.6: Precision Formats and Hardware Throughput on H100: The table uses dense peak throughput where Tensor Core support exists; structured sparsity can roughly double several of these advertised peaks. The choice of precision affects both the training dynamics (convergence, numerical stability) and the infrastructure requirements (memory capacity, bandwidth utilization). TF32 preserves the FP32 exponent width but reduces mantissa precision so Tensor Cores can accelerate common FP32 training workloads.

Format	Bits	Exponent	Mantissa	H100 Dense TFLOP/s	Typical Use
FP32	32	8	23	~67	Master weights, loss computation
TF32	19	8	10	494	Training (NVIDIA default)
BF16	16	8	7	989 TFLOP/s	Training, fine-tuning
FP16	16	5	10	989 TFLOP/s	Training with loss scaling
FP8 (E4M3)	8	4	3	1,979 TFLOP/s	Forward pass, weights

Format	Bits	Exponent	Mantissa	H100 Dense TFLOP/s	Typical Use
FP8 (E5M2)	8	5	2	1,979 TFLOP/s	Backward pass, gradients
INT8	8	N/A	N/A	1,979 TFLOP/s	Post-training quantization
INT4	4	N/A	N/A	3,958	Weight-only quantization

The infrastructure implications are substantial. A fleet designed for BF16 training, a common baseline for large models, delivers 989 TFLOP/s per GPU on an H100. The same fleet running FP8 training delivers 1,979 TFLOP/s per GPU, effectively doubling the compute density without additional hardware. For a 10,000-GPU cluster priced at roughly \$350,000 per 8-GPU node, the difference between BF16 and FP8 training is equivalent to adding another 10,000 GPUs, or roughly \$438 million in node hardware.

However, not all workloads can use FP8 without accuracy degradation. The reduced mantissa precision (3 bits in E4M3) means that values must be scaled carefully to avoid overflow (values exceeding the representable range saturate or become nonfinite, depending on format and implementation) or underflow (small values rounded to zero). The Transformer Engine’s dynamic per-tensor scaling addresses this challenge for standard Transformer architectures, but custom model architectures with unusual activation distributions may require manual precision tuning. The infrastructure team must therefore work closely with the model team to determine the lowest precision that maintains acceptable accuracy, as this decision directly affects the effective throughput and therefore the required cluster size.

For inference, **quantization** is one of the most impactful optimizations for serving economics because it directly alters the hardware topology required for large models. Our 175B model at FP16 requires 350 GB, necessitating a minimum of five 80 GB H100 GPUs simply to load the parameters. At INT8, this drops to 175 GB, fitting on three GPUs. At INT4, it shrinks to 87.5 GB, fitting on two GPUs. For memory-bandwidth-bound inference, reading 4-bit weights instead of 16-bit weights effectively quadruples the available bandwidth for weight loading, proportionally reducing per-token latency. A production team deploying at INT4 rather than FP16 can reduce the memory footprint and bandwidth demand of the inference fleet substantially, subject to the quality loss of the chosen quantization method and workload.

For training, many workloads use **mixed-precision training**, a strategy that decouples storage precision from arithmetic precision. A “master copy” of weights remains in FP32 for numerical stability, while the computationally intensive forward and backward passes are cast to BF16 or FP16 to exploit the full throughput of Tensor Cores. Gradients are accumulated in FP32 to prevent underflow before the optimizer updates the master weights. The H100’s Transformer Engine extends this paradigm by dynamically selecting between FP8 and FP16 on a per-layer basis, potentially doubling throughput again for layers resilient to reduced precision. The cumulative effect on training velocity can be multiple-fold when the model remains numerically stable at the lower precision.

2.3.5.2 Energy cost of data movement

The Roofline Model and token latency analysis demonstrate that data movement limits performance. Data movement also dominates energy consumption, with direct implications for fleet economics. A useful normalization is an FP16 operand: reading one 16-bit value from HBM at roughly 4 pJ/bit costs about 64 picojoules (pJ), while one FP16 multiply-accumulate (MAC) costs roughly 1 pJ. The raw operand fetch can therefore cost about $64\times$ the arithmetic operation, before tiling and reuse amortize that movement across many MACs.

This operand-level ratio explains why accelerator architects devote so much silicon area to data reuse. A Tensor Core’s tile-based execution model loads a small matrix into local registers and reuses each element hundreds of times (once per element in the opposing matrix), amortizing the HBM access cost across hundreds of 1 pJ compute operations. Without this reuse, the energy budget would be dominated by memory access, and most of the chip’s power would be spent heating wires rather than switching transistors.

At fleet scale, the energy cost of data movement determines the electricity bill. For a 10,000-GPU cluster running at 700 W per GPU, approximately 400–500 W per GPU is consumed by the memory subsystem (HBM reads and writes, on-chip network transfers, register file accesses), and only 150–250 W is consumed by the Tensor Cores performing useful arithmetic. The rest goes to clock distribution, I/O, and leakage. Improving data reuse, through techniques like kernel fusion, FlashAttention, and activation checkpointing, reduces the energy wasted on data movement and increases the fraction of power that performs useful computation.

The energy perspective provides a physical foundation for understanding why different parallelism strategies have different efficiencies. Tensor parallelism requires data movement over NVLink (approximately 5 pJ per bit at the link level, plus the energy of the NVSwitch chips). Data parallelism requires data movement over InfiniBand (approximately 15–20 pJ per bit, including the energy of the HCA and switch). Pipeline parallelism moves less data but requires more complex scheduling. Each parallelism strategy represents a different point in the trade-off between communication energy and computation efficiency.

Napkin Math 2.3: The energy cost of data movement

The iron law of modern computing is that moving data costs significantly more energy than manipulating it. We can prove this by analyzing the energy hierarchy of a single operation at the 4nm process node.

Performing one FP16 multiply-accumulate (**MAC**) operation – the atomic unit of deep learning – consumes approximately 1 picojoule (pJ). This is the baseline cost of useful work. Reading a single FP16 operand (16 bits) from HBM consumes roughly 4 pJ per bit, totaling 64 pJ. Reading that same operand from off-package DRAM costs approximately 20 pJ per bit, or 320 pJ. The asymmetry is staggering: reading a value from HBM costs 64× more energy than computing on it. Retrieving it from standard DRAM costs 320× more.

The macro impact appears when serving our 175B model. Generating a single token requires loading the entire 350 GB weight tensor from HBM:

$$\text{Data Movement Energy} = 350 \text{ GB} \times 8 \text{ bits/byte} \times 4 \text{ pJ/bit} \approx 11.2 \text{ Joules}$$

The computational cost for the associated ≈ 175 billion MACs (about 350 billion FLOPs) is trivial by comparison:

$$\text{Computation Energy} = 175 \times 10^9 \text{ MACs} \times 1 \text{ pJ/MAC} \approx 0.175 \text{ Joules}$$

Moving the weights to the compute units consumes 64× more energy than the math itself in this simplified decode model. This energy penalty is why HBM is engineered for physical proximity to the GPU die – shorter traces mean less capacitance and lower energy per bit. It also explains why techniques that reduce data movement, such as quantization (moving fewer bits) and kernel fusion (preventing round-trips to memory), are the primary levers for improving both system performance and power efficiency.

2.3.5.3 Benchmarking accelerator performance

A procurement team comparing accelerators needs a published number that predicts the performance the organization will actually achieve. Peak TFLOP/s, memory bandwidth, and TDP describe *potential*, not *achieved* performance, so the decision turns on whose measured results to trust and under what rules they were produced. The industry-standard reference is MLPerf, maintained by MLCommons: MLPerf Training reports the time to train reference models to a target accuracy, and MLPerf Inference reports serving throughput and latency under realistic batching and streaming conditions. Both capture complete system performance, including software stack efficiency, communication overhead, and memory management, not just the raw silicon.

The number that actually predicts an organization's results is the *closed*-division result, and understanding why is the core of reading MLPerf well. The closed division requires every submission to use the same model architecture, hyperparameters, and training recipe, isolating the hardware

and system software as the only variables and making results directly comparable across vendors. The open division allows arbitrary model modifications, custom kernels, and software optimizations, which demonstrate a platform's ceiling but make cross-vendor comparison unreliable. Infrastructure teams should weight closed-division results more heavily, because they reflect the performance achievable with standard frameworks and configurations, not the performance achievable only by the vendor's own optimization team.

For our 175B model, no single benchmark captures the full picture. The training phase is compute bound at large batch sizes, making peak TFLOP/s and scaling efficiency the dominant metrics. The inference phase at batch size 1 is memory-bandwidth-bound, making GB/s per dollar the relevant metric. The fine-tuning phase falls between these extremes, with moderate batch sizes placing the workload near the Roofline ridge point. A comprehensive evaluation must benchmark all three phases on the candidate hardware, using the organization's actual model and data pipeline rather than relying solely on published MLPerf numbers.

🔍 Systems Perspective 2.4: Beyond peak specifications

When evaluating accelerator options, the following metrics provide a more complete picture than peak TFLOP/s alone:

- **Model FLOPs utilization (MFU):** The ratio of achieved FLOP/s during real training to peak hardware FLOP/s. An MFU of 50 percent means the hardware spends half its time on useful computation and half waiting for data, synchronizing, or idling.
- **Time-to-Train (TTT):** The wall-clock time to train a reference model to a target metric. This captures all system-level effects that MFU alone does not, including I/O stalls, checkpointing overhead, and job restart delays.
- **Cost per Token:** For language model training, the total cost (hardware amortization plus electricity) divided by the number of tokens processed. This metric normalizes across different hardware generations, cluster sizes, and pricing models.
- **Tokens per Second per Dollar:** The inverse of cost per token, useful for comparing the economic efficiency of different systems.

No single metric tells the whole story. A system with high MFU but high cost per GPU-hour may be less economical than a system with lower MFU but cheaper hardware. The right metric depends on whether the organization is optimizing for time (training must finish by a deadline), cost (minimize total expenditure), or throughput (maximize tokens processed per unit time).

2.3.5.4 Inference-specific infrastructure considerations

While this chapter focuses primarily on training infrastructure (because training drives the most demanding infrastructure requirements), the infrastructure for serving trained models at scale deserves separate attention because the design constraints differ fundamentally from training. Training infrastructure is optimized for *throughput*: maximizing the total number of tokens processed per unit time across the entire cluster. The workload is a single, long-running job that occupies the full cluster for days or weeks. The communication pattern is predictable and repetitive. The acceptable latency for any individual operation is milliseconds to seconds.

Serving infrastructure is optimized for *latency* and *cost per query*: minimizing the time each user waits for a response while keeping the per-query cost low enough for the business model to be viable. The workload consists of millions of independent, short-lived requests arriving at irregular intervals. The communication pattern is minimal (each request is processed independently on a single node or small group of nodes). The acceptable latency is tens of milliseconds for interactive applications.

The differing requirements drive distinct hardware and architecture choices, summarized in table 2.7.

Table 2.7: Training vs. Serving Infrastructure: Training and serving optimize different hardware behaviors, so capacity planning must compare utilization, model placement, network traffic, and cost in the mode the fleet will actually run.

Dimension	Training infrastructure	Serving infrastructure
GPU utilization	Large batch sizes push workloads into the compute-bound regime, so clusters commonly achieve 30–50% MFU.	Low-batch serving is deeply memory bound and can achieve less than 5% MFU, so batching improves utilization at the cost of latency.
Model placement	Tensor and pipeline parallelism distribute a single model across many GPUs.	Replicas of the model, or large shards of it, handle independent requests, so memory demand scales with concurrent serving capacity.
Network traffic	Gradient synchronization requires high-bandwidth, low-latency inter-GPU communication.	Independent requests need little inter-GPU traffic but substantial client-facing bandwidth for millions of API requests per second.
Cost metric	Training cost is a fixed, one-time expenditure measured in dollars per run.	Serving cost is a variable expense measured in dollars per 1,000 tokens generated, and popular models can exceed their training cost within weeks.

The table shows why serving cannot be planned as training with smaller batches: the optimization target changes from synchronized throughput to latency-bounded, continuously billed requests.

The implication is that effective serving infrastructure often uses different hardware, different software, and different facility designs than the training infrastructure. Some organizations use previous-generation GPUs (A100s) for serving because the memory bandwidth per dollar can be competitive with newer GPUs, and the lower TDP (400 W vs. 700 W) allows higher rack density and lower cooling costs.

The inference workload itself bifurcates into two distinct phases with opposing bottlenecks. The **prefill** phase processes the input prompt, performing a large matrix-matrix multiplication that is compute bound and achieves high Tensor Core utilization. The **decode** phase generates tokens one by one, performing matrix-vector multiplications that are deeply memory-bandwidth-bound. To maximize hardware utilization, high-performance serving systems employ **continuous batching**, which schedules requests at the iteration level rather than the request level. This allows the engine to inject a new prefill computation for a waiting request into the idle compute slots of an ongoing decode batch, dynamically filling the GPU’s arithmetic pipelines. For our 175B model, serving 10,000 requests per second with a 50 ms time-to-first-token service level agreement (SLA) requires distributing traffic across hundreds of 8-GPU replicas (each holding the full model via tensor parallelism), with a load balancer routing requests to the replica with the lowest queue depth. Unlike training, where 99.9 percent reliability can be acceptable with checkpointing, inference architectures must account for tail latency, where a single slow replica can violate the SLA for the entire request batch.

2.3.5.5 The accelerator decision matrix

A practical decision framework synthesizes these workload-specific characteristics by mapping each archetype (section 1.6.1) to the hardware resource that dominates its performance and cost. Table 2.8 makes the selection rule explicit: choose for the binding constraint, not the largest advertised peak number.

Table 2.8: The Accelerator Decision Matrix: The optimal accelerator depends not on peak specifications but on which physical resource – compute, bandwidth, or capacity – is the binding constraint for the target workload. The Roofline Model provides the diagnostic: compute the arithmetic intensity, locate the workload relative to the ridge point, and select hardware that maximizes the binding resource per dollar.

Workload	Binding Constraint	Key Metric	Recommended Class
LLM Training (>100B)	Compute (high batch size)	Peak TFLOP/s, NVLink BW	H100/B200, TPU v5p
LLM Inference (batch=1)	Memory bandwidth	GB/s per dollar	A100, H100 (bandwidth/\$)
LLM Inference (batched)	Compute + bandwidth	TFLOP/s and GB/s	H100, B200

Workload	Binding Constraint	Key Metric	Recommended Class
Vision Model Training	Compute (large spatial dims)	Peak TFLOP/s	H100/B200, GPU preferred
Recommendation (embeddings)	Memory capacity	GB per dollar	CPU DRAM + GPU hybrid
Fine-tuning (<13B)	Memory capacity	HBM capacity	A100 (cost-effective)
Research/Prototyping	Flexibility	Software ecosystem	GPU (CUDA), avoid ASICs

The binding constraint shifts with the lifecycle phase, as table 2.8 shows for the 175B running example. During training, large batch sizes push the workload into the compute-bound regime, making peak TFLOP/s the dominant metric. The H100 or B200, with their high Tensor Core throughput and fast NVLink for tensor parallelism, are the natural choices. During inference at low batch sizes, the same model becomes deeply memory bound, and the relevant metric shifts to bandwidth per dollar. An A100 with adequate HBM bandwidth at a lower price point may deliver better cost-per-token than an H100 whose additional TFLOP/s go unused.

The organizational dimension adds a further consideration. Research labs that modify model architectures weekly need the flexibility of the GPU’s CUDA ecosystem, where custom kernels can be written and tested in hours. Production teams running a fixed Transformer architecture at scale for months may benefit from TPUs, where the XLA compiler’s whole-program optimization can achieve higher sustained utilization than hand-tuned CUDA kernels for standard operations. Custom ASICs make economic sense only for organizations with enough scale to amortize the \$50–\$200 million NRE cost and enough workload stability to justify a 2–3 year design cycle. The accelerator spectrum is ultimately an economic question answered at the intersection of workload physics, organizational scale, and time horizon.

Checkpoint 2.3: Accelerator selection

Your team needs to deploy a 70B-parameter model for both training and inference. Training will use batch size 2048 across 256 GPUs for 3 months. Inference will serve 10,000 requests per second at batch size 1 for 2 years.

- ☐ **Training intensity:** Use the Roofline Model to determine the arithmetic intensity of each workload on an H100.
- ☐ **Hardware split:** Decide whether training and inference should use the same hardware or different hardware.
- ☐ **Two-year cost:** Calculate the 2-year inference cost difference between H100s (\$4.00/GPU-hour) and A100s (\$2.00/GPU-hour), accounting for throughput at the workload’s arithmetic intensity.

With the accelerator’s physics established, we face a concrete problem. Our 175B model requires 350 GB of memory for its weights alone in FP16, and Adam-style training state raises the requirement to multiple terabytes once optimizer moments, gradients, and activations are included. A single H100 provides 80 GB of HBM. No single accelerator can hold this model. We must expand to the next physical level: the node, where figure 2.11 contrasts the two dominant approaches to wiring multiple accelerators within a single chassis.

2.4 The Node

The node is the first scale level where accelerator choice becomes an interconnect problem. Multiple GPUs can now share one chassis, but their useful behavior depends on whether the local fabric behaves like a slow ring, a dense mesh, or a switch-backed crossbar.

Aggregating accelerators solves the capacity problem only if the interconnect between them is fast enough that the group behaves as one machine rather than as several machines passing messages. The 175B model’s weights span at least five accelerators, and the full training state spans an entire 8-H100 node and more, so the parameters of a single layer now live on different chips and must be reassembled on every forward and backward pass. Whether that reassembly is cheap or

NVSwitch eliminates hop-count latency: every GPU reaches every other GPU at full NVLink bandwidth, enabling tensor-parallel AllReduce within a single node.

Figure 2.11: Intra-Node GPU Topology Comparison: Three approaches to wiring GPUs inside a node. (Left) Ring: sequential pass-through, ~50 GB/s per link, latency scales with distance. (Center) Full Mesh: all-to-all direct links, $N - 1$ links per GPU, impractical beyond ~8 GPUs. (Right) NVSwitch Crossbar: non-blocking fabric with 112 GB/s per NVLink and 900 GB/s aggregate, any-GPU-to-any-GPU in one hop, enabling tensor-parallel AllReduce within a node.

ruinous depends entirely on the local fabric, which is why the node is the first scale level where the accelerator’s specifications matter less than the wires between accelerators. The training system must combine tensor parallelism with optimizer sharding and memory offload, and each of those strategies places a different demand on the interconnect.

Definition 2.5: Node

Node is the ML training cluster’s physical server chassis that aggregates multiple accelerators (typically 8) through a high-speed intra-node interconnect (NVLink or ICI), creating the fundamental boundary between high-bandwidth local communication and the order-of-magnitude slower inter-node network fabric.

1. **Significance:** The NVLink bandwidth within a DGX H100 node reaches 900 GB/s bidirectional, or 450 GB/s per direction, while inter-node InfiniBand NDR provides 50 GB/s, a $9\times$ per-direction gap that constrains where each parallelism strategy can run. Tensor parallelism, which AllReduces every layer’s output, must stay within the node; pipeline parallelism, which transfers only stage-boundary activations, can span nodes over InfiniBand. The node is also the primary failure domain: a single node failure in a bulk synchronous parallel (BSP) training job, where workers advance in lockstep at step barriers, idles the entire cluster until recovery.
2. **Distinction:** Unlike a single accelerator (which provides fast HBM bandwidth but limited capacity), a node aggregates $8\times$ the HBM capacity and $8\times$ the compute of a single chip – enough to place large FP16 weight shards ($8 \times 80 \text{ GB} = 640 \text{ GB}$ on DGX H100), but not enough to keep the full Adam training state in HBM.
3. **Common pitfall:** A frequent misconception is that nodes in a distributed training job operate independently. In BSP training, all nodes are synchronously coupled at every step barrier: a performance degradation on one node (from thermal throttling, a faulty NIC, or a slow storage read) stalls the entire cluster and drops overall MFU for the duration of that step.

The node exists because of a gap in the memory hierarchy. HBM provides enough *bandwidth* to feed the accelerator’s arithmetic units, but not enough *capacity* to hold the full 175B-parameter running example. Host DRAM provides capacity (512 GB to 2 TB per server) but not enough bandwidth.

The node bridges this gap by aggregating the HBM of multiple accelerators into a shared pool, connected by an interconnect fast enough to allow cooperative computation across all of them. The key engineering insight is that by placing 8 accelerators in a single chassis and connecting them with a high-speed fabric, the node creates a virtual accelerator with $8\times$ the memory capacity and $8\times$ the compute throughput of any individual chip, while the fast interconnect ensures that this virtual accelerator can operate nearly as efficiently as a single monolithic device.

The economic argument for multi-accelerator nodes is equally compelling. Consider the alternative: building a single accelerator with enough HBM to hold a 175B model (350 GB in FP16). Current packages provide roughly 16–24 GB per HBM stack, so a 350 GB single-accelerator design would require on the order of 15–22 HBM stacks – far beyond the 5-stack H100 or 8-stack B200-class package. The manufacturing cost of such a package would be prohibitive (yield decreases with package and interposer area), and the power delivery to a single chip with enough Tensor Cores to use all that bandwidth would exceed any practical cooling solution. By distributing the computation across 8 accelerators connected by NVLink, the node achieves the aggregate memory capacity and compute throughput of this hypothetical super-chip while remaining within manufacturable and coolable boundaries.

Understanding how the node partitions memory across its components is essential for selecting parallelism strategies. Consider the memory budget for training our 175B model. The model weights in FP16 require 350 GB. The Adam optimizer maintains two additional copies of every parameter (first and second moments) in FP32 precision, adding $175 \times 10^9 \times 2 \times 4 \text{ bytes} = 1,400 \text{ GB}$. Gradients require another 350 GB. The total is approximately 2.1 TB before activations, far exceeding both a single accelerator’s 80 GB HBM and an 8-H100 node’s 640 GB aggregate HBM.

When using ZeRO or FSDP-style optimization (which shards optimizer states, gradients, and optionally parameters across data-parallel workers), the training system avoids replicating this full 2.1 TB state on every GPU. Tensor parallelism first reduces each GPU’s active weight shard; data-parallel sharding then spreads optimizer state and gradients across many workers; activation checkpointing reduces the activation peak; and offload moves cold optimizer state to host DRAM over PCIe. The node is therefore a high-bandwidth compute and communication unit, not a standalone container for the entire training state.

The node’s internal memory hierarchy, consisting of HBM (fast, small), host DRAM (medium speed, larger), and Non-Volatile Memory Express (NVMe) storage (slow, very large), forms a tiered system that distributed training frameworks exploit aggressively. Chapter 5 examines these memory optimization strategies in detail.

2.4.1 Bandwidth hierarchy

The defining characteristic of multi-accelerator systems is not the *number of chips* but the *speed at which they can exchange data*. Data movement speed drops by orders of magnitude as it crosses physical boundaries. Each boundary represents a different physical medium, a different connector technology, and a different set of engineering constraints. This physical ordering of data transfer rates, from on-chip SRAM at the fast end to the wide-area network at the slow end, is the **bandwidth hierarchy**, and understanding it is essential because it dictates where in the hierarchy each type of parallelism can operate efficiently.

The hierarchy reflects the physical cost of distance: shorter signal paths over denser wiring achieve higher throughput at lower energy per bit, so at each boundary the effective bandwidth (BW) drops by roughly an order of magnitude while latency (L_{lat}) rises. That gradient sets a scaling ceiling for distributed training. The common mistake is to treat all cluster communication as equal, but parallelism placement must be hierarchy-aware: putting high-frequency synchronization such as tensor parallelism on a slow tier idles the compute units (R_{peak}) and collapses scaling efficiency (η_{scaling}).

The bandwidth hierarchy is best understood as a series of concentric zones around each accelerator. The innermost zone is the HBM on the same package, with terabytes per second of bandwidth and sub-microsecond latency. The next zone encompasses the other accelerators within the same node,

reachable over NVLink at hundreds of gigabytes per second with microsecond-scale latency. The outermost zone spans all other nodes in the cluster, connected by InfiniBand at tens of gigabytes per second with latency measured in single-digit microseconds. At each zone boundary, the bandwidth drops by roughly an order of magnitude while the latency increases by roughly an order of magnitude. Table 2.9 maps those zones to the parallelism strategies they can support.

Table 2.9: The Bandwidth Hierarchy: Each physical boundary introduces an order-of-magnitude bandwidth cliff. These cliffs are not engineering failures to be optimized away; they reflect fundamental differences in the physics of each interconnect medium. The cliffs dictate model partitioning: Tensor Parallelism, which requires AllReduce after every layer, is strictly confined to the intra-node domain.

Domain	Interconnect	Bandwidth	Latency	Scaling Limit
Intra-Package	Silicon Interposer	~3.3 TB/s	<100 ns	Single Chip
Intra-Node	NVLink/ICI	~900 GB/s	~1 μ s	Node (8–16 Chips)
Intra-Node (IO)	PCIe Gen5 x16	~64 GB/s	~2 μ s	CPU-GPU, NIC-GPU
Inter-Node	InfiniBand NDR	~50 GB/s	~5–10 μ s	Pod (Thousands)

The concentric view in figure 2.12 presents the same hierarchy spatially, so each outward boundary crossing reads as both a bandwidth drop and a latency increase.

Figure 2.12: The Infrastructure Bandwidth Hierarchy: Concentric zones visualize the bandwidth tiers an ML workload crosses. HBM (3.35 TB/s) sits at the innermost zone; each outward boundary crossing drops bandwidth $\sim 10\times$ and raises latency $\sim 10\times$: NVLink/NVSwitch (900 GB/s), InfiniBand NDR (50 GB/s), and Storage/Network File System (7 GB/s) at the outermost zone. Exploiting this hierarchy through tiered algorithms is the primary task of distributed systems engineering.

As table 2.9 shows, parallelism strategies must respect these boundaries. A simple synchronization calculation makes the bandwidth gaps concrete.

Napkin Math 2.4: The physics of the staircase

Problem: A 10 GB buffer is synchronized across the fleet. How much does the physical “Layer” of the fleet affect transfer time?

Math: Transfer time is $T_{\text{transfer}} = D_{\text{vol}}/\text{BW}$.

1. **HBM (intra-chip):** 10 GB / 3,350 GB/s $\approx$ 3.0 ms.
2. **NVLink (intra-node):** 10 GB / 450 GB/s $\approx$ 22.2 ms.
3. **InfiniBand (inter-node):** 10 GB / 50 GB/s $\approx$ 200 ms.

Systems insight: Moving data across the cluster is 9 $\times$ slower than moving it within a node. This “Bandwidth Staircase” is the primary driver of all parallelization strategies: we use tensor parallelism where bandwidth is abundant (NVLink) and data parallelism where it is scarce (InfiniBand). A model that “fits” in memory but ignores the staircase will spend 90 percent of its time waiting for the network.

Each cliff in the bandwidth staircase exists for a different physical reason, rooted in the signal-propagation regime at its distance scale. The **intra-package** interconnect achieves terabytes per second because signals travel through lithographically patterned copper traces on a silicon interposer, with path lengths measured in millimeters. At these distances, signal attenuation is negligible, no amplification is needed, and the signaling rate is limited only by the trace geometry and the transceiver design.

NVLink achieves hundreds of gigabytes per second using high-speed SerDes¹² transceivers over short copper cables or traces within a chassis, with path lengths of tens of centimeters. At these distances, signal attenuation is measurable but manageable with simple equalization circuits. The SerDes transceivers use PAM-4 (4-level pulse amplitude modulation) signaling at 112 Gb/s per lane, packing 2 bits per symbol to double the data rate relative to NRZ (nonreturn-to-zero) signaling.

PCIe uses a standardized protocol with flow control overhead, reducing effective bandwidth. While PCIe Gen5 uses the same 32 GT/s signaling rate as NVLink’s individual lanes, the protocol overhead (packet headers, flow control credits, error checking) consumes approximately 20 percent of the raw bandwidth. The standardization that makes PCIe universally compatible also makes it less efficient than proprietary interconnects.

InfiniBand crosses meters of cable between racks, requiring signal amplification, error correction, and switch hops that add both latency and protocol overhead. Active optical cables (AOCs) convert electrical signals to light at the transmitter, propagate through optical fiber, and convert back to electrical signals at the receiver. Each electro-optical conversion adds approximately 2–5 nanoseconds of latency and consumes power for the laser driver and photodetector. Switch hops add another 100–300 nanoseconds each for packet routing and buffering.

As table 2.9 illustrates, the practical consequence is that parallelism strategies must respect these boundaries. Tensor parallelism (TP), which splits individual matrix multiplications across accelerators and requires an AllReduce operation after every layer, generates communication volume proportional to the model’s hidden dimension hundreds of times per second. At NVLink bandwidth, this synchronization takes roughly 1 ms per layer. At InfiniBand bandwidth, the same synchronization takes 10–20 ms, which would leave the accelerators idle for the majority of each training step.

TP is therefore confined to within a single node, while data parallelism (which synchronizes gradients only once per training step) spans the inter-node network. The bandwidth hierarchy is the physical law that determines the topology of distributed training.

The hierarchy also explains why pipeline parallelism occupies an intermediate position in the bandwidth requirements. In pipeline parallelism, the model is divided into sequential stages, with each stage assigned to a different group of accelerators. The communication between stages consists of activations flowing forward during the forward pass and gradients flowing backward during the backward pass, with a volume proportional to the batch size times the hidden dimension.

For our 175B model with hidden dimension 12,288 and a microbatch of 4 sequences at 2,048, the activation tensor at each stage boundary is approximately $4 \times 2,048 \times 12,288 \times 2B$ bytes (FP16) $\approx$

¹² | **SerDes (Serializer/Deserializer):** From Latin *serialis* (in a row) and *de-* (reverse). A circuit pair that converts parallel data to a serial bit stream for transmission and back again. Modern high-speed links use PAM-4 signaling (4-level pulse amplitude modulation, encoding 2 bits per symbol) at very high lane rates, and the transceiver energy becomes a material part of node power. This is why dense interconnects such as NVLink, InfiniBand, and PCIe must be treated as power and cooling loads, not just as bandwidth specifications.

201 MB. This is far smaller than the 350 GB gradient AllReduce required by data parallelism, which is why pipeline parallelism places less demanding requirements on the inter-node network.

Activation transfers occur once per microbatch per stage boundary, far less frequently than tensor parallelism's per-layer AllReduce. Pipeline parallelism can therefore tolerate the lower bandwidth of inter-node links, making it the preferred strategy for spanning multiple nodes when the model's depth exceeds a single node's capacity.

The result is a natural mapping between parallelism types and interconnect domains: tensor parallelism within the node (NVLink), pipeline parallelism across nearby nodes (InfiniBand), and data parallelism across the full cluster (InfiniBand with gradient compression). This mapping is so fundamental that it has become a de facto standard in production-scale Transformer training systems, with the details differing primarily in the number of pipeline stages, the degree of tensor parallelism, and the degree of data parallelism.

The mapping also determines how the job scheduler assigns nodes to training jobs. Nodes within the same tensor-parallel group should be physically adjacent (ideally in the same chassis, connected via NVLink). Nodes within the same pipeline-parallel group should be in the same rack or adjacent racks (minimizing InfiniBand switch hops). Data-parallel groups can span the entire cluster because their communication (gradient AllReduce) is the least bandwidth-intensive and most latency-tolerant of the three parallelism types. One intra-node boundary remains before that mapping reaches the scheduler: the PCIe hierarchy that connects accelerators to host CPUs, NICs, storage, and DRAM.

2.4.1.1 The PCIe hierarchy within a node

While NVLink provides a high-bandwidth freeway for GPU-to-GPU communication, **PCIe Gen5** serves as the universal glue connecting the heterogeneous components of the node. It links GPUs to the host CPU, GPUs to InfiniBand Host Channel Adapters (HCAs), the host CPU to NVMe storage, and the host CPU to system DRAM. Understanding this topology is critical because PCIe bandwidth – though substantial at ~64 GB/s per direction (128 GB/s bidirectional) per x16 link – is often the bottleneck for operations that cross the accelerator boundary, such as data loading, checkpointing, and inter-node gradient synchronization.

A standard DGX H100 node features two host CPUs, each managing a **PCIe root complex** with 128 lanes. These lanes are distributed to maximize simultaneous throughput: 8 GPUs each receive a dedicated x16 link, and 8 InfiniBand HCAs each receive their own x16 link. This configuration provides an aggregate theoretical bandwidth of nearly 2 TB/s within the chassis. However, this bandwidth is shared among competing traffic streams. During a single training step, the PCIe bus simultaneously carries host-to-GPU data batches, GPU-to-HCA gradient shards for inter-node AllReduce (via GPUDirect RDMA), and periodic CPU-to-NVMe checkpoint writes. Contention between these streams can cause unexpected pipeline stalls, particularly when gradient synchronization saturates the links typically used for data loading.

The dual-CPU architecture introduces significant **Non-Uniform Memory Access (NUMA)** effects. The 8 GPUs are physically partitioned, with 4 connected to CPU 0's root complex and 4 to CPU 1's. A GPU connected to CPU 0 can access CPU 0's DRAM at full PCIe bandwidth but must traverse the inter-processor interconnect (UPI or Infinity Fabric) to access CPU 1's DRAM. This traversal incurs additional latency and reduces effective bandwidth by up to 50 percent. Robust data loading pipelines must employ *NUMA-aware scheduling*, pinning data loader worker processes to the CPU cores physically closest to the target GPUs. Empirical benchmarks show that aligning data loaders with the correct NUMA domain can improve data ingestion throughput by 20–30 percent, preventing the CPU from becoming the bottleneck in high-throughput training runs.

The practical consequence is that placement is part of the parallelism strategy: a scheduler that ignores PCIe roots, NIC locality, and NUMA domains can turn an otherwise valid tensor- or pipeline-parallel plan into a host-bound bottleneck. Chapter 5 formalizes how these intra-node and inter-node boundaries interact with data, tensor, and pipeline parallelism.

2.4.2 Dense node designs

Given the bandwidth hierarchy, the engineering challenge within a node is clear: connect 8 accelerators with enough bandwidth that they can function as a single logical device for tensor-parallel operations. The solution is a specialized switching fabric that provides full bisection bandwidth

between all accelerator pairs. Understanding the design of this fabric requires appreciating why simpler alternatives fail.

The simplest approach would be to connect the 8 GPUs in a ring, where each GPU has links to its two neighbors. A ring is inexpensive (requiring only N links for N GPUs) and works well for ring-AllReduce, where data flows sequentially around the ring in a circular pattern. The ring-AllReduce algorithm achieves optimal bandwidth utilization for gradient synchronization because each GPU simultaneously sends data to its right neighbor and receives data from its left neighbor, keeping all links busy throughout the operation.

However, tensor parallelism requires *all-to-all* communication: every GPU must exchange partial results with every other GPU after each layer. This is a fundamentally different communication pattern from the sequential flow of ring-AllReduce, and the ring topology handles it poorly. In a ring of 8 GPUs, communicating between opposite sides requires 4 hops, reducing effective bandwidth by $4\times$ compared to a direct link. A fully connected mesh, where every GPU has a direct link to every other GPU, eliminates this problem but requires $N(N-1)/2 = 28$ links for 8 GPUs, a wiring challenge that becomes impractical as the link count grows quadratically. The NVSwitch crossbar provides the best of both worlds: full bisection bandwidth with a manageable number of switch chips.

Consider the NVIDIA DGX H100 architecture. Eight H100 GPUs sit on a single baseboard, each connected to four NVSwitch chips via 18 NVLink 4.0 lanes. The NVSwitch chips form a non-blocking crossbar¹³: any GPU can communicate with any other GPU at the full 900 GB/s bidirectional bandwidth simultaneously, without contention. This is the equivalent of giving every pair of GPUs their own private highway, rather than forcing them to share a single road.

The result is that the 8 GPUs within a DGX H100 can be treated as a single logical device with 640 GB of aggregate HBM and a combined compute throughput of 8×1979 TFLOP/s. This abstraction is critical for software: the training framework can partition a model across the 8 GPUs using tensor parallelism as if they were a single larger processor, with the NVSwitch fabric making the partitioning nearly transparent from a performance perspective.

The physical layout of the DGX H100 baseboard reflects this design goal. The 8 GPUs are arranged on the baseboard with the 4 NVSwitch chips positioned centrally. Each GPU connects to all 4 NVSwitch chips via NVLink lanes, and each NVSwitch chip has 64 NVLink ports that cross-connect the GPUs.

The NVSwitch chips themselves consume approximately 200 W each (800 W total for the NVSwitch fabric), a nontrivial power overhead that is justified by the bisection bandwidth it provides. To put this in perspective, the NVSwitch fabric alone consumes more power than an entire previous-generation GPU (the V100 drew 300 W). Without NVSwitch, achieving full all-to-all connectivity would require 28 direct GPU-to-GPU links, a wiring nightmare that would also consume more total NVLink lane capacity.

During a tensor-parallel forward pass, each GPU holds one shard of each weight matrix and computes its portion of the matrix multiplication. For a Transformer layer with hidden dimension 12,288 (typical for a 175B model), each of the 8 GPUs holds a $12,288 \times 1,536$ slice of the weight matrix. After each GPU computes its partial result, an AllReduce operation sums the partial results across all 8 GPUs over NVLink.

The AllReduce for a single layer's output involves exchanging approximately $4 \times 2,048 \times 12,288 \times 2$ bytes (FP16) across the NVLink fabric. For a typical microbatch size of 4 sequences at 2,048 tokens, this is roughly 201 MB per AllReduce, which completes in about 0.2 ms at 900 GB/s.

Even with 96 layers (forward pass) and 96 layers (backward pass), the cumulative AllReduce time is about 42.9 ms per training step. This is possible because the NVSwitch crossbar allows all 8 GPUs to communicate simultaneously without contention, unlike a ring topology where data must traverse multiple hops sequentially.

The communication overhead is small relative to the compute time per layer, which is approximately 2–5 ms depending on the sequence length and batch size. The resulting tensor-parallel scaling efficiency within the node is typically 85–95 percent, meaning that using 8 GPUs achieves 6.8–7.6 $\times$ the throughput of a single GPU.

The remaining 5–15 percent efficiency loss comes from two sources. First, the AllReduce communication itself, even at NVLink bandwidth, consumes a fraction of each layer's execution time.

¹³ | **Crossbar Switch:** A topology providing a dedicated path between every input-output pair simultaneously. An $N \times N$ crossbar has N^2 crosspoints, achieving full bisection bandwidth. NVSwitch implements a 3-stage crossbar using four switch chips (each with 64 NVLink ports), consuming ~800 W total – more than an entire V100 GPU – but this power cost is justified because it enables all-to-all tensor parallelism within a node, the communication pattern that would otherwise dominate training time.

Second, some operations in the Transformer (layer normalization, dropout, activation functions) are not tensor-parallelized because their computation is small relative to the matrix multiplications. These sequential operations must complete on every GPU before the next layer's tensor-parallel computation can begin, introducing small but cumulative idle time.

Example 2.3: The NVLink bandwidth surprise

Scenario: Early users of multi-GPU nodes often attempted tensor parallelism over PCIe, expecting the 64 GB/s bandwidth to suffice.

Diagnosis: Tensor parallelism requires AllReduce after *every* Transformer layer, not just *once* per training step. A model with 96 layers generates 96 AllReduce operations per forward pass and another 96 during the backward pass, totaling 192 synchronization events per step. At PCIe bandwidth, each AllReduce for a 12,288-dimensional hidden state takes approximately 3.1 ms, accumulating to 604 ms of pure communication overhead per step. With a 200 ms compute-step anchor, the accelerators spend roughly 75.1 percent of their time waiting for PCIe transfers. Switching to NVLink reduces each AllReduce to 0.2 ms, bringing total communication overhead to 42.9 ms and restoring accelerator utilization to over 82.3 percent.

Systems lesson: For tensor parallelism, the interconnect is the bottleneck, and the difference between PCIe and NVLink is not incremental; it is the difference between a functional and a nonfunctional system.

Beyond NVLink, the node also connects to the external network via InfiniBand Host Channel Adapters (HCAs) and to host storage via PCIe. The DGX H100 includes eight InfiniBand ConnectX-7 HCAs, one per GPU, enabling GPUDirect RDMA: the network adapter can read from and write to GPU HBM directly, without staging data through host DRAM or involving the host CPU in the data path.

GPUDirect RDMA is critical for inter-node gradient synchronization, where each GPU's gradient shard must be sent to its peers on other nodes. Without GPUDirect, each gradient transfer would require two extra copies: first from GPU HBM to host DRAM (over PCIe), and then from host DRAM to the network adapter (over another PCIe path). The double-copy adds latency (two PCIe traversals instead of one direct DMA operation) and halves the effective bandwidth (each byte traverses the PCIe bus twice).

GPUDirect RDMA eliminates both copies by allowing the InfiniBand HCA to read directly from GPU HBM, bypassing the host CPU and host DRAM entirely. The data path goes from GPU HBM through the NVLink-to-Pcie bridge to the InfiniBand HCA in a single transfer. The single-hop data path is one of the reasons that modern training clusters achieve inter-node communication bandwidth close to the raw InfiniBand line rate.

The host CPU manages job scheduling, data preprocessing, data loading from storage, and network protocol processing, but it sits outside the critical path of the GPU-to-GPU computation. The separation is deliberate: the host handles the “slow” operations (disk I/O, network management, job coordination) while the GPU-NVSwitch fabric handles the “fast” operations (matrix math, gradient synchronization).

The host CPU's role is analogous to an operating system kernel in a traditional computer: it manages resources, handles exceptions, and coordinates I/O, but it does not perform the application's core computation. In a well-optimized training loop, the host CPU is almost never on the critical path, and its performance specifications (core count, clock speed) are less important than its I/O capabilities (PCIe lane count, memory channels, NVMe controller bandwidth).

The host CPU also runs the training framework's Python runtime, which orchestrates kernel launches, manages the computation graph, and coordinates collective communication operations. In well-optimized training loops, the host CPU is pipelining the next batch's data loading and preprocessing while the GPUs are executing the current batch's forward and backward passes, keeping all components busy simultaneously.

As the “data center tax” on host CPUs has grown – with up to 30 percent of CPU cycles consumed by network protocol processing, storage virtualization, and security functions – ML nodes can incorporate **Data Processing Units (DPUs)** or SmartNICs. Devices like the NVIDIA BlueField DPU

offload these infrastructure tasks to dedicated ARM cores and hardware accelerators integrated into the network adapter itself. By moving the control plane for RDMA, firewall rules, and storage protocols to the DPU, the host CPU recovers cycles for the ML pipeline: data loading, tokenization, and kernel orchestration. The DPU also acts as an isolated security domain, allowing cloud providers to maintain control over the network and storage layer via the DPU while granting customers full access to the host CPU and GPUs. For our 175B model training, DPU offload can keep RDMA protocol processing outside the host CPU critical path for gradient synchronization, which flows from GPU HBM toward the network fabric without host CPU involvement.

2.4.2.1 Alternative node architectures

These alternatives are accelerator-system designs, not interchangeable product names. An AMD MI300X is a GPU-class accelerator whose package emphasizes very large HBM capacity, while Intel/Habana Gaudi designs emphasize Ethernet/RDMA attachment as a first-class communication path. Comparing them against a DGX H100 node reveals where each architecture spends its scarce budget.

The DGX H100 answers a general node-design problem by making local accelerator exchange cheap. A switch-rich design spends power, board area, and cost on universal any-to-any exchange. That choice is easy to justify when tensor parallelism is the critical path, because each Transformer layer turns local accelerator communication into part of the model's inner loop. The 900 GB/s H100 NVLink fabric therefore buys a software abstraction: the training framework can treat eight accelerators as one tightly coupled device for the layers that must be split across chips.

Other systems move that boundary. TPU pods use the Inter-Chip Interconnect (ICI) and a mesh-oriented topology instead of making a central switch the defining component of the node; the TPU v5p profile in MLSysIM models ICI at 1,200 GB/s. The mesh can reduce switch cost and expose a regular structure to the compiler, but it also makes placement more visible: the runtime must respect neighbor relationships rather than assuming that every chip pair has the same communication path. That is a reasonable trade when the workload is regular enough for the compiler and collective libraries to map communication onto the topology.

The MI300X shifts the pressure point from local switching toward memory capacity. Its package exposes 192 GB of HBM at 5.3 TB/s, compared with 80 GB on an H100-class accelerator. An eight-accelerator MI300X node would therefore provide 1,536 GB of aggregate HBM, enough to hold the 350 GB FP16 weight tensor for our 175B running model. That does not eliminate the optimizer, gradient, activation, and fragmentation problem introduced in section 2.4, but it changes how often the system must spill state into slower memory tiers and how much microbatch headroom remains before offload becomes mandatory.

Gaudi takes a different route by integrating RDMA-capable Ethernet into the accelerator and using a more network-centric design for communication. The Gaudi 2 profile exposes 300 GB/s of aggregate RoCE bandwidth through 24 attached 100 GbE ports, while an H100-class NVLink node offers 900 GB/s of local GPU exchange and the newer Gaudi 3-class accelerator still exposes 128 GB of HBM. The question is whether simplifying the fabric and using Ethernet consistently across node and pod is worth giving up the very high local exchange bandwidth of a switch-rich NVLink design. That trade can be attractive when data parallelism, inference serving, or cluster cost dominates, and less attractive when tensor-parallel collectives sit inside every layer.

These alternatives are not a ranking of vendors. They are different placements of scarce resources: switching bandwidth in the node, regular topology in the pod, HBM capacity in the package, or network attachment on the accelerator. For the 175B model used throughout this chapter, the tensor-parallel portion of training makes local accelerator communication unusually important, so the DGX-style answer is natural. In other regimes, especially memory-heavy recommenders, topology-regular training, or cost-sensitive serving fleets, a different boundary can become the one that matters most. Software ecosystem maturity, supply availability, and total cost of ownership then decide whether the theoretical architectural fit becomes a deployable system.

2.4.2.2 Node health and reliability

The node is the fundamental failure domain in the fleet hierarchy. When a single GPU fails within a node, the entire node typically becomes unusable for the training job, because tensor parallelism

requires all 8 GPUs to participate in every AllReduce operation. A single missing GPU breaks the collective communication, stalling all other GPUs in the node. The *least reliable* component, not the *average*, therefore determines the node's effective MTBF.

The components most prone to failure within a node form a diagnostic list, roughly in order of frequency:

- **GPU memory:** HBM can encounter ECC-uncorrectable errors that remove the GPU from service.
- **NVLink connections:** Signal integrity can degrade over time, causing link retraining or communication errors.
- **Power supplies:** Capacitors age under sustained high-load operation.
- **Cooling components:** Pumps in liquid-cooled systems and fan bearings in air-cooled systems introduce mechanical failure modes.

A well-managed fleet tracks the error rates of each component and preemptively migrates workloads away from nodes showing early warning signs. The most important early warning indicators are increasing corrected ECC error rates (which often precede uncorrectable errors by hours to days), rising junction temperatures at constant workload (indicating cooling degradation), and intermittent NVLink retraining events (indicating cable or connector degradation). Proactive replacement of components showing these warning signs can prevent the much more costly outcome of an unplanned job failure during a multi-week training run.

Node-level health monitoring is therefore a critical operational practice. Modern fleet management systems continuously collect telemetry from each GPU (temperature, power draw, ECC error counts, NVLink error rates) and from the host BMC (baseboard management controller). Automated health checkers run short diagnostic workloads on idle nodes to verify that all GPUs, NVLinks, and InfiniBand connections are functioning correctly before the job scheduler assigns training work to that node. Without this proactive monitoring, a silently degraded node can corrupt training gradients (if the error is in the arithmetic path) or slow the entire job (if the error causes NVLink retraining, which temporarily reduces bandwidth). Chapter 7 discusses fleet-level fault tolerance strategies in detail.

For our 175B model training across 128 nodes, the probability of at least one node experiencing a hardware issue during a two-week training run is substantial. Under a composite node-level MTBF assumption of 1,000 hours, which includes GPUs, host components, power, cooling, and network links, the expected number of node failures during a run of 336 hours is approximately 43. This means the training run will experience, on average, roughly 3.1 failures/day. A GPU-only lower bound from the canonical per-GPU MTBF of 50,000 hours would predict only 6.9 GPU-driven node outages over the same run, before adding host, power, cooling, and network failure terms. Each failure requires detecting the degraded node, draining its workload, substituting a spare node, and resuming from the last checkpoint – a process that takes 10 minutes–30 minutes with automated tooling. With automated recovery, the direct restart overhead is roughly 2.1 percent–6.4 percent of the run; without spare nodes and automated recovery, multi-hour interventions can push overhead into the 20–30 percent range, consuming millions of dollars in wasted GPU-hours.

2.4.3 Node memory partitioning

A common misconception is that a model's memory footprint equals its weight storage. In practice, training state dwarfs the weights: Adam optimizer moments, gradients, and activations collectively consume $5\text{--}7\times$ more memory than the parameters alone, and these components reside in different tiers of the node's memory hierarchy.

As table 2.10 shows, for our 175B model, the training memory breaks down as follows:

Table 2.10: Training Memory Breakdown for a 175B-Parameter Frontier Model: The optimizer state alone (first and second moments in FP32) consumes $4\times$ the memory of the model weights, making optimizer memory the dominant component of training memory. This is why memory optimization techniques focus heavily on optimizer state sharding and offloading.

Component	Precision	Memory per Parameter	Total for 175B Model
Model Weights	FP16	2 bytes	350 GB
Gradients	FP16	2 bytes	350 GB
Optimizer (Adam m)	FP32	4 bytes	700 GB
Optimizer (Adam v)	FP32	4 bytes	700 GB
Activations	Mixed	Variable	100–400 GB
Total			2.2–2.5 TB

Table 2.10 makes the partitioning concrete. The same 2.2–2.5 TB budget established earlier reappears here, but now decomposed by component and tier: the Adam optimizer state in FP32, not the FP16 weights, is the dominant term, and the activation peak (which scales with batch size and sequence length) is the most variable. The lesson for parallelism selection is that the weights are the smallest piece of what the node must hold, so a strategy that only shards weights leaves the largest consumers, optimizer state and activations, untouched.

A DGX H100 node provides 640 GB of aggregate HBM across its 8 GPUs, plus 2 TB of host DDR5 DRAM. The HBM capacity alone is insufficient for the full training state. To appreciate why, consider the memory arithmetic for different parallelism strategies. With **pure data parallelism**, each GPU must hold the complete model: 350 GB weights + 350 GB gradients + 1,400 GB optimizer states = 2,100 GB – physically impossible on an 80 GB device. Even **ZeRO Stage 3**, which shards all three components across only 8 GPUs, yields $2,100 \text{ GB} / 8 \approx 262.5 \text{ GB}$ per GPU, still more than triple the available HBM. The solution is to combine tensor parallelism (which splits the model’s layers across GPUs, reducing per-GPU weights to $350 \text{ GB} / 8 = 43.75 \text{ GB}$) with data-parallel sharding across many replicas. In a configuration with TP-8 within each node and 128-way data parallelism across the cluster, each GPU holds 43.75 GB of weight shards. The optimizer state is likewise partitioned, first by the 8-way tensor split and then across the 128 data-parallel replicas, so each GPU holds approximately $1,400 \text{ GB} / (1024) \approx 1.4 \text{ GB}$ of optimizer state, or 10.9 GB per 8-GPU tensor-parallel group, before gradients, activations, buffers, and fragmentation. The weight-plus-optimizer subtotal of roughly 45.1 GB is only the starting point; the memory-budget exercise below shows why gradients and activations still require checkpointing and offload. This arithmetic is why tensor parallelism, optimizer sharding, activation checkpointing, and memory tiering are used together for large-model training.

ZeRO Stage 3 fully shards optimizer states, gradients, and parameters across all GPUs participating in data parallelism. With sharding across the 8 GPUs in a node, each GPU holds only $1/8$ of each component, reducing per-GPU memory to roughly 262.5 GB of equivalent storage ($2,100 \text{ GB total state} \div 8$). This still exceeds 80 GB per GPU, so the sharding must be combined with other techniques. Activation checkpointing stores only a subset of intermediate activations for the backward pass and recomputes the remaining activations from the nearest checkpoint. It trades roughly 33 percent more FLOPs for up to $10\times$ lower activation memory.

CPU offloading stores optimizer states in host DDR5 DRAM and transfers them to GPU HBM only when the parameter update needs them. The PCIe Gen5 link at 64 GB/s introduces a transfer delay, but the overhead is manageable because the parameter update is a small fraction of total step time. NVMe offloading extends the same idea to SSDs for even larger models, with sequential read bandwidth of 5–7 GB/s and a larger latency penalty that requires careful pipelining to overlap with computation.

The node’s memory hierarchy thus operates as a tiered system. HBM holds the active computation: weight shards that are needed for the current layer’s matrix multiplication, the current microbatch’s activations, and the gradients being accumulated during the backward pass. DDR5 holds the bulk optimizer state, which is accessed only during the parameter update step at the end of each training iteration. NVMe provides overflow capacity for the largest models, storing seldom-accessed shards that can be prefetched during computation.

The training framework’s memory manager orchestrates the flow of data between these tiers, operating much like a hardware cache controller but at a coarser granularity. The analogy to hardware caching is instructive: just as a CPU’s cache controller uses prefetching to hide memory latency by loading data before the processor needs it, the training framework’s memory manager uses software-level prefetching to hide the PCIe transfer latency by loading weights before the GPU needs them. During the forward pass of layer ℓ , the manager simultaneously prefetches the weights for layer $\ell + 1$ from DDR5 to HBM (if they have been offloaded) and evicts the weights for layer $\ell - 2$ from HBM back to DDR5 (if memory is tight).

The pipelining ensures that each layer’s computation can proceed without waiting for data transfers, at the cost of increased software complexity and careful tuning of the prefetch depth. If the prefetch is too shallow, the computation stalls waiting for data. If the prefetch is too aggressive, HBM fills up with data that will not be used for several layers, crowding out the activations and gradients needed for the current computation. The capacity-bandwidth trade-off across these tiers determines which data a training framework can keep “hot” and which it must prefetch; table 2.11 quantifies the three-order-of-magnitude bandwidth gap that the memory manager must bridge.

Table 2.11: Node Memory Hierarchy: Each tier trades capacity for bandwidth. The training framework’s memory manager must orchestrate data flow across these tiers to fit models whose total state exceeds the aggregate HBM capacity.

Mem- ory Tier	Capacity	Bandwidth	Latency	Role
GPU HBM3	80 GB $\times$ 8 = 640 GB	3.35 TB/s per GPU	<1 μ s	Active com- puta- tion
Host DDR5	2 TB	hundreds of GB/s aggregate	~100 ns	Opti- mizer state
NVMe SSD	8–30 TB	up to 7 GB/s per drive	~100 μ s	Over- flow, check- points

The orchestration is complex but essential: without it, training our 175B model on H100-class hardware would be impossible. Chapter 5 examines these memory optimization strategies and their interaction with parallelism in full detail.

2.4.3.1 Putting it together: Memory budget exercise

To solidify the memory planning concepts, consider a concrete sizing exercise for our 175B model on a DGX H100 node.

Example 2.4: Memory budget for 175B training on DGX H100

Given:

- Model: 175B parameters
- Node: 8 $\times$ H100 GPUs, 80 GB HBM each (640 GB total HBM)
- Host: 2 TB DDR5
- Parallelism: 8-way tensor parallelism within the node

Step 1: Weight Distribution With 8-way TP, each GPU holds 1/8 of every weight tensor. Per-GPU weight memory: 43.75 GB (FP16).

Step 2: Optimizer State with ZeRO Stage 1 ZeRO Stage 1 shards the optimizer states across data-parallel workers. Within a single node using only TP (no data parallelism), the optimizer is not sharded. Each GPU stores the full optimizer state for its TP shard: 43.75 GB $\times$ 4 (FP32 m and v) = 175 GB.

The total exceeds the 80 GB HBM capacity. The fix is to offload optimizer states to host DDR5. The 2 TB of DDR5 can hold the full 1,400 GB of optimizer state with room to spare.

Step 3: Activations With activation checkpointing (recomputing every other layer), the activation memory for a microbatch of 4 sequences at 2,048 token length is approximately 15–25 GB per GPU. Without checkpointing, it would be 100–200 GB per GPU, which is impossible.

Step 4: Gradient Accumulation Gradients match the weight size: 43.75 GB per GPU in FP16.

Total per-GPU HBM usage:

- Weights: 43.75 GB
- Activations: ~20 GB (with checkpointing)
- Gradients: 43.75 GB
- Buffers and fragmentation: ~5 GB
- **Total:** ~113 GB (exceeds 80 GB HBM)

Resolution: Use gradient accumulation (accumulate over 2–4 microbatches before AllReduce, reducing peak activation memory) and gradient offloading (store inactive gradient shards in DDR5). With these techniques, the per-GPU HBM usage drops to approximately 70–75 GB, fitting within the 80 GB envelope with a small margin for NCCL communication buffers.

Systems insight: Model capacity is not the only memory constraint. Training fits only when weights, gradients, optimizer state, activations, communication buffers, and fragmentation are managed together.

The example illustrates why memory planning for large models is a careful engineering exercise rather than a simple capacity calculation. Beyond memory-tier placement, the bandwidth hierarchy imposes a sharp penalty on data that must cross the node boundary, a cost the next calculation makes explicit.

Napkin Math 2.5: The cost of crossing the cliff

Problem: A training step must synchronize a 1 GB gradient buffer. How much longer does the synchronization take when it crosses the node boundary (InfiniBand) compared to staying within the node (NVLink)?

1. **Intra-Node (NVLink):** Bandwidth = 450 GB/s one-way effective bandwidth; the bidirectional aggregate is 900 GB/s, but this transfer-time calculation moves one buffer in one direction. $T_{\text{intra}} = 1 \text{ GB} / 450 \text{ GB/s} \approx 2.2 \text{ ms}$
2. **Inter-Node (InfiniBand NDR):** Bandwidth = 50 GB/s. $T_{\text{inter}} = 1 \text{ GB} / 50 \text{ GB/s} \approx 20 \text{ ms}$

Systems insight: Crossing the node boundary increases communication time by approximately 9×. In a training loop where gradient synchronization happens at every step, this penalty would stall the accelerators for the majority of each iteration, reducing utilization to well below 50 percent. This is why training frameworks use tensor parallelism within the node (fast NVLink) and data parallelism across nodes (tolerant of slower InfiniBand).

2.4.4 Data loading and I/O pipeline

The discussion so far has focused on how data moves within the node (HBM to Tensor Core, GPU to GPU via NVLink, GPU to host via PCIe). Training also requires feeding the node with a continuous stream of training data from external storage. If the data loading pipeline cannot keep up with the GPU's consumption rate, the most expensive component in the system (the GPU) sits idle waiting for data. This is the **I/O bottleneck**, and avoiding it requires careful engineering of the data loading pipeline.

For language model training, the training throughput determines the data consumption rate. If the cluster processes 500,000 tokens per second and each token requires 2 bytes of input data (token ID), the raw data ingestion rate is only 1 MB/s, which is trivially handled by any storage system.

However, the actual I/O demand is much larger because training data must be tokenized, shuffled, batched, and transferred to GPU memory. A realistic data pipeline turns raw bytes into GPU-ready batches through five ordered stages:

1. **Reading:** Raw text is read from a distributed file system (NFS, Lustre, or cloud object storage like S3) into host memory. For large datasets (terabytes of text), the data is typically stored in a binary format (TFRecord, WebDataset, or memory-mapped files) to minimize parsing overhead.
2. **Preprocessing:** Tokenization, sequence packing, and random cropping are performed on the host CPU. These operations are parallelized across multiple CPU cores using data loader workers (typically 4–8 workers per GPU).
3. **Batching:** Individual sequences are assembled into microbatches, padded to uniform length, and organized into tensors.
4. **Transfer:** The assembled batch is transferred from host DRAM to GPU HBM over PCIe. For tokenized language modeling, this transfer is usually small because token IDs and masks are compact; multimodal batches or pipelines that materialize FP16 embeddings on the host can reach 100–200 MB and take milliseconds at PCIe Gen5 bandwidth.
5. **Prefetching:** While the GPU processes the current batch, the data loader prefetches and preprocesses the next 2–4 batches in parallel, ensuring that the next batch is already in GPU HBM when the current computation completes.

The critical design goal is to make the data pipeline invisible to the GPU: the prefetching must be deep enough that a batch is always ready when the GPU needs it, regardless of transient variations in storage bandwidth or preprocessing time. When this pipeline is well-tuned, the GPU utilization is limited only by compute and communication, not by data loading. When it is poorly tuned, the GPU can spend 10–30 percent of its time waiting for data, which directly reduces training throughput.

The traditional data path routes every byte through the host CPU: storage controller to host DRAM (one PCIe traversal), then host DRAM to GPU HBM (a second PCIe traversal). This “bounce buffer” architecture doubles the traffic on the PCIe root complex and makes the CPU a bottleneck for I/O-intensive workloads, capping effective bandwidth at 3–4 GB/s per NVMe drive due to kernel context switching and interrupt handling overhead. **GPUDirect Storage (GDS)** eliminates this inefficiency by establishing a direct DMA path between the NVMe controller and GPU memory, bypassing the host CPU entirely. A single NVMe drive can deliver 5–7 GB/s directly to GPU HBM through GDS, saturating the drive’s internal bandwidth rather than the host’s I/O subsystem. For a standard node equipped with four NVMe drives, GDS unlocks an aggregate storage-to-GPU bandwidth of 20–28 GB/s, freeing the CPU to focus exclusively on preprocessing tasks like tokenization and sequence packing. The storage chapter’s GPUDirect Storage discussion in section 4.5 examines this direct path in detail.

The required prefetch depth is not arbitrary but follows from the statistics of I/O latency variance. If the GPU processes one batch every T_{compute} seconds and the storage system delivers a batch every $T_{\text{I/O}}$ seconds with standard deviation $\sigma_{\text{I/O}}$, the minimum prefetch depth k required to maintain a 99.7 percent probability of zero stalls is $k \geq \lceil T_{\text{I/O}}/T_{\text{compute}} + 3\sigma_{\text{I/O}}/T_{\text{compute}} \rceil$. For our 175B model training run where $T_{\text{compute}} = 2.0$ seconds and the storage layer delivers batches at $T_{\text{I/O}} = 1.5 \pm 0.5$ seconds, the required depth is $\lceil 0.75 + 0.75 \rceil = 2$ batches. In production environments where “noisy neighbors” on shared file systems induce heavy tail latencies, engineers typically over-provision this buffer to 4–8 batches to insulate the GPU from the erratic physics of distributed storage. The memory cost of this prefetch buffer is negligible compared to the cost of a GPU stall for tokenized language workloads, though multimodal pipelines must budget larger host-side batch buffers.

As cluster sizes expand, a new storage bottleneck emerges. When training our 175B model across 128 nodes, the system acts as a synchronized “thundering herd” – all 128 nodes simultaneously demand the next microbatch of tokens at the start of every training step. A shared parallel filesystem like Lustre, even with 500 GB/s of aggregate throughput, will buckle when 128 clients simultaneously pull data, causing read latencies to spike from milliseconds to seconds. The architectural solution is **tiered storage** with aggressive local caching. By provisioning each training node with local NVMe SSDs capable of delivering 25 GB/s per node, the cluster decouples its immediate data dependency from the shared filesystem. A background process prefetches data from the central store to the

local NVMe cache asynchronously, smoothing out I/O spikes. For the 128-node cluster, local NVMe creates an aggregate read bandwidth of 3.2 TB/s (128×25 GB/s), eclipsing the capability of even the most expensive centralized storage arrays and ensuring the GPUs are never starved.

🔍 Systems Perspective 2.5: The data loading trap

A subtle failure mode occurs when data loading appears fast in benchmarks but degrades under production conditions. Single-node benchmarks often read data from local NVMe SSDs, achieving 5–7 GB/s read bandwidth. In production, where data resides on a shared storage system accessed by hundreds of nodes simultaneously, the effective per-node bandwidth may drop to 100–500 MB/s due to network congestion and storage controller contention. Teams that design their data pipelines based on single-node benchmarks may discover that their GPUs are I/O-starved in production. Chapter 4 examines the storage architecture strategies that address this bottleneck, including the tiered storage hierarchies that ensure training data reaches GPUs without stalling.

For our 175B model, a single DGX H100 node provides 640 GB of aggregate HBM, enough to hold the FP16 model weights but not the full Adam training state without sharding and offload. Training also requires processing trillions of tokens, and a single node's compute throughput limits training time to months. To complete training in a reasonable timeframe (weeks rather than months), we need tens or hundreds of nodes. Stacking those nodes into a physical enclosure brings us to the next level of infrastructure, where the constraints shift from bandwidth and capacity to raw power and heat.

2.5 The Rack

A standard 42U server rack in a traditional data center draws 5–10 kW and can be cooled by room-temperature air pushed through perforated floor tiles. Now place four DGX H100 nodes in that same rack: 32 GPUs, each drawing 700 W, plus host CPUs, memory, networking, power conversion losses, and cooling overhead. The rack power reaches 33.5 kW, an order of magnitude beyond what traditional data center infrastructure was designed to deliver or cool. At this density, the engineering constraints shift from silicon and signal integrity to power delivery and thermodynamics. The rack is where the power wall and the laws of heat transfer become the dominant design forces.

For our 175B model, training across 1,024 GPUs requires 32 racks (4 nodes of 8 GPUs each per rack). Each rack dissipates 33.5 kW as heat, the thermal output of a small industrial furnace. The aggregate facility-relevant power draw of the training cluster is approximately 1.1 MW, enough to power several hundred homes. Delivering this power reliably, converting it efficiently, and removing the resulting heat without allowing any component to exceed its thermal limit is a multi-disciplinary engineering challenge that spans electrical, mechanical, and civil engineering. A failure at any point in the power delivery chain, from the utility substation to the individual GPU voltage regulator, can halt the entire training run, wasting hours of computation and potentially corrupting the training state.

📖 Definition 2.6: Rack

Rack is the physical infrastructure unit, a standardized 42U enclosure, that houses multiple compute nodes, a Top-of-Rack (ToR) switch (the first network aggregation point connecting all nodes in the rack to the broader cluster fabric), power distribution units, and cooling distribution manifolds, defining the granularity at which power and cooling capacity must be provisioned.

1. **Significance:** AI rack power density has grown dramatically: a rack of 4 DGX H100 nodes contains 32 GPUs at 700 W each, totaling 22.4 kW of GPU power alone, plus 11+ kW for CPUs, NVSwitch, NICs, power conversion losses, and cooling overhead, reaching 33–40 kW per rack. This far exceeds the 5–10 kW typical of general-purpose data center

Modern GPU racks cross the air-cooling envelope.

racks, requiring dedicated liquid cooling infrastructure and electrical circuits that must be co-designed with the building.

2. **Distinction:** Unlike a node (the compute unit), a rack is the infrastructure unit: it is the physical level at which cooling manifolds, power distribution, and the ToR switch are integrated—making the rack the minimum replaceable and serviceable unit for facility operations, not the node.
3. **Common pitfall:** A frequent misconception is that rack placement is a logistical afterthought. Nodes within the same rack share a ToR switch and have single-hop connectivity; nodes in different racks cross at least two switch hops. Placing all pipeline-parallel stages of a training job within the same rack minimizes inter-stage latency and reduces inter-rack fabric load.

The rack opener promised that the laws of heat transfer become the dominant design force at this level, and the reason is a hard physical limit on how fast a moving fluid can carry heat away from a surface. Air is a poor coolant: it has low density and low heat capacity, so a given volume of air absorbs little energy before its temperature rises to the point where it can no longer cool the silicon. Forced-air cooling, even with hot-aisle/cold-aisle containment and high-static-pressure fans, removes heat at a rate set by how much air the facility can physically push through the rack. That rate tops out around 30 kW per rack. Below roughly 10 kW, room-temperature air through perforated floor tiles suffices, which is why traditional 42U racks were never a thermal problem. Engineered air cooling stretches the envelope toward 30 kW, but no amount of additional fan power moves past it: beyond that density the air leaving the rack is already too hot to absorb more heat, and adding fans consumes power and produces noise without removing additional watts. A rack of four DGX H100 nodes sits at 33–40 kW, already past the air ceiling, and Blackwell-class racks push toward 100 kW and beyond, the point at which air cooling fails outright. Air is not throttled at these densities; it is disqualified.

This thermal ceiling is what forces the rack from air to liquid: above the air-cooling threshold the only way to remove the heat is to put a far denser coolant in direct contact with the silicon, which is why high-density AI racks are liquid-cooled by physical necessity rather than by choice. Section 15.4.6 takes up the cooling architectures that meet this requirement, the efficiency comparison between air and liquid cooling, and the facility-power overhead the choice carries every hour the cluster runs.

2.5.1 Rack design considerations

The physical design of an ML rack differs substantially from a traditional server rack in ways that go beyond power and cooling. In a conventional 42U rack, servers are installed as independent 1U or 2U pizza-box units, each with its own fans, power supplies, and cable connections. ML racks use a fundamentally different form factor. A DGX H100 occupies 8U and contains 8 GPUs, the NVSwitch fabric, multiple power supplies, and (in liquid-cooled configurations) coolant manifolds with quick-connect fittings. Four DGX units in a 42U rack leave only 10U for networking switches, cable management, and PDUs.

The transition from traditional server form factors to ML-optimized designs is driven by the same power density challenge that forced the transition from air cooling to liquid cooling. A traditional 1U server dissipates 300–500 W and requires only modest airflow for cooling. A DGX H100 node dissipates approximately 8.4 kW across its 8 GPUs, NVSwitches, and supporting components, requiring either massive airflow (in air-cooled configurations) or liquid cooling plumbing (in liquid-cooled configurations). The form factor must accommodate both the compute hardware and the thermal management infrastructure, which is why ML nodes are substantially taller (8U vs. 1U) than traditional servers.

Cable management is a nontrivial engineering challenge. Each DGX H100 node has 8 InfiniBand cables (one per GPU), 2 Ethernet management cables, power cables, and (for liquid-cooled units) coolant hoses. A fully populated rack has over 40 high-speed cables, each of which must be routed carefully.

Three physical constraints govern cable routing:

- **Airflow clearance:** Cables must not obstruct airflow in air-cooled designs, because even a partial blockage can create hot spots that throttle nearby components.
- **Bend radius:** High-speed cables have a minimum bend radius, typically 10–15× the cable diameter for active optical cables, below which the signal path is damaged and can produce bit errors or complete link failure.
- **Electromagnetic interference:** Bundling too many high-speed copper cables together can degrade signal quality on neighboring links.

In large installations, the cable plant alone can take weeks to install and test, and cable routing errors are one of the most common causes of postinstallation debugging delays.

As rack power densities climb toward 100 kW for liquid-cooled clusters, the inefficiency of per-server AC conversion becomes untenable. Traditional designs dedicate volume in every chassis to redundant AC power supply units (PSUs), while many dense-rack designs use **rack-level DC power distribution**. In this architecture, a centralized power shelf converts mains AC to a **48V DC busbar** that runs the height of the rack, replacing individual server PSUs. This consolidation eliminates one conversion stage, yielding a system-wide efficiency gain of 2–3 percent – a meaningful reduction in thermal load when training a 175B-parameter model across thousands of GPUs. Power is delivered via the 48V bus directly to the server backplane, where compact DC-to-DC converters step it down to 12V and finally to the GPU’s sub-1V operating voltage. Pioneered by Google and Meta through the Open Compute Project (OCP), this topology reduces failure points and recovers valuable chassis volume for hydraulic cooling loops and high-bandwidth interconnects.

The **Top-of-Rack (ToR) switch** deserves special attention. In traditional data centers, a ToR switch provides 1–10 Gb/s Ethernet connectivity to each server, aggregated into uplinks to higher-level switches. In an ML rack, the ToR switch is an InfiniBand or high-speed Ethernet switch providing 400 Gb/s per port, and it must handle the bursty, synchronized traffic patterns of distributed training.

The placement and configuration of ToR switches directly affects the network topology. Rail-optimized designs (used by Meta and others) assign each GPU within a node to a specific “rail” that connects to a dedicated ToR switch. In a conventional design, all 8 GPUs in a node connect to the same ToR switch, creating a potential bottleneck when multiple GPUs simultaneously send AllReduce traffic. In a rail-optimized design, GPU 0 in every node connects to ToR switch 0, GPU 1 to ToR switch 1, and so on. This ensures that AllReduce traffic within a parallelism group (where all participants are the same GPU index across different nodes) is confined to a single switch rather than traversing the full fabric.

The rail-optimized design requires 8 ToR switches per rack group instead of 1, which increases switch cost and cabling complexity. However, it eliminates cross-switch congestion for the most common communication pattern (data-parallel AllReduce across nodes), improving scaling efficiency by 5–15 percent compared to a conventional single-ToR design. Chapter 3 examines rail-optimized topologies in detail, including the formal analysis of their bandwidth properties and the conditions under which they outperform fat-tree alternatives.

2.5.1.1 Facility reliability and environmental controls

Rack design also defines physical failure domains. Data centers housing ML infrastructure implement multiple layers of physical security and environmental monitoring, not only for regulatory compliance but also because a single rack of DGX H100 nodes (\$1.4 million in hardware alone) concentrates enough value, heat, and liquid-cooling risk to justify controls that would be excessive for traditional server equipment.

Environmental monitoring is therefore part of the compute design rather than a facilities afterthought. Water detection sensors beneath raised floor tiles and around liquid cooling piping can identify leaks within seconds and trigger automatic coolant isolation valves. Aspiring smoke detection systems continuously sample air from inside racks, detecting combustion byproducts at concentrations far below what sprinkler-activating detectors can sense. Vibration sensors on the building structure and rack frames catch seismic events or construction-induced vibration that could damage disk drives or loosen cable connections. Humidity control keeps relative humidity between 40–60 percent to prevent both static discharge and condensation.

These environmental controls are not afterthoughts but integral parts of the infrastructure design that affect reliability and uptime. A water leak that reaches a DGX H100 baseboard can cause

millions of dollars in damage and weeks of downtime. A fire in a single rack can shut down an entire data center hall for days while the fire suppression system is recharged and the affected area is decontaminated. The 2021 OVHcloud fire in Strasbourg shows how a single-building incident, absent the right compartmentalization, escalates into a site-wide failure domain.

War Story 2.1: The data center that became the failure domain

Context: OVHcloud operated four data centers at its Strasbourg site, serving customers whose systems depended on the site's physical power, fire, and recovery design (OVHcloud 2021).

Failure mode: On March 10, 2021, a fire broke out in SBG2. OVHcloud reported that SBG2 was destroyed, SBG1 was severely damaged, and other Strasbourg data centers were powered down even when not directly burned.

Consequence: The incident forced service interruptions and data-recovery work across a site that many customers had treated as stable infrastructure rather than as a shared physical failure domain.

Systems lesson: Compute infrastructure is not only GPUs and network topology. Fire compartments, power isolation, backup geography, and disaster-recovery assumptions determine whether a rack-scale incident becomes a site-scale outage.

Once rack-level controls are in place, the reliability question moves up to facility redundancy. The same failure-domain logic that isolates a leaking rack also decides how much duplicate power, cooling, and recovery capacity the site should buy.

Data center reliability is commonly classified using the Uptime Institute Tier system, with **Tier III** and **Tier IV** representing common options for mission-critical compute (Uptime Institute 2026). A Tier III facility is concurrently maintainable: redundant capacity components and distribution paths let operators maintain or replace equipment without shutting down IT operations. Tier IV adds fault tolerance through independent, physically isolated systems, so a single equipment failure or distribution-path interruption should not affect IT operations. The practical difference is not a magic availability number; it is how much failure prevention the building buys in electrical and mechanical infrastructure before software-level resilience takes over.

For ML training infrastructure, the calculus differs from traditional enterprise computing. A training run is a long-running batch process, not a real-time transaction system. If a facility-level outage occurs during a two-week training run, the cost is usually a restart from the last checkpoint rather than permanent data loss. Many ML training deployments therefore pair concurrently maintainable facility designs with aggressive application-level fault tolerance: instead of buying every possible layer of building-level redundancy, engineers invest in checkpointing, job restart, and storage systems that can absorb rare facility interruptions. This software resilience commoditizes part of the facility risk, treating the data center as a fallible utility rather than a fortress. Avoided facility-resiliency spend can then be redirected toward accelerator capacity, networking, or storage, which may produce more training progress for the same budget.

Checkpoint 2.4: Infrastructure physics

A team is planning to deploy 256 H100 GPUs (32 nodes) in an existing air-cooled data center with 250 kW of available power capacity and cooling rated for 200 kW at PUE 1.5.

- ☐ **Facility power:** Calculate the total power draw, including cooling overhead.
- ☐ **Binding capacity:** Identify whether power capacity or cooling capacity is the binding constraint.
- ☐ **Required modifications:** Specify what modifications would be needed to support the full deployment.

The rack concentrates power and heat into a physical volume where thermodynamics, not software, sets the limits. A single rack of 32 GPUs, however, is far from sufficient for our 175B model, which may

require thousands of accelerators to train in a reasonable timeframe. The next level of infrastructure aggregates hundreds of racks into a unified computing system: the pod, whose network topology (figure 2.13) is designed around the communication pattern the workload must sustain. Full any-to-any bisection is one design point; torus and rail-optimized designs trade that universality for lower cost or better locality.

2.6 The Pod

Training our 175B model on a single DGX H100 node (8 GPUs, roughly 16,000 TFLOP/s aggregate) would take several months, assuming we can fit the model at all. Reducing training time to weeks requires 100–1,000 nodes operating in concert. A pod is the cluster-scale unit that makes this possible: many racks under one high-speed fabric, power envelope, and cooling design. Pod design is the first point where topology, power, and failure domains become shared infrastructure rather than per-rack concerns.

Figure 2.13: Pod-Scale Network Topologies: Two dominant pod topologies compared. (Left) Fat-Tree (3-Tier) with Leaf, Spine, and Core tiers: full bisection bandwidth, used by InfiniBand clusters such as DGX SuperPOD. (Right) 2D Torus with wrap-around links: bisection bandwidth scales as $\mathcal{O}(\sqrt{N})$, cheaper at scale but rewards workloads with strong locality; used by Google TPU pods. The choice shapes which parallelism strategies run efficiently.

The engineering challenge of the pod is wiring those nodes together into a network fast enough to keep gradient synchronization from becoming the bottleneck. The pod aggregates hundreds of racks into a single, coordinated computing system where the network fabric serves the same role that the system bus serves within a single machine.

The scale of this challenge is worth appreciating concretely. A 1,024-node DGX H100 cluster contains 8,192 GPUs, 4,096 NVSwitch chips, 8,192 InfiniBand HCAs, several hundred InfiniBand switches, tens of thousands of cables, and consumes approximately 7–10 MW of power. It occupies roughly 250 racks across one or more data center halls.

The physical weight of such a cluster is also substantial. Each DGX H100 node weighs approximately 130 kg (287 pounds), so 1,024 nodes weigh over 133 metric tons. Combined with racks, switches, cables, and cooling infrastructure, the total weight can exceed 300 metric tons. The data center floor must be structurally engineered to support this concentrated load, with typical floor

loading requirements of 1,500–2,500 kg per square meter for ML clusters, compared to 500–1,000 kg per square meter for traditional server installations. This structural requirement is often overlooked during facility planning and can be a blocking constraint for retrofitting existing buildings.

The physical layout of the data center hall reflects these density constraints. The extreme power density of ML training racks necessitates rigid hot aisle/cold aisle containment in air-cooled sections, where cold air is forced into the enclosed front of the rack and waste heat is captured immediately at the rear exhaust. The “spine” of the hall – the central cable corridor connecting all racks to the aggregation switches – must accommodate thousands of fiber optic cables and power feeds. Overhead cable trays are preferred over under-floor routing to improve airflow and accessibility, carrying the heavy copper power feeds and fragile fiber interconnects that form the nervous system of the cluster. The layout must also accommodate the liquid cooling infrastructure: CDU placement, coolant piping runs, and isolation valves that allow individual racks to be serviced without draining the entire cooling loop. These physical layout decisions, made during facility design, constrain the network topology options available to the training team years later.

Training a 175B model on this cluster requires $6 \times 175 \times 10^9 \times 300 \times 10^9$ total floating-point operations (assuming 300 billion training tokens). At 45 percent MFU – a strong but achievable figure for well-tuned large-model training – the cluster sustains $8,192 \times 1979 \times 10^{12} \times 0.45$ FLOP/s, or about 7.30 EFLOP/s, yielding a physics-limit training time of approximately 12 hours.

In practice, communication overhead, pipeline bubbles, checkpoint I/O, hardware failures, and maintenance windows compound to extend the actual wall-clock time beyond the physics limit. A simplified multiplier chain reaches an approximately 18-hour system minimum; production schedules can stretch to days or weeks once queueing, data readiness, debugging, reruns, and site-specific operational margins enter the plan. The central theme is unchanged: at pod scale, infrastructure imperfections dominate over the raw capability of the silicon. Recovering this lost time is the central challenge of distributed systems engineering, and the solutions span hardware (better networks), software (overlapped communication), and operations (proactive maintenance to minimize downtime).

Napkin Math 2.6: Training time for 175B

We can derive the training time for our 175B model from first principles.

1. **Total FLOPs:** Using the approximation $6 \times P \times D$, where $P = 175 \times 10^9$ and $D = 300 \times 10^9$ tokens: 3.15×10^{23} FLOPs
2. **Cluster throughput:** 8,192 H100 GPUs at 1979 TFLOP/s peak, operating at 45 percent MFU: $8,192 \times 1979 \times 10^{12} \times 0.45$ FLOP/s sustained ≈ 7.30 EFLOP/s
3. **Idealized Training Time** (the “physics limit”): $(3.15 \times 10^{23} \text{ FLOPs}) / (8,192 \times 1979 \times 10^{12} \times 0.45 \text{ FLOP/s}) \div 3600 \approx 12.0$ hours
4. **Real-world multipliers:**
 - Communication overhead (scaling efficiency ≈ 0.85): $\div 0.85 \rightarrow 14.1$ hours
 - Pipeline bubbles ($\approx 5\%$): $\times 1.05 \rightarrow 14.8$ hours
 - Checkpoint overhead ($\approx 3\%$): $\times 1.03 \rightarrow 15.3$ hours
 - Hardware failures and restarts ($\approx 10\%$ of wall time): $\times 1.10 \rightarrow 16.8$ hours
 - Maintenance windows ($\approx 5\%$): $\times 1.05 \rightarrow 17.6$ hours

Total: 17.6 hours in this simplified system-minimum chain, or 0.1 weeks when expressed in weeks. Real production calendars may still stretch to days or weeks after queueing, debugging, reruns, and site-specific operational margins are included. Recovering this lost time is the domain of distributed systems engineering – the subject of Chapter 5.

At this scale, the unit of analysis is no longer a rack or pod of independent servers; the facility has to behave as one coherent machine.

Definition 2.7: Warehouse-scale computer (WSC)

Warehouse-Scale Computer (WSC) is a building-scale computing system in which thousands of servers are operated as a single coherent machine (with the network fabric serving as the system bus, distributed storage as the disk subsystem, and a cluster orchestrator as the operating system), enabling training workloads that would be physically impossible on any single machine.

1. **Significance:** A WSC of 10000 H100 GPUs delivers approximately 9.89 EFLOP/s FP16 peak (and ~19.8 EFLOP/s at FP8), enabling 175B-class training workloads at scales impossible on a single node. However, the system is only as fast as its bisection bandwidth: non-blocking InfiniBand at 50 GB/s per GPU provides 500 TB/s aggregate injection bandwidth; if the fabric is 4:1 oversubscribed, effective bisection bandwidth drops to 125 TB/s, potentially bottlenecking AllReduce and dropping training throughput by 30–60 percent.
2. **Distinction:** Unlike a general-purpose compute cluster (which runs many independent jobs on separate nodes with no requirement for tight coupling), a WSC training cluster operates as a single synchronous instrument in which every node must participate in every AllReduce, making the failure or slowdown of a single node a cluster-wide performance event.
3. **Common pitfall:** A frequent misconception is that WSC design is primarily software engineering or IT operations. WSC design is building-level computer architecture: the physical layout (rack placement to minimize inter-rack hops), power delivery chain (PUE targets, liquid cooling manifolds), and network topology must be co-designed as a unified system: a mistake at any layer propagates through all layers.

The concept was formalized by Luiz Andre Barroso, Urs Holzle, and Parthasarathy Ranganathan at Google in *The Datacenter as a Computer* (Barroso et al. 2019). The key insight is that at Google’s scale, *the data center is the computer*, and traditional computer architecture principles must be applied at the building level rather than the chip level.

2.6.1 WSC architecture principles

The concept of the Warehouse-Scale Computer, articulated by Barroso, Holzle, and Ranganathan at Google, reframes the data center from a *room full of computers* to a *single computer that happens to fill a room* (Barroso et al. 2019). This reframing has profound implications for physical design.

In a traditional data center, each server is an independent unit with its own operating system, storage, and network identity. The facility simply provides power, cooling, and physical security. Servers can be added, removed, or replaced independently, and the workloads running on different servers are unrelated to each other.

In a WSC, the individual server is analogous to a core in a multicore processor: it has no independent utility and exists only as part of the larger system. A DGX H100 node running in isolation cannot train a 175B model; it becomes useful only when connected to hundreds of other nodes through a carefully designed network fabric, with a distributed storage system providing training data and checkpoint storage, and a fleet orchestrator coordinating the work across all nodes.

Two physical consequences follow directly from this reframing. The first is that the network, not the compute, sets the ceiling: within a single node NVLink supplies enough bandwidth for tensor parallelism, but across nodes the fabric must carry gradient tensors, activation checkpoints, and pipeline stage outputs, so a building-scale machine is only as fast as the wires that bind its cores. Chapter 3 develops that fabric in full; here it is enough to note that the WSC reframing makes the interconnect a first-class architectural component rather than a peripheral.

The second consequence is that *failure is a physical certainty, not an exceptional event*. A single GPU has a mean time between failures (MTBF) of approximately 50,000 hours (the canonical GPU MTTF anchor `Systems.Reliability.Gpu.mttf_hours` used in Chapter 7), but reliability degrades linearly with component count: a cluster of 10,000 such GPUs experiences a failure roughly once every five hours. Section E.1.2 derives why the fleet-level rate is simply the per-component lifetime divided

by the component count. This is a building-level property of the physical machine, and it is why a WSC must be designed from the start so that individual component failures degrade rather than halt the running workload, with dual-path power feeds, redundant switch fabrics, and persistent checkpoint storage at every level.

The third consequence is that the building blocks combine differently depending on the workload they must carry. A pod is not assembled from a single canonical part list; the interconnect, the switching, and the memory placement are each chosen against the communication and capacity pattern the dominant workload imposes. Table 2.12 contrasts three production pods to make the point: an NVIDIA SuperPOD wires GPUs through an InfiniBand fat-tree for any-to-any flexibility, a Google TPU pod hard-wires chips into a torus for dataflow throughput, and Meta’s Grand Teton arranges the same class of accelerators around embedding memory rather than raw compute.

Table 2.12: Pod Architecture by Workload: Each pod’s interconnect, switching, and memory emphasis reflects the communication and capacity pattern of its dominant workload, not a single best design. The economics that decide which workload an organization optimizes for are taken up in section 12.3.

System	NVIDIA SuperPOD	Google TPU Pod	Meta Grand Teton
Interconnect	InfiniBand Fat-Tree	3D Torus ICI	RoCE (RDMA over Ethernet)
Switching	External Switches	Direct Chip-to-Chip	Leaf/Spine Ethernet
Topology	Any-to-any	Nearest-Neighbor Mesh	Hierarchical Rail
Optimization	Flexibility	Dataflow Throughput	Embedding Memory
Dominant Workload	Diverse Research	LLM Training	Recommendation

Grand Teton is the clearest case of memory placement, not compute, driving the layout. Meta’s recommendation and ranking models use embedding tables that can reach terabytes, far exceeding the HBM capacity of any single accelerator, while the dense neural-network layers that operate on those embeddings are comparatively small. The design splits the two across the memory hierarchy: the terabyte-scale embedding tables reside in host CPU DRAM (roughly \$3–5/GB), and the dense layers execute on GPUs, where the compute density justifies the \$10–15/GB cost of HBM. The embedding lookups are memory-capacity-bound but not bandwidth-bound: each request touches only a small slice of a vast table, so cheap, high-capacity DRAM is the right home for them, and the expensive accelerator memory is reserved for the work that saturates it. The systems lesson is that optimal infrastructure is workload-specific, not specification-maximizing: deploying compute-optimized nodes for a memory-capacity-bound workload would strand most of the accelerator’s throughput on a problem its silicon was never the bottleneck for.

How the fleet then operates within those physical limits, how it detects degradation, sizes its checkpoint cadence against the failure rate, schedules jobs across the fabric, and how it is sited, priced, and procured, is taken up where the fleet is operated and paid for: section 12.3 for siting, build-vs-buy, and capacity planning, section 12.6 for fleet telemetry and gray-failure detection, Chapter 8 for gang scheduling and topology-aware placement, and section 7.1.2 for the checkpoint-interval trade-off. The physical building blocks are now in place; the operating discipline builds on top of them.

These physical constraints define warehouse-scale computer design. New technologies do not remove the walls; they move them. The technologies below matter because they change where the memory, communication, or power constraint binds.

2.7 Infrastructure Technologies That Move the Walls

A new data center will host three or four generations of accelerators over its 15-year structural lifetime, so future-facing technologies matter only when they change a durable planning constraint. The useful test is not whether a technology is novel, but which wall it moves, what new wall appears after the move, and which fleet-design decision changes as a result. Compute Express Link (CXL) moves the memory-capacity boundary. Wafer-scale integration moves the chip-to-chip communication boundary. Advanced packaging moves the die boundary inside the accelerator package. None of them repeals the physics of data movement; each relocates the place where infrastructure teams must spend power, cooling, cost, and software complexity.

2.7.1 Compute express link (CXL)

¹⁴ | **CXL (Compute Express Link):** An open standard (CXL Consortium, founded by Intel in 2019) that adds cache-coherent memory semantics atop the PCIe physical layer through CXL.io, CXL.cache, and CXL.mem. CXL 3.0 extends the model toward memory pooling, allowing capacity to be shared through a fabric rather than fixed permanently inside one server chassis.

An important node-architecture technology is **Compute Express Link (CXL)**¹⁴, a cache-coherent interconnect built on the PCIe physical layer that enables CPUs, accelerators, and memory expansion devices to share a coherent address space. Its value is not that it makes remote memory fast. Its value is that it makes capacity less rigid. Instead of treating each node's host DRAM as a fixed local pool and each accelerator's HBM as an isolated high-speed island, a CXL fabric can expose memory expanders or pooled memory to the devices that need capacity at a particular phase of the training step.

For ML training, the natural target is cold or phase-local state rather than the active matrix-multiply working set. The Adam optimizer state for our 175B model occupies 1,400 GB, and it is touched during parameter updates rather than streamed through every Tensor Core operation. A shared CXL pool could therefore reduce per-node memory pressure by holding optimizer shards, embedding-table spillover, or local data-cache buffers outside the accelerator HBM tier. The training framework still has to schedule this state carefully, but the placement problem becomes less binary than "fits in this node" or "spills to storage."

The new wall is bandwidth. A representative CXL memory path over PCIe Gen5 x16 provides 64 GB/s, while H100 HBM provides 3.35 TB/s. That 52× gap means weights and activations for the forward and backward passes still belong in HBM. CXL is a capacity tier, not an HBM replacement. The fleet-design implication is concrete: planners should ask whether server platforms, rack layouts, and orchestration software can absorb CXL memory pooling, not whether CXL removes the need for high-bandwidth accelerator memory.

2.7.2 Wafer-scale integration

At the opposite extreme from CXL sits the wafer-scale engine introduced in section 2.2.1, which collapses the cluster onto a single die and makes on-chip bandwidth nearly free. The architecture and yield mechanics were covered there; what matters for infrastructure planning is the wall it moves. By putting the working set on the wafer, the chip-to-chip communication wall largely disappears, but a new wall takes its place: capacity and injection bandwidth.

Our 175B running model needs 350 GB for FP16 weights alone, far beyond the 44 GB of on-wafer SRAM. Cerebras addresses this through weight streaming: external MemoryX units feed weights to the wafer over a 1.2 TB/s path while the wafer executes each layer, decoupling model capacity from the on-wafer memory. That can be a good match for inference and for workloads whose computation stages cleanly, but training reintroduces harder scheduling questions because activations, gradients, and optimizer updates must be coordinated across forward and backward passes. The wafer trades the communication wall for a streaming-bandwidth wall.

The lesson for infrastructure planners is not that wafer-scale systems replace GPU fleets. It is that memory proximity and memory capacity trade against each other. WSE-style designs buy extraordinary local bandwidth by putting the working set near the arithmetic, while CXL buys flexible capacity by moving memory farther away. HBM sits between those extremes: off-chip but on-package, smaller than host memory but fast enough for the active computation. The right architecture is the one whose memory tier matches the workload's reuse pattern.

2.7.3 Advanced packaging

Underpinning both directions is the evolution of **advanced packaging**. Packaging moves the boundary inside the accelerator package rather than all the way out to the rack or all the way in to a single wafer, and it matters because the reticle limit is only about 858 mm² for a single exposure. **2.5D interposers**, such as TSMC's CoWoS, mount compute dies and HBM stacks on a shared silicon substrate, allowing chiplet-based accelerators to behave like a single device for most software. **3D stacking**, with approaches such as SoIC, places SRAM caches or logic directly above one another and shortens data paths further. The H100-to-B200 transition shows the fleet consequence: the package can deliver far more local arithmetic and die-to-die bandwidth, but the rack must absorb higher power density, tighter cooling requirements, and less tolerance for power transients before the silicon advantage becomes useful infrastructure.

The common theme is relocation rather than elimination. CXL moves capacity outward into a fabric and leaves bandwidth as the limiting discipline. Wafer-scale integration moves communication

inward and leaves capacity and yield as the limiting disciplines. Advanced packaging compresses die-to-die distance and leaves power density as the limiting discipline. Infrastructure planning therefore still begins by identifying where the next byte moves, how quickly it must arrive, and what physical system must be built so that movement does not dominate the workload.

2.8 Fallacies and Pitfalls

Because the bottlenecks move rather than disappear, the same planning mistakes recur: teams optimize the visible specification and miss the binding constraint. Compute infrastructure mistakes usually come from optimizing the visible specification while ignoring the binding physical constraint. The fallacies below translate the chapter's node, rack, pod, and facility lessons into operational warnings.

Fallacy: *More GPUs always means faster training.*

Engineers frequently assume that training time scales linearly with GPU count: doubling the GPUs should halve the training time. In practice, communication overhead grows with cluster size and eventually dominates.

Amdahl's Law establishes the theoretical limit: the sequential fraction of the computation (gradient synchronization, pipeline bubble time, data loading stalls) bounds the maximum speedup regardless of parallelism. For a 175B-parameter model with 350 GB of gradients, the AllReduce at each training step requires every GPU to exchange data with every other GPU.

On a cluster of 1,024 GPUs, this synchronization can consume 30–50 percent of the total step time if the network is not carefully engineered. Scaling from 1,024 to 2,048 GPUs doubles the hardware cost but may reduce training time by only 30–40 percent, yielding rapidly diminishing returns. The scaling efficiency curve is concave: the first 100 GPUs provide nearly linear speedup, the next 900 provide diminishing returns, and beyond 2,000–4,000 GPUs the marginal benefit per GPU approaches zero for most model sizes.

The correct approach is to profile useful compute time, exposed communication time, and idle time at the current scale before buying the next pod. If the added GPUs mostly increase exposed communication, procurement is buying idle time rather than training progress. Section 5.4.1 later turns this local ratio into a scaling-efficiency estimate before committing to procurement.

Pitfall: *Planning training throughput from peak FLOP/s alone.*

Procurement teams often select accelerators by comparing peak FLOP/s specifications. This reasoning ignores the Roofline Model's central insight: if the workload's arithmetic intensity falls below the ridge point, memory bandwidth, not compute, limits performance. The H100's ridge point is approximately 295.2 FLOP/byte. LLM inference operates at 1–2 FLOP/byte, achieving less than 1 percent of peak FLOP/s. Even LLM training, which benefits from batching, typically achieves 30–50 percent of peak FLOP/s due to memory-bound attention kernels, activation recomputation, and communication stalls. Selecting hardware by peak FLOP/s alone is analogous to selecting a car by top speed while ignoring fuel efficiency for a daily commute.

Fallacy: *Power and cooling constraints can be handled after accelerator purchase.*

Teams plan GPU purchases based on compute requirements without verifying that the target facility can deliver the required power and cooling. These are hard physical limits with long lead times.

A single rack of four DGX H100 systems requires 33.5 kW of power. Upgrading a data center's electrical infrastructure (new transformers, switchgear, and UPS capacity) requires 12–18 months of lead time. Cooling plant upgrades (chillers, piping, pumps) require 6–12 months. Even seemingly simple changes, such as upgrading the PDU in a single rack from 20 kW to 60 kW, can require new cabling and circuit breaker panels.

Organizations that order hardware without confirming facility readiness risk having millions of dollars of GPUs sitting in shipping containers in the parking lot while the building is retrofitted. This scenario is not hypothetical: several organizations experienced exactly this situation during the 2023–2024 GPU rush, when GPU delivery times shortened faster than data center construction timelines.

Pitfall: *Buying a newer accelerator without checking the workload's arithmetic intensity.*

A team deploys B200 GPUs (4,500 TFLOP/s FP8 peak) for an inference workload serving a 7B-parameter model at batch size 1. The arithmetic intensity is approximately 1 FLOP/byte, placing the workload deep in the memory-bound region.

The B200's memory bandwidth (8 TB/s) is only $2.4\times$ higher than the H100's (3.35 TB/s), so this batch-1 workload tracks bandwidth rather than headline compute. If the headline comparison is B200 FP8 against H100 FP16/BF16-class throughput, the compute peak is about $4.6\times$ higher but decode still improves by only about $2.4\times$. The team paid for compute they cannot use. An H100 with its lower cost per unit of memory bandwidth would have been a more cost-effective choice for this specific workload.

Fallacy: *Air cooling is sufficient for AI workloads.*

Operators of legacy facilities assume air cooling can scale to dense AI racks with enough additional fans and chiller capacity. It cannot. Air physically cannot remove heat fast enough above roughly 30 kW per rack; dense AI racks can consume 60 to 120 kW, and Blackwell-class rack designs push past 130 kW. Attempting to air-cool such a cluster leads to thermal throttling, sustained clock reductions, and ultimately component failure—not a performance penalty but a hardware liability. Liquid cooling is not an optimization for these clusters; it is a thermodynamic requirement that the rack-density choice forces independently of any TCO analysis.

Fallacy: *All GPU-hours are equivalent in TCO analysis.*

A common error in cost comparisons is to treat one GPU-hour on an H100 as interchangeable with one GPU-hour on an A100 or V100. In reality, the effective cost per unit of useful computation varies enormously across GPU generations: newer accelerators deliver far more useful throughput per dollar. An H100 GPU-hour delivers $6.3\times$ the TFLOP/s of an A100 GPU-hour and $15.8\times$ the TFLOP/s of a V100 GPU-hour. A training run that takes 10,000 V100 GPU-hours would require only approximately 632 H100 GPU-hours to complete the same amount of computation. The relevant metric is not cost per GPU-hour but cost per useful TFLOP-hour, which accounts for both the price per hour and the effective throughput delivered. Organizations that benchmark cloud options by GPU-hour cost alone systematically overestimate the expense of newer, more efficient hardware.

Pitfall: *Upgrading the network before identifying the training bottleneck.*

Teams sometimes invest heavily in upgrading their network fabric (from 200 Gb/s to 400 Gb/s InfiniBand, for example) expecting a proportional improvement in training speed. The improvement depends entirely on whether the training loop is communication-bound at the current network bandwidth. If the compute time per training step is 20 seconds and the communication time is 2 seconds, the workload is compute bound: doubling the network speed reduces total step time from 22 to 21 seconds, a mere 4.5 percent improvement. The same investment in additional GPUs (reducing compute time) or higher-MFU software optimization (reducing wasted compute) would yield far greater returns. The Roofline Model applies to the cluster as a whole, not just to individual chips: diagnose whether the bottleneck is compute or communication before investing in either.

Fallacy: *Average power draw is sufficient for cooling design.*

Accelerator power draw varies dynamically between communication phases (lower power) and compute phases (higher power, at or near TDP). The average power draw across a training step is typically 70–85 percent of TDP. Teams that design their cooling infrastructure for this average, rather than for the TDP-level peak, discover that chip temperatures spike during compute phases, triggering thermal throttling that reduces sustained throughput. The cooling system must be sized for the worst-case thermal load (all GPUs at TDP simultaneously), even though this peak is sustained for only a fraction of each training step. The penalty for undersized cooling is insidious: the system appears to function normally (no crashes, no errors), but MFU quietly degrades by 10–20 percent because the GPUs are throttling their clock frequency to stay within thermal limits.

Pitfall: *Selecting models by HBM capacity without checking bandwidth.*

Procurement teams sometimes focus exclusively on whether a model's weights “fit” in the available HBM, neglecting the bandwidth dimension. A model that fits in HBM but cannot be served at acceptable latency due to insufficient bandwidth is just as unusable as a model that does not fit. Consider two scenarios for serving a 70-billion-parameter model: (a) an accelerator with 192 GB of HBM2e at 2.04 TB/s bandwidth, and (b) an accelerator with 80 GB of HBM3 at 3.35 TB/s bandwidth. Option (a) has more than enough capacity (the model requires only 141 GB in FP16) but delivers tokens at $141\text{ GB}/2.04\text{ TB/s} = 69.2\text{ ms per token}$. Option (b) requires careful quantization to fit (141

GB in FP16 would not fit in 80 GB, but 71 GB in INT8 does) but delivers tokens at 71 GB/3.35 TB/s = 21 ms per token, which is 3.3× faster. For latency-sensitive serving, option (b) is the better choice despite its smaller capacity. The right accelerator is the one whose bandwidth and capacity jointly satisfy the workload’s requirements.

Fallacy: *Data loading can be fixed after deployment.*

Teams that focus all their predeployment optimization on GPU kernel performance and communication efficiency sometimes discover, postdeployment, that their GPUs are starved for data. The data loading pipeline (storage I/O, preprocessing, host-to-GPU transfer) must sustain a throughput equal to or greater than the GPU cluster’s consumption rate. For language model training, the raw data ingestion rate is modest (megabytes per second), but the preprocessing pipeline (tokenization, sequence packing, shuffling) can become a CPU bottleneck when each GPU consumes data faster than a single CPU core can prepare it. The fix is straightforward but must be planned in advance: allocate sufficient CPU cores for data loading workers (typically 4-8 per GPU), stage training data on fast local NVMe storage rather than relying on shared network filesystems, and pipeline the data loading to overlap with GPU computation.

Pitfall: *Buying homogeneous clusters without modeling workload diversity.*

The intuition that uniform hardware simplifies scheduling and reduces stragglers often leads organizations to retire capable older generations prematurely. For our 175B model, the cost-optimal strategy frequently involves a mixed-generation fleet. While training requires the raw FLOP/s and interconnect bandwidth of H100s to minimize synchronization overhead, inference serving is memory-bandwidth-bound rather than compute-bound.

An A100 offers 2.04 TB/s of bandwidth at a significantly lower capital expenditure than the H100’s 3.35 TB/s. By dedicating H100 nodes to training and A100 nodes to inference, an organization can reduce TCO by 15–25 percent compared to an all-H100 fleet. The fallacy lies in conflating *job-level* homogeneity – which is critical to prevent stragglers within a single distributed training run – with *cluster-level* homogeneity. A sophisticated scheduler can effectively manage a heterogeneous fleet, routing bandwidth-intensive inference jobs to older hardware where the bandwidth-per-dollar ratio is competitive, while reserving peak compute nodes for training throughput.

Fallacy: *The last mile is a minor installation detail.*

Engineering teams often allocate 90 percent of their planning effort to hardware selection and facility design, assuming that racking and stacking is a deterministic commodity task. In reality, the last mile – physically installing servers, routing cables, filling coolant loops, and running burn-in tests – frequently delays production availability by 2–4 months. A cluster for our 175B model involves thousands of cables; a single loose InfiniBand connection or a pinched fiber optic cable can degrade effective bisection bandwidth by 50 percent, stalling distributed training. Insidious issues like firmware incompatibilities between GPU driver versions and InfiniBand switch firmware, or NUMA misconfigurations in the BIOS, often manifest only under sustained load. Experienced infrastructure teams allocate 15–20 percent of the total project timeline specifically for commissioning and burn-in, running synthetic stress tests (NCCL-tests, HPL benchmarks) for weeks to weed out “infant mortality” failures before a single production job is scheduled.

Pitfall: *Treating commissioning and burn-in as schedule slack.*

Commissioning is part of the system build, not a buffer that can be consumed when hardware delivery slips. Burn-in tests, cable validation, firmware qualification, thermal soak, and NCCL stress runs are the first time the node, rack, network, and facility layers operate as one machine. Compressing that phase turns installation defects into production failures, where each debugging cycle idles the full fleet rather than a small acceptance-test window.

2.9 Summary

The physical infrastructure of machine learning spans from the transistor to the data center, with the running example of training a 175B-parameter model grounding each concept in quantitative reality. The chapter’s central lesson is a constraint cascade: accelerator power determines rack cooling, rack density determines pod layout, pod topology determines scaling efficiency, and scaling efficiency determines whether the economics make sense.

That cascade begins at the accelerator. Matrix multiplication workloads demanded Tensor Cores and systolic arrays; weight streaming exposed the memory wall and drove HBM; model states that

exceeded single-chip capacity required multi-accelerator nodes and NVLink. It continues beyond the server, where synchronous training creates power transients, rack densities above 100 kW force liquid cooling, and pod-scale communication determines whether more GPUs accelerate training or simply wait on the network.

Two analytical themes organize those details. The generality tax recurs at every level: accelerators trade control flexibility for arithmetic throughput, networks trade any-to-any flexibility for workload-specific efficiency, and cooling systems trade general-purpose air handling for liquid loops that match dense racks. The Roofline Model introduced in section 2.3.2 supplies the common diagnostic task: identifying whether useful work at each boundary is limited by compute or by data movement.

The resulting hierarchy mirrors the classical memory hierarchy at warehouse scale. HBM is fast and small, NVLink is fast within a node, InfiniBand is slower across nodes, and distributed storage is slowest but largest. The bandwidth hierarchy introduced in section 2.4.1 therefore dictates the parallelism hierarchy: tensor parallelism maps to NVLink, pipeline parallelism maps to rack-local fabrics, and data parallelism spans the full pod. Software parameters such as precision, checkpoint interval, batch size, and gradient accumulation are not independent knobs; they are responses to those physical limits.

Our 175B-parameter model has served as the persistent architectural forcing function connecting every layer of this hierarchy. At the accelerator level, processing a single token requires about 350 billion floating-point operations, yet the arithmetic is not the limiting resource on Tensor Cores. At the memory level, the 350 GB FP16 weight tensor exceeds a single accelerator's HBM capacity and saturates HBM bandwidth once it is sharded or compressed for serving; streaming these weights at 3.35 TB/s creates a bandwidth-floor latency of over 100 ms per token for one accelerator-equivalent HBM path. Moving to the node level, the full training state – comprising weights, gradients, optimizer states, and activations – expands beyond 2 TB, shattering the 80 GB limit of individual chips and requiring tensor parallelism, data-parallel sharding, and memory offload. At the rack level, the thermal density of 32 such accelerators drawing 700 W each, plus host CPUs, memory, and networking overhead, necessitates 33.5 kW of power delivery and liquid cooling infrastructure. At the pod level, training within a viable two-week window requires synchronizing over 1,000 GPUs across a non-blocking InfiniBand fabric, where the statistical certainty of hardware failure forces a checkpointing strategy that trades compute cycles for reliability. At the economics level, bursty cloud rental can beat ownership, while owned clusters become compelling only when sustained utilization is high enough to amortize hardware, power, cooling, and facility risk. Every constraint in this chapter – from the width of the HBM bus to the topology of the data center network – traces back to the single arithmetic fact that this model does not fit on a single chip.

The practical method transfers beyond this particular model. Identify the binding constraint at each level, quantify its effect, and propagate the consequence upward through the stack. Selecting the fastest accelerator is counterproductive if the cooling infrastructure cannot remove its heat. Building the densest rack is futile if the power grid cannot supply its demand. Deploying the widest network is wasteful if the workload's communication pattern does not use the bandwidth. Infrastructure engineering is therefore systems engineering in its purest form: a quantitative discipline for reasoning about how chip-level choices alter rack power, facility cooling, network topology, reliability strategy, and total cost of ownership.

Key Takeaways: The data center is the computer

- **The generality tax:** Accelerators achieve 10–100× higher throughput than CPUs by dedicating silicon area to matrix arithmetic rather than branch prediction and out-of-order execution. The trade-off is reduced flexibility. Each step along the spectrum from GPU to TPU to custom ASIC reclaims more die area for arithmetic.
- **Memory wall diagnosis starts with roofline:** For single-request LLM inference, memory bandwidth determines latency because arithmetic completes in microseconds while data transfer takes milliseconds. The ridge point ($I_{\text{ridge}} = \text{peak FLOP/s divided by memory BW}$) separates memory-bound LLM decode ($I \approx 1$) from compute-bound training ($I > 2,000$).

- **Bandwidth hierarchy dictates parallelism:** The $9\times$ per-direction bandwidth cliff between NVLink and InfiniBand confines tensor parallelism to within a node and data parallelism to across nodes. Pipeline parallelism spans nodes when model depth exceeds a single node's capacity.
- **Peak vs. sustained:** Model FLOPs Utilization (MFU) of 40–50 percent is considered good for large-scale training. Capacity planning must use sustained throughput, not peak specifications.
- **Facility efficiency is part of the computer:** Liquid cooling can deliver 90–95 percent of facility power to computation, compared to 50–65 percent for air-cooled facilities. At pod scale, network topology, cooling architecture, and power delivery must be co-designed for the dominant workload.
- **Failure at scale:** A 10,000-GPU cluster experiences roughly one GPU failure every five hours. Checkpointing strategy is a first-order performance concern that must be designed into the system from the start.
- **Lifetime cost beats purchase price:** Ownership cost includes electricity, facility construction, networking, and staffing, not just the purchase price, so owning infrastructure pays off only above a utilization threshold that hardware price alone never reveals. Section 12.3 works the build-vs-buy breakeven and the full fleet cost where the fleet is operated and paid for.

For most of computing history, the computer was the chip. This chapter marks where that stops being true. Once a model no longer fits on a single accelerator, a single fact propagates upward through every layer: the chip sets the node's power, the node sets the rack's heat, the rack sets the pod's topology, and the topology sets whether the economics close. No layer can be tuned in isolation, because each inherits its limits from the one beneath it. At this scale the unit of computation is no longer the *processor* but the *building*, which is why the rest of this volume treats the data center, not the GPU, as the machine being engineered.

What's Next: From silicon to wires

We have mapped physical infrastructure from Tensor Core transistors to megawatt data-center substations. A fleet of disconnected nodes, however, is not yet a computer; it is a warehouse of expensive accelerators. The network fabric turns those nodes into a unified training system by carrying gradients, activations, and checkpoints between them. The chapter repeatedly exposed the same constraint: communication bandwidth limits scaling efficiency. The bandwidth hierarchy showed a $9\times$ cliff between NVLink and InfiniBand, and the topology examples showed that fabric design can change AllReduce time by $2\text{--}3\times$. Chapter 3 examines the physics, protocols, collectives, and topology decisions that determine whether a 10,000-GPU cluster behaves like one coherent machine or thousands of isolated devices.

Research Questions: For further inquiry

- Given a target workload, how should a team decide whether the next dollar should buy FLOP/s, HBM bandwidth, network capacity, or facility power?
- How can the same model require different accelerator choices for training and inference?
- What makes the data center, rather than the accelerator, the relevant unit of computation?
- When is specialization worth the loss of flexibility across accelerators, ASICs, wafer-scale systems, CXL, and advanced packaging?

Purpose

Why does the network connecting accelerators matter more than the accelerators themselves at scale?

A single accelerator can perform trillions of operations per second, but distributed training requires those operations to coordinate across thousands of devices. Every synchronization point, whether gradient averaging, activation exchange, or parameter update, depends on network bandwidth and latency. When network capacity cannot keep pace with accelerator throughput, accelerators sit idle waiting for data to arrive, and adding more accelerators makes the problem worse rather than better. At sufficient scale, network design dominates system performance: the topology determines which communication patterns are efficient, the bandwidth determines how large models can be partitioned, and the latency determines how tightly coupled training can be. Organizations that treat networking as an afterthought discover that their expensive accelerators deliver a fraction of theoretical performance because the network became the bottleneck nobody planned for. In C^3 terms, the fabric is where the communication tax is levied: its topology and bandwidth set how tightly communication bounds compute across the fleet.

Learning Objectives

- Model network communication cost using the α - β framework and identify bandwidth-dominated vs. latency-dominated regimes
- Compare high-performance transport protocols by latency, lossless guarantees, and operational complexity
- Analyze network topologies (fat-tree, rail-optimized, dragonfly) by computing $BW_{\text{bisection}}$ and hop count for ML collective patterns
- Evaluate congestion-control mechanisms and their impact on tail latency during distributed training
- Design network virtualization strategies for multi-tenant GPU clusters using device sharing and traffic isolation
- Diagnose network performance bottlenecks using RDMA counters, link-level telemetry, and bandwidth testing tools

3.1 The Synchronization Backbone

One slow link stalls every peer that waits on it.

CONSIDER a 175-billion-parameter language model partitioned across 1,024 GPUs, where dense accelerator nodes are no longer useful unless they synchronize as one machine. Each training step requires an AllReduce of 350 GB of gradient data, meaning every GPU must send and receive its share before the next step can begin. If even one link in the fabric is slow, all 1023 other GPUs wait. The network fabric is not auxiliary infrastructure; it is the synchronization backbone that determines whether this cluster trains efficiently or wastes millions of dollars in idle compute. The 350 GB figure follows from the model-size and gradient-volume assumptions used throughout the fleet examples.

In the fleet stack shown in figure 1.13, the fabric turns isolated accelerator nodes into a coherent training system. Accelerators, power delivery, cooling, racks, and pods define what each node can compute in isolation; the fabric determines whether the nodes can act together before communication cost overwhelms computation. Figure 3.1 organizes that design space into five co-dependent levels, from physical signaling to cluster-scale orchestration. The acronyms in the figure are a roadmap: each mechanism is defined when it becomes the binding constraint.

At scale, communication cost can dominate computation cost. The fleet law in equation 1.3 makes this explicit: the nonoverlapped communication term $T_{\text{comm}}(N) - T_{\text{overlap}}$ determines how much of each training step is exposed to the network fabric. The fabric constrains every layer above it in the stack by determining whether communication can be overlapped, which collective algorithms are viable, and how network partitions interact with node failures.

The physical network fabric exists to carry three fundamental collective communication patterns:

- **AllReduce:** An AllReduce¹ sums gradients across thousands of GPUs so that every device holds the identical average, forming the heartbeat of synchronous training.
- **AllGather:** An AllGather² collects different model portions so that every GPU can reconstruct the full model state.
- **AllToAll:** An AllToAll, the most demanding pattern, requires every GPU to send unique data to every other GPU, a requirement critical to expert parallelism³.

Chapter 6 covers the *algorithms* that orchestrate these patterns; the fabric layer supplies the *physics* of the wires and switches that carry them. The distinction matters because the fabric's physical properties (bandwidth, latency, and topology) determine which patterns are efficient and which become bottlenecks.

Systems Perspective 3.1: The network as a gradient bus

In a single machine, the memory bus moves data between the processor and memory. In a distributed training cluster, the network fabric serves the analogous role: it is the **Gradient Bus**

¹ | **AllReduce:** A collective operation that sums data from all nodes and distributes the result back to all nodes. Chapter 6 develops the mathematical cost models for ring and tree-based AllReduce implementations.

² | **Collective Primitives:** Higher-level communication patterns involving groups of nodes. While Chapter 6 derives the algorithms for AllGather, ReduceScatter, and AllToAll, this chapter addresses the physical fabric requirements ($BW_{\text{bisection}}$, switch radix) that enable them at scale.

³ | **Mixture-of-Experts (MoE):** An architecture that activates only a subset of model “experts” per input, necessitating AllToAll communication. Section 10.5.4 examines how MoE decouples model capacity from per-token compute cost (O).

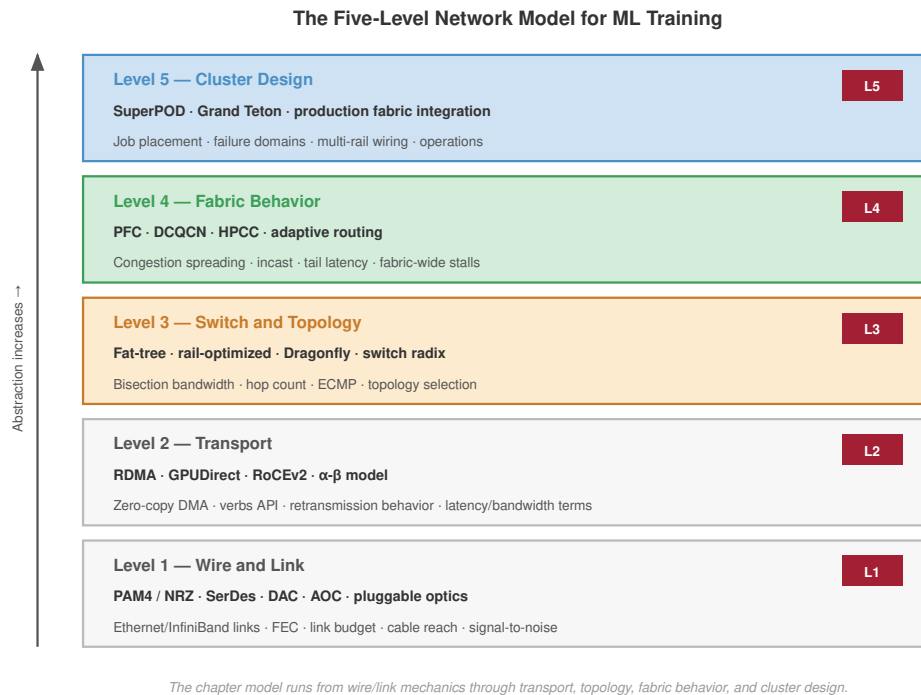

Figure 3.1: The Five-Level Network Model for ML Training: Five layered levels span from the physical wire to cluster-scale design. Level 1, Wire and Link: PAM4/NRZ signaling, SerDes, DAC, AOC, pluggable optics, Ethernet and InfiniBand link layers. Level 2, Transport: RDMA, GPUDirect, RoCEv2, zero-copy DMA, and the α - β communication model. Level 3, Switch and Topology: fat-tree, rail-optimized, Dragonfly, adaptive routing. Level 4, Fabric Behavior: PFC, DCQCN, HPCC congestion control, adaptive routing, incast handling. Level 5, Cluster Design: NVIDIA SuperPOD, Meta Grand Teton, and other production fabric integrations.

that moves parameter updates between workers. Just as the memory wall in section 2.3 limits single-device throughput, network fabric bandwidth determines multi-device throughput (the communication wall). Protocols, topologies, congestion control, and collective-routing choices all determine how close that bus comes to its physical limits.

The concrete bandwidth cliff that separates intra-node from inter-node communication makes this gradient bus analogy precise. Chapter 2 established that a single H100 delivers 989 TFLOP/s of FP16 throughput with 3.35 TB/s of memory bandwidth. Within a node, eight such accelerators communicate through NVLink at 900 GB/s of aggregate bidirectional bandwidth. The moment computation crosses a node boundary, however, the available per-direction bandwidth drops by a factor of 9 $\times$, from 450 GB/s of NVLink (one direction of that bidirectional link) to 50 GB/s (NDR InfiniBand per port). This cliff, the transition from intra-node to inter-node communication, is the central challenge of network fabric design. Section C.2 collects the canonical NVLink and InfiniBand bandwidth specifications and the 1K-GPU cluster reference configuration that anchor these figures. For our 175B model, moving 350 GB of gradients through 50 GB/s links means that the AllReduce alone can take seconds, during which every GPU in the cluster sits idle unless the fabric and collective algorithms can overlap that transfer with computation. Figure 3.2 makes this hierarchy concrete by plotting the bandwidth at each level across four GPU generations.

Figure 3.2: The Bandwidth Hierarchy: Bandwidth at four levels of the communication hierarchy across four GPU generations, on a logarithmic scale. While HBM and NVLink bandwidth have grown roughly $9\times$ and $6\times$ respectively from V100 to B200, InfiniBand has grown only $4\times$. The annotations show the ratio of NVLink bidirectional-total bandwidth to one InfiniBand port, quantifying the cliff that distributed training must cross at every synchronization point; on a like-with-like per-direction basis the H100-to-NDR cliff is about half that, roughly $9\times$ (see text).

Figure 3.2 reveals that this cliff is not an artifact of one accelerator generation. Its annotations compare NVLink’s bidirectional-total bandwidth against one InfiniBand port, so they read larger (about $19\times$ for the H100 generation) than the like-with-like cliff. On a per-direction basis, crossing from the local NVLink domain to one InfiniBand port reduces bandwidth by roughly $9\times$, despite absolute bandwidth improvements at every tier. The persistent cliff reflects fundamental physics: on-package interconnects (NVLink) operate over millimeters of copper, while inter-node links (InfiniBand) span meters of cable and must traverse switches. The ratio determines which parallelism strategies are efficient. Tensor parallelism, which requires continuous high-bandwidth exchange of activations, is viable within a node but impractical across nodes. Pipeline and data parallelism, which tolerate lower inter-node bandwidth, must carry the burden of cross-node communication. Every topology and protocol decision in this chapter attempts to minimize the impact of this hierarchy on collective communication performance.

The ratio becomes visible during a single training step. Figure 3.3 uses a normalized timeline: the compute phases are held fixed at 100 ms, and the AllReduce block represents a small gradient shard chosen to make the intra-node and inter-node contrast visible. It is not the full 175B-parameter gradient exchange; it isolates how crossing the node boundary changes utilization.

The 12.5 percentage-point utilization gap represents millions of dollars in wasted compute over a months-long training run. Network fabric design is therefore the central engineering challenge of distributed training, not an afterthought.

3.2 How ML Networking Inverts Data-Center Assumptions

A network architect from the world of large-scale web services would find the traffic patterns of a distributed training cluster counter-intuitive. Traditional data-center traffic is characterized by a vast number of small, independent, and asynchronous flows. Millions of users accessing a web service generate a stochastic traffic pattern that is well-served by standard Transmission Control Protocol/Internet Protocol (TCP/IP) and statistically multiplexed, oversubscribed networks.

ML training workloads are the complete opposite: synchronous, periodic, and dominated by a small number of massive, collective communication operations. This ML networking inversion re-

Figure 3.3: The Bandwidth Cliff in a Training Step: Illustrative normalized timelines for the same compute phases: an 8-GPU intra-node job (top) using NVLink at 900 GB/s, and a 64-GPU inter-node job (bottom) using InfiniBand at 50 GB/s. The AllReduce phase (red) grows from a thin sliver to a dominant fraction of the step. Without communication–computation overlap, GPUs sit idle during the entire AllReduce, and the utilization gap between the two scenarios is 12.5 percentage points (99.5 percent versus 87 percent).

verses the core assumptions of traditional network design. Table 3.1 shows the practical consequence: the fabric is optimized for global synchronization time, not average per-flow throughput.

Table 3.1: ML Networking Inverts Traditional Data-Center Assumptions: Where web services require fairness for millions of independent flows, ML training requires a globally synchronized, lossless fabric optimized for a handful of massive collective operations.

Workload Pattern	Traditional Data-Center Assumption	ML Reality
Traffic Pattern	Asynchronous, stochastic, many-to-many	Synchronous, periodic collectives
Flow Type	Millions of small, short-lived flows	A few massive, long-lived “elephant” flows
Performance Metric	Average throughput, per-flow fairness	Tail latency, global synchronization time
Loss Tolerance	Tolerant (TCP retransmits)	Intolerant (one dropped packet stalls all)
Congestion	Localized, independent events	Global, correlated (incast)

As table 3.1 summarizes, the synchronicity inversion is the most fundamental. Web traffic is asynchronous; one user’s slow connection does not affect another’s. The Bulk Synchronous Parallel (BSP)⁴ model governs distributed training: all 1,024 GPUs in a training job must complete their gradient exchange before any of them can proceed to the next step. The slowest link therefore dictates the performance of the entire cluster. A single congested switch port that delays one GPU’s packets by 100 ms effectively wastes 100 ms of compute time for all 1,024 GPUs. *Tail latency is not an outlier; it is the bottleneck.*

The flow inversion compounds this problem. Traditional networks are designed for fairness among millions of “mice flows”⁵, yet ML training is dominated by a few “elephant flows” corresponding to the gradient AllReduce. A single AllReduce on a 175B parameter model can involve exchanging 350 GB of data. Standard flow control and routing mechanisms like Equal-Cost Multi-Path (ECMP), which hash each flow onto one of several equal-cost paths, are poorly suited to this traffic pattern. A static hash cannot subdivide one elephant flow across all available links, and it can inadvertently map multiple elephant flows to the same link, creating massive congestion while other links sit idle.

The loss inversion completes the picture. TCP/IP was designed for unreliable networks and handles packet loss gracefully through retransmission. RDMA-based protocols used in ML clusters (InfiniBand, RoCE) assume a lossless fabric. A single dropped packet can trigger Go-Back-N recovery, which restarts transmission from the missing packet rather than only repairing the one lost frame, and can stall the sender for milliseconds, creating a catastrophic straggler that delays the entire synchronous training step. ML fabrics must therefore be engineered for zero packet loss. InfiniBand uses credit-based flow control; Ethernet-based RoCE deployments use carefully tuned Priority Flow Control (PFC), a link-layer backpressure mechanism that pauses senders before buffers overflow and therefore depends on sufficient switch buffering.

These inversions explain *why* running large-scale distributed training over a standard enterprise Ethernet network is inefficient or impossible. The network fabric for ML is a distributed, high-performance “bus” for collective communication, designed from the ground up for the unique physics of synchronous, large-scale parallelism.

3.2.1 The five-level model

Each of these inversions traces back to a specific physical or protocol constraint. A **Five-Level Model** specific to high-performance interconnects makes these constraints concrete:

⁴ **BSP (Bulk Synchronous Parallel):** Proposed by Valiant (1990) as a bridging model between parallel hardware and software. Synchronous data-parallel training has the same barrier shape: workers compute local gradients, exchange them, and update from a shared step boundary, making tail latency a binding throughput constraint (Coyak et al. 2017; Sivasubramanian 2020). Here, “mice” are many short flows and “elephants” are rare massive flows that dominate bandwidth. In ML clusters, one AllReduce elephant flow can carry 350 GB, and ECMP’s static hash cannot subdivide it across every available path.

determine whether that throughput survives real collective traffic (Alizadeh et al. 2010; Zhu et al. 2015; Li et al. 2019; Gangidi et al. 2024).

- **Level 5: Cluster Design** (section 3.7). Production supercomputers like the NVIDIA SuperPOD and Meta Grand Teton integrate these layers into a unified Gradient Bus (NVIDIA 2023; Meta Engineering 2024).

The levels are not an inventory of networking topics; they are the causal chain that turns synchronous ML traffic into infrastructure requirements. Large gradient messages first stress the wire and transport, then force topology choices that preserve bisection bandwidth, then expose congestion behavior that ordinary enterprise networks can hide, and finally determine whether the whole cluster behaves like one training machine.

The remainder of this chapter ascends this stack, starting from the copper and glass at the bottom. Having reached the top rung, the chapter then turns to the operational layers that surround the fabric in production: sharing it across tenants, observing it under load, and evolving it as the underlying technology moves the ceiling.

3.3 Level 1: Wire and Link

Before analyzing protocols and topologies, we must understand the physical medium. Every network design decision is ultimately constrained by *what* the wire can carry. At 400 Gb/s and beyond, the physics of signal transmission imposes hard limits on cable length, power consumption, and error rates. These are not engineering inconveniences; they are fundamental constraints that shape cluster geometry.

3.3.1 Signal integrity and PAM4

Definition 3.1: PAM4 signaling

PAM4 Signaling is an electrical modulation scheme used in high-speed ML cluster fabrics that encodes two bits per symbol period with four distinct voltage levels, doubling the data rate achievable over a given physical medium without requiring a higher symbol rate.

1. **Significance:** PAM4 enables 400 Gb/s and 800 Gb/s link speeds that sustain the BW required for large-scale gradient synchronization. However, the reduced gap between voltage levels increases susceptibility to noise, requiring Forward Error Correction (FEC), typically Reed-Solomon RS(544,514), that adds about 100 ns of host-FEC processing latency per link in common high-speed Ethernet discussions (Anslow 2016; Yin et al. 2022). Across a three-tier fat-tree (three hops each way), FEC alone can contribute hundreds of nanoseconds of fixed latency to every packet, setting a hard floor on the fabric's fixed per-message startup latency, the quantity that section 3.4.4 formalizes as the α term of the communication cost model.
2. **Distinction:** Unlike NRZ (Non-Return-to-Zero) binary signaling, which uses only two voltage levels and offers better noise margin but is limited to half the data rate per lane, PAM4 trades signal-to-noise ratio for bandwidth density—the same copper trace carries twice the data at the cost of requiring FEC at every port.
3. **Common pitfall:** A frequent misconception is that doubling bits per symbol is a free throughput gain. PAM4 links require FEC at both endpoints, making them fundamentally higher-latency than equivalent NRZ links; latency-sensitive collectives like AllReduce pay this FEC tax on every packet regardless of message size.

To achieve 400 Gb/s, we *cannot* simply toggle a voltage on and off faster. Signal attenuation in copper and chromatic dispersion in fiber impose a hard ceiling on the **symbol rate** (the number of signal transitions per second). High-speed links overcome this by using PAM4 to pack more information into each transition.

However, the gap between adjacent voltage levels in PAM4 shrinks by a factor of three compared to NRZ, making the link highly susceptible to noise. Consequently, high-speed links operate near the

physical limits of reliable detection and require **Forward Error Correction (FEC)** at the physical layer, commonly using Reed-Solomon RS(544,514)-family codes in high-speed Ethernet designs (Anslow 2016; Ethernet Alliance 2025). FEC processing is an implementation-dependent latency term; IEEE 802.3df operator material treats roughly 100 ns of host KP4 FEC and hundreds of nanoseconds of end-to-end module latency as meaningful at AI/HPC fabric timescales (Yin et al. 2022). For our 175B model training, which generates 350 GB of gradient traffic per step across 1,024 GPUs, this latency floor is nonnegotiable. A packet crossing three switch hops in a fat-tree incurs a scenario budget of 300 ns–600 ns of one-way FEC decoding and encoding latency, or 600 ns–1200 ns over a three-hop path in each direction. This “physics tax” sets a hard floor on the fabric’s fixed startup latency, formalized in section 3.4.4 as the α term, limiting the speed of latency-sensitive collectives like AllReduce regardless of software optimizations. Figure 3.4 shows the signaling trade-off directly: PAM4 doubles the bits per symbol relative to NRZ, but the smaller voltage gaps reduce noise margin and make FEC part of the link’s latency floor.

Figure 3.4: Signaling Evolution: NRZ vs. PAM4: To increase bandwidth without doubling clock frequency, high-speed interconnects moved from NRZ (2 voltage levels, 1 bit per symbol) to PAM4 (4 voltage levels, 2 bits per symbol). The trade-off is reduced noise margin: the ‘eye’ of the signal is smaller, necessitating Forward Error Correction (FEC) and increasing the irreducible α latency of the fabric.

3.3.2 Reach and medium: Copper vs. optics

The choice of physical medium determines how far a link can reach before latency, power, and cost reshape the cluster geometry. Table 3.2 compares the recurring cable and optics options by the attributes that decide where each one belongs.

Table 3.2: Cable and Optics Placement Trade-Offs: Common interconnect media occupy different reach, latency, and cost points, so cluster designers use copper inside racks and optics as distance begins to dominate placement.

Medium	Reach	Cost profile	Latency impact	Typical placement
DAC (Direct Attach Copper)	~3 meters	Lowest cost (~\$50) and no optical module power	Lowest media latency; passive copper avoids optical conversion	Within a rack

Medium	Reach	Cost profile	Latency impact	Typical placement
AOC (Active Optical Cable)	3 to 30 meters	Higher cost (~\$500) from permanently attached transceivers	Electrical/optical conversion plus Forward Error Correction (FEC) adds hundreds of nanoseconds	Rack-to-rack or row-scale links
Pluggable optics	More than 30 meters	Highest module and power cost, but replaceable optics and fiber cords	Optical conversion and FEC add latency; distance enables topology reach	Network core and pod-scale links

⁶ | **FEC (Forward Error Correction)**: At 400G and 800G speeds, signal integrity is fragile enough that Ethernet PHY designs rely on FEC to reconstruct corrupted bits (Anslow 2016; Ethernet Alliance 2025). The exact latency depends on the PHY and module architecture; for ML fabric modeling, treating FEC as a per-hop latency budget is the conservative point, because a multi-hop path accumulates that budget before software can hide it.

For optical links, Forward Error Correction (FEC)⁶ is part of the latency budget that makes reach a topology decision rather than a simple cable choice. The comparison in table 3.2 is the cluster-geometry trade-off in miniature: copper is cheap and low latency but keeps accelerators close together, optical interconnects extend a row or pod at higher power and latency, and pluggable optics reaches the core only when the topology needs distance more than it needs minimum per-hop cost.

🔍 Systems Perspective 3.2: The cost of distance

In an ML fleet, distance is money. A 10,000 GPUs cluster requires ~20,000 optical links at the spine layer alone. At \$500 each with 20 W per pluggable link, that represents \$10 million in cabling and 400 kW of continuous power for transceivers alone. The cost dictates **cluster geometry**: architects pack accelerators as densely as possible (70–100 kW per rack) to maximize cheap copper and minimize expensive optics.

3.3.3 SerDes, link budget, and power

Every port depends on a **Serializer/Deserializer (SerDes)** circuit that converts parallel data from the switch ASIC into a serial stream. As bandwidth scales, these circuits have become the dominant power consumer in the network fabric. Consider the energy implications for our cluster of 1,024 GPUs: maintaining full BW_{bisect} for the 350 GB of gradient traffic requires roughly 3,000 high-speed links. If each 400 Gb/s port consumes 25 W (combined SerDes and optical transceiver power), the interconnect alone draws 75 kW continuously—10.5 percent of the cluster’s power budget dedicated merely to moving bits, not computing on them.

The **link budget**, a strict decibel (dB) allowance for signal attenuation, governs the reach of these links. As signals traverse copper, they lose energy to skin effect and dielectric absorption. The link budget is the difference between the transmitter’s output power and the receiver’s sensitivity limit. For a standard 50G PAM4 lane, the budget might be 30 dB. If a 3-meter DAC cable introduces 18 dB of loss and the connectors add another 2 dB, 10 dB of margin remains. However, as frequency doubles to support 100G lanes (for 800 Gb/s ports), the loss per meter increases sharply. The physics forces a brutal trade-off: to maintain signal integrity without exceeding the power budget, cable reach must decrease. Copper links operating at 800 Gb/s are limited to roughly 1–2 meters, physically constraining the diameter of a compute rack and forcing the use of expensive, power-hungry optics for any connection leaving the cabinet. In 1.6 Tb/s-class planning scenarios, SerDes and optical power can account for a large fraction of cluster energy, making power-per-bit a primary scaling constraint. The wire sets hard limits on reach and speed; the transport layer must build a reliable communication primitive on top of these physical links.

3.4 Level 2: Transport and the Performance Model

Large-scale training requires sustained, synchronized bulk transfers. A single AllReduce operation across 1,024 accelerators may move terabytes of gradient data. This pattern demands networks optimized for Remote Direct Memory Access (RDMA) to eliminate CPU overhead and **lossless delivery** to ensure predictable performance.

3.4.1 RDMA and GPUDirect

Definition 3.2: Remote direct memory access (RDMA)

Remote Direct Memory Access (RDMA) is a networking technology used in ML training fabrics that allows one machine to read or write the memory of another machine directly, bypassing the operating system kernel and CPU of both endpoints by offloading transport processing to the network interface card.

1. **Significance:** RDMA reduces end-to-end message latency from the 50–100 μs typical of kernel TCP to approximately 1–2 μs , cutting the L_{lat} term in the iron law by 25–50 $\times$. For a 175B-parameter model exchanging 350 GB of gradient data across 1,024 GPUs, RDMA also eliminates 700 GB of redundant memory copies per step by allowing the NIC to read GPU memory directly without staging through host RAM (GPUDirect RDMA).
2. **Distinction:** Unlike traditional TCP/IP, where the CPU processes every packet through the kernel network stack (consuming tens of CPU cores to saturate a 400 Gb/s link), RDMA offloads the entire transport to dedicated NIC hardware, freeing the CPU to orchestrate computation rather than move data.
3. **Common pitfall:** A frequent misconception is that RDMA works reliably on any Ethernet network. RDMA lacks TCP's retransmission logic; a single dropped packet can stall an entire 1,024-GPU AllReduce for 100–500 ms as the Go-Back-N recovery retransmits from the loss point. RDMA requires a lossless fabric—InfiniBand or Ethernet with Priority Flow Control—to operate correctly at scale.

Standard TCP/IP is architecturally unfit for the 400 Gb/s era. The protocol stack was designed when network speeds were orders of magnitude slower than CPU memory bandwidth, but at these line rates that relationship has inverted. Processing a 400 Gb/s stream through the Linux kernel imposes a crushing interrupt tax: copying payload data between user space and kernel buffers can consume the entire memory bandwidth of a dual-socket server, requiring tens of CPU cores merely to keep the pipe full. The result is a CPU wall where the host processor becomes the bottleneck for network traffic, starving the application logic it is meant to serve.

RDMA bypasses this entire layer. By offloading the transport logic to the NIC hardware, it allows applications to read and write directly to remote memory. For ML, GPUDirect RDMA⁷ extends this zero-copy principle to the accelerators themselves (NVIDIA 2026a). Without GPUDirect, a gradient update follows a tortuous path: GPU memory $\rightarrow$ CPU system RAM $\rightarrow$ kernel buffer $\rightarrow$ NIC. GPUDirect short-circuits this to a single PCIe transaction: GPU $\rightarrow$ NIC, as figure 3.5 contrasts. For our 175B model's 350 GB gradient exchange, the optimization eliminates 700 GB of redundant memory copies across the cluster per step, reducing latency and freeing the CPU to orchestrate complex pipelining logic rather than acting as a data mover.

3.4.2 InfiniBand and RoCE

GPU clusters commonly choose between two RDMA transport stacks, and the decision is a reliability-versus-operations trade-off. Table 3.3 compares where each stack places the burden of losslessness and congestion control.

Table 3.3: RDMA Transport Stack Trade-Offs: InfiniBand and RoCE expose RDMA semantics through different operational contracts, one built around native losslessness and the other around Ethernet compatibility.

Stack	Fabric behavior	Operational burden	Typical fit
InfiniBand (IB)	Purpose-built HPC switched fabric (InfiniBand Trade Association 2000) with credit-based flow control, so losslessness is native at the link layer	Subnet Manager (SM) and Virtual Lanes (VLs) govern routing and traffic isolation	Dedicated training clusters where predictable tail latency outweighs Ethernet ecosystem flexibility

⁷ | **GPUDirect RDMA:** Introduced by NVIDIA for Kepler-class GPUs and CUDA 5.0, GPUDirect RDMA enables a direct PCIe path between GPU memory and third-party peer devices such as network interfaces (NVIDIA 2026a). Before GPUDirect, every gradient transfer had to stage through host memory, consuming CPU memory bandwidth that competes with data loading. Eliminating this bounce path is one reason overlapping communication with backward-pass computation is feasible at scale.

Stack	Fabric behavior	Operational burden	Typical fit
RoCE (RDMA over Converged Ethernet)	RoCEv2 carries RDMA semantics by encapsulating InfiniBand transport headers in UDP/IP packets	Priority Flow Control (PFC), ECN, and workload-aware routing or admission control must approximate InfiniBand's native losslessness (Guo et al. 2016; Gangidi et al. 2024)	Multi-vendor Ethernet fleets that can absorb more congestion-control tuning

8 | **InfiniBand:** Formed in 1999 from the merger of two competing server I/O standards (Future I/O and NGIO), InfiniBand was originally designed to replace PCI as a general-purpose system interconnect. Its pivot to HPC networking preserved the credit-based, hardware-managed flow control that server I/O demanded—and this heritage is precisely why InfiniBand provides native losslessness without the PFC fragility that plagues Ethernet-based RDMA fabrics.

The InfiniBand⁸ row reflects a protocol heritage that favors hardware-managed losslessness over Ethernet compatibility.

This stack choice is visible at the protocol boundary. Figure 3.6 compares the two stacks, showing how RDMA-based protocols expose a user-space **Verbs API** that bypasses the kernel's traditional TCP/IP stack.

3.4.3 Losslessness and the go-back-n problem

The critical takeaway from figure 3.6 is that the Verbs API provides a uniform programming model, but the reliability guarantees beneath it differ fundamentally: InfiniBand enforces losslessness in hardware, while RoCE must construct it from Ethernet's best-effort foundations using PFC and ECN. ML collectives assume in-order, lossless delivery, but the hardware implementation of this reliability introduces a critical fragility. TCP handles packet loss gracefully via Selective Acknowledgement, retransmitting only the specific missing segment. RDMA protocols like RoCEv2, by contrast, typically rely on simpler recovery paths such as **Go-Back-N** retransmission when rare packet drops occur (Gangidi et al. 2024). The NIC's physical constraints drive this choice: implementing complex reassembly logic for out-of-order packets requires substantial on-chip SRAM, which consumes precious die area needed for SerDes blocks and packet processing engines. The NIC hardware is optimized for throughput, not state management.

The trade-off is a severe penalty upon failure. If a network switch drops a single packet 900 MB into a 1 GB gradient transfer, the receiver discards all subsequent packets, forcing the sender to retransmit the entire tail of the message, potentially 100 MB of data for a single missed frame. At 400 Gb/s, this retransmission triggers a latency spike orders of magnitude larger than the wire delay. In a synchronous training loop where thousands of GPUs wait for the slowest member, a single dropped packet idles the entire cluster. The network fabric must therefore behave as a lossless medium, pushing the complexity of flow control into the switches via Priority Flow Control (PFC) to ensure buffers never overflow.

Checkpoint 3.1: Protocol selection

Consider a 2,048-GPU training cluster that will run both large language model training (gradient messages of several gigabytes) and reinforcement learning (frequent small control messages).

- ☐ **Protocol fit:** Recommend a protocol and justify the choice for both the large gradient messages and the frequent small control messages.
- ☐ **RoCE requirements:** Specify the additional infrastructure RoCE needs compared to InfiniBand.
- ☐ **Shared fabric:** Reevaluate the protocol choice when the cluster also serves inference traffic to external users over the same physical network.

3.4.4 The α - β performance model

Protocol choice determines whether the fabric can behave as a lossless medium; performance modeling then asks how fast that medium can carry a given message. The α - β model decomposes message transfer time as $T(n) = \alpha + n/\beta$, where α is the fixed startup latency and β is the sustained bandwidth (Hockney 1994). Section D.1 develops the full derivation and works the model through concrete message regimes, separating latency-dominated from bandwidth-dominated transfers; section 6.2.1 later applies the same decomposition to collective algorithms. Topology choice directly

Figure 3.5: GPUDirect RDMA Data Path: Comparison of traditional vs. GPUDirect data paths. Traditional RDMA (top) requires data to be copied to host RAM before transfer to the NIC. GPUDirect RDMA (bottom) enables the NIC to access GPU memory directly via the PCIe bus, eliminating redundant copies and reducing latency for bulk gradient transfers.

shifts both parameters: a fat-tree minimizes α by providing short equal-cost paths, while a ring amplifies α with cluster size because messages traverse a hop count that grows with the number of participants N .

The model reveals two regimes that lead to different engineering responses. For messages with $n < \alpha\beta$, startup cost α dominates the transfer time; small control messages and pipeline bubbles fall in this latency-bound region. For messages with $n > \alpha\beta$, the n/β term dominates; gradient AllReduce falls in this bandwidth-bound region.

For NDR InfiniBand with $\alpha \approx 1.5 \mu\text{s}$ and $\beta \approx 50 \text{ GB/s}$, the crossover point $n^* = \alpha \cdot \beta \approx 75 \text{ KB}$. Messages smaller than this gain little from more bandwidth; messages larger than this gain little from lower latency. That crossover separates two fundamentally different optimization strategies: reducing hop count to lower α , or adding link bandwidth to raise β . Applying the model to the concrete message sizes that our 175B training job generates on every iteration makes this distinction actionable.

Napkin Math 3.1: The alpha-beta crossover

Problem: A fabric designer is comparing InfiniBand NDR (1.5 μs , 50 GB/s) against a slower Ethernet baseline (5 μs , 12.5 GB/s). For a 4 KB control message and a 350 MB gradient shard, which part of $T(n) = \alpha + n/\beta$ dominates, and why does the faster fabric help for different reasons in each regime?

Math: Apply $T(n) = \alpha + n/\beta$ for a 4 KB control message and a 350 MB gradient shard.

1. Small message (4 KB):

- InfiniBand: $1.5 \mu\text{s} + 4\text{KB}/50\text{GB/s} = 1.5 + 0.08 = \mathbf{1.58\text{s}}$
- Ethernet: $5.0 \mu\text{s} + 4\text{KB}/12.5\text{GB/s} = 5.0 + 0.32 = \mathbf{5.32\text{s}}$
- **Result:** InfiniBand is 3.4 $\times$ faster purely due to lower α .

Figure 3.6: Traditional TCP/IP vs. RDMA/RoCE v2 Stacks: Side-by-side comparison. Traditional TCP/IP (left) traverses application, OS kernel (context switch), Socket API, TCP/UDP, IP/Ethernet, and NIC, with latency of 10–20 μ s and 2–3 $\times$ CPU copies. RDMA/RoCE v2 (right) exposes a user-space Verbs API that bypasses the kernel, offloading transport to the RDMA NIC (GPUDirect reads GPU HBM directly), with latency of 1–3 μ s and zero-copy CPU overhead.

2. Large message (350 MB):

- InfiniBand: $T = \alpha + n/\beta = 7.0$ ms
- Ethernet: $T = \alpha + n/\beta = 28.01$ ms
- **Result:** InfiniBand is 4 $\times$ faster purely due to higher β .

Systems insight: For large-scale training, the crossover point ($n^* = \alpha\beta$) is typically around 75 KB. Since gradients are megabytes to gigabytes, we are almost always in the bandwidth-dominated regime. However, pipeline parallelism and distributed coordination rely on small messages in the latency-dominated regime, where wire-speed upgrades provide zero benefit and only topology and hop-count reductions matter.

To see *why* this distinction matters in practice, consider two messages that our 175B model training job sends every iteration. The first is a 4 KB pipeline-scheduling control message that coordinates microbatch handoffs between pipeline stages. Applying the model: $T(n) \approx 1.58$ μ s for the control message. The bandwidth term contributes only 5.1 percent of the total. Doubling the link speed would save a negligible fraction of a microsecond. For this message, the most direct way to reduce transfer time is to reduce the hop count (which lowers α), not to buy faster links.

The second message is a 350 MB gradient shard for one layer’s AllReduce. Now: $T(n) \approx 7.0$ ms. The latency term is invisible. Doubling bandwidth to 100 GB/s would halve this transfer time, a direct and proportional gain. These two cases illustrate *why* network design must address both α and β simultaneously: topology and hop count control the latency-dominated regime, while link speed and path diversity control the bandwidth-dominated regime.

Figure 3.7 makes these two regimes visible across the full range of message sizes. For InfiniBand, the crossover occurs at approximately 75 KB: messages smaller than this are latency-dominated (the flat region on the left), while larger messages are bandwidth-dominated (the linear region on the right). Ethernet RoCE crosses slightly earlier, at about 62.5 KB, because its lower per-link bandwidth makes the transfer term overtake the higher fixed latency at a smaller message size. The $5\times$ latency gap between InfiniBand and Ethernet RoCE dominates for small messages but becomes irrelevant for the multi-megabyte gradient transfers that dominate training communication.

Figure 3.7: The α - β Crossover: Transfer time as a function of message size for InfiniBand NDR and Ethernet RoCE. Small messages are latency-dominated (flat region), while large messages are bandwidth-dominated (linear region). The crossover point marks where investing in bandwidth begins to pay off more than reducing latency.

Beyond classifying individual transfers, the same model identifies when communication overtakes computation. The α - β analysis above focused on the transfer time of individual messages across a single link, treating the network as a point-to-point channel. In a data-parallel training loop, however, the relevant question is whether the collective AllReduce across the full cluster finishes before the next compute step is ready to begin. When the gradient vector grows large enough, the aggregate transfer time for a ring AllReduce exceeds the per-step computation time, and the network becomes the pacing constraint for the entire training job.

Napkin Math 3.2: AllReduce bottleneck threshold

Problem: When does Ring AllReduce become the bottleneck for a 1024-GPU H100 cluster training models at GPT-2 scale and beyond?

Setup: The baseline cluster trains a GPT-2-scale model with 1.5 billion parameters (6 GB of FP32 gradients). Each GPU computes at 989 TFLOP/s FP16/BF16 peak. The network uses NDR InfiniBand ($\alpha = 1.5 \mu\text{s}$ and $\beta = 50 \text{ GB/s}$ per link).

Step 1: Compute time per iteration. Assume each GPU processes a synthetic microbatch requiring 5.00×10^{13} FLOPs, chosen to produce a compute phase of about 101 ms for this bottleneck example. At 989 TFLOP/s with 50 percent utilization:

$$T_{\text{compute}} = 101.1 \text{ ms}$$

Step 2: Communication time for Ring AllReduce. With $N = 1024$ and a gradient payload M of about 6 GB:

- Ring cost model: $T_{\text{ring}} \approx \frac{2(N-1)}{N} \frac{M}{\beta} + 2(N-1)\alpha$; Chapter 6 derives the algorithmic steps behind this expression.
- Total Communication: $T_{\text{ring}} \approx 242.8 \text{ ms}$

Step 3: Communication fraction.

$$\text{Comm. fraction} = 70.6\%$$

With overlap between communication and computation (possible because the backward pass produces gradients layer by layer), the effective overhead can be reduced, but the network is already a major contributor to iteration time for this configuration.

At 70 billion parameters (280 GB of gradients), the bandwidth term becomes the bottleneck if per-GPU computation stays similar through batch-size scaling:

$$T_{\text{ring}} \approx 11192.1 \text{ ms}$$

Now communication dominates computation under pure data parallelism. Our 175B model, far larger than this scale, would be even more severely bottlenecked. Models beyond a few billion parameters therefore require tensor and pipeline parallelism to partition the model, rather than relying solely on data parallelism, which must AllReduce the full gradient vector.

The α - β model quantifies the speed of a single link, but our 175B-parameter model requires 1,024 GPUs to work in concert. Scaling these transport primitives from a pair of nodes to a warehouse-scale supercomputer demands a **network topology**: a specific pattern of connections that maximizes $\text{BW}_{\text{bisection}}$ while minimizing the hop count and cabling cost for global collective operations.

3.5 Level 3: Switch and Topology

The physical arrangement of switches determines the bisection bandwidth $\text{BW}_{\text{bisection}}$ and whether the fabric is non-blocking. These two properties govern how well the network supports the global communication patterns that dominate distributed training, a constraint captured by the bisection bandwidth theorem (principle 4).

The first property, bisection bandwidth, quantifies the worst-case throughput ceiling that the topology imposes on global collectives. A cluster can have thousands of fast links at the edge and still starve its AllReduce operations if the cross-sectional capacity at the narrowest point in the switching hierarchy is insufficient.

Definition 3.3: Bisection bandwidth

Bisection Bandwidth is a network topology metric defined as the minimum aggregate link capacity crossing any partition that divides the cluster into two equal halves, representing the worst-case throughput ceiling for all-to-all communication patterns such as AllReduce.

1. **Significance:** Bisection bandwidth $\text{BW}_{\text{bisection}}$ directly sets the cluster-scale bandwidth ceiling for global synchronization. A 1,024 GPUs fat-tree with 400 Gb/s links at 1:1 subscription provides $\text{BW}_{\text{bisection}} = 512 \times 50 \text{ GB/s} = 25.6 \text{ TB/s}$ per direction; a 4:1 oversubscribed spine reduces this to 6.4 TB/s, making each AllReduce step 4× slower and turning the network into the dominant iron law bottleneck rather than the accelerator.
2. **Distinction:** Unlike aggregate bandwidth (the sum of all edge link speeds, which can be high even in a poorly connected topology), $\text{BW}_{\text{bisection}}$ measures global connectivity—a star topology with 1,000 edge links all meeting at one central switch has high aggregate bandwidth but $\text{BW}_{\text{bisection}}$ limited by that switch's backplane capacity.
3. **Common pitfall:** A frequent misconception is that adding more leaf switches always increases $\text{BW}_{\text{bisection}}$. In a three-tier fat-tree, oversubscribing the spine layer (using fewer up-

links than downlinks per pod switch) reduces $BW_{\text{bisection}}$ below the edge-link total regardless of how many leaf switches are present.

For ML training, where all-to-all communication is standard, full $BW_{\text{bisection}}$ is the foundational requirement. A fabric that falls short forces every synchronization step to bottleneck at the narrowest cross-section, and the entire cluster idles while gradients trickle through.

Bisection bandwidth is a metric; the topology property that delivers full $BW_{\text{bisection}}$ under arbitrary traffic patterns is a non-blocking fabric. A non-blocking design guarantees that the uplink capacity at every switch tier matches or exceeds the downlink capacity, so no internal contention reduces the cross-sectional throughput below its theoretical maximum. When a fabric is oversubscribed, the effective $BW_{\text{bisection}}$ drops by the oversubscription ratio, and every global collective slows proportionally. Section B.4.1 shows how to diagnose the regime where communication, rather than computation, becomes the binding constraint, so that an oversubscribed spine can be recognized as a fabric problem before it is mistaken for slow accelerators.

Definition 3.4: Non-blocking fabric

Non-blocking Fabric is an ML cluster network topology in which any permutation of input-output port pairs can communicate simultaneously at full line rate without internal contention, achieved by ensuring that uplink capacity at every switch tier equals or exceeds downlink capacity.

1. **Significance:** In ML fleets, a non-blocking fabric ensures that AllReduce traffic from any accelerator subset does not compete for shared links, preserving the full $BW_{\text{bisection}}$ term for global collectives. A 2:1 oversubscribed spine halves the effective $BW_{\text{bisection}}$, doubling AllReduce time for global gradients and dropping scaling efficiency η_{scaling} accordingly—in a 30 percent-communication workload, this costs roughly 23.1 percent of total cluster throughput.
2. **Distinction:** Unlike oversubscribed fabrics common in web data centers, where upper-tier links are shared among many lower-tier nodes, a non-blocking fabric provides dedicated path capacity for every possible pairing of senders and receivers simultaneously.
3. **Common pitfall:** A frequent misconception is that non-blocking means zero congestion. Endpoint congestion (incast) can still occur if multiple senders simultaneously target the same receiver port, regardless of how much internal fabric capacity is available.

Fat-trees build on Clos-style non-blocking network ideas to provide full $BW_{\text{bisection}}$ (Clos 1953), rail-optimized networks trade some global flexibility for lower cost, and dragonflies reduce cabling while accepting workload-placement constraints (Kim et al. 2008). This trade-off between guaranteed bandwidth and economic scalability drives every topology decision in large-scale ML clusters; the topology comparison later in this section makes that bandwidth-cost trade-off concrete.

3.5.1 Top-of-rack (ToR) and the failure domain

The Top-of-Rack (ToR) switch serves as the fundamental physical aggregation point, defining both bandwidth limits and the minimum **failure domain** for the cluster. In a high-density AI configuration using standard DGX nodes, a single rack typically houses 4 nodes, each containing 8 GPUs, for a total of 32 accelerators. The ToR switch unites these devices but also creates a critical vulnerability: if the ToR fails, it instantly partitions 32 GPUs from the training job, forcing the global scheduler to halt and recover from the last checkpoint.

To mitigate congestion at this edge, network architects maximize the switch **radix**, the number of ports available. A high-radix switch with 64 ports allocates 32 ports downlink to the servers (ensuring full bandwidth for the 32 GPUs) and 32 ports uplink to the spine. This 1:1 subscription ratio guarantees non-blocking performance at the rack level. For our cluster of 1,024 GPUs, the physical topology comprises approximately 32 such racks.

The same rack boundary also shapes recovery. The job scheduler must be topology-aware for performance, while reliable replica placement must keep redundant state and replacement capacity outside the same rack failure domain so that a single lost rack does not take down the entire training run (see section 7.9.2.3).

3.5.2 Fat-tree (Clos) networks

The ToR provides non-blocking bandwidth within a single rack, but connecting 32 racks into a cluster that preserves full BW_{bisect} across every possible communication pair requires a topology that scales cross-sectional capacity with cluster size. The fat-tree (also called a Clos network) achieves this by adding parallel spine switches at each tier, so the aggregate uplink capacity always matches the total edge bandwidth feeding into it. In this vocabulary, leaf switches attach servers or racks, spine switches connect leaves within a pod, and core switches connect multiple pods when a third tier is needed.

Definition 3.5: Fat-tree

Fat-Tree is a hierarchical ML cluster network topology in which the number of parallel paths (and therefore aggregate cross-sectional capacity) increases at each switch tier toward the spine, providing full BW_{bisect} and multiple equal-cost routes between any two nodes (Al-Fares et al. 2008).

1. **Significance:** A k -ary fat-tree built from radix- k switches supports $k^2/2$ hosts in a two-tier (pod) configuration and $k^3/4$ hosts in a three-tier configuration with full BW_{bisect} . With $k = 64$, a two-tier pod supports 2,048 GPUs and a three-tier fabric supports 65,536 hosts. Because every AllReduce can use any available spine path, the fabric sustains simultaneous full-rate communication from all accelerators, meeting the BW_{bisect} requirement for global gradient synchronization.
2. **Distinction:** Unlike a standard tree (where bandwidth at the root is a single bottleneck shared by all leaves), a fat-tree replaces each root with multiple spine switches whose combined uplink capacity matches the total edge bandwidth, eliminating the bottleneck.
3. **Common pitfall:** A frequent misconception is that fat-trees guarantee zero network cost. They require $\mathcal{O}(N \log N)$ switches and dense cabling: a non-blocking three-tier fat-tree at the 4,000-GPU scale needs hundreds of switches and tens of thousands of optical cables, costing \$20–100 million in switching hardware alone.

Leaf, spine, and core tiers provide multiple equal-cost paths instead of a single oversubscribed root, which is how a fat-tree creates that capacity guarantee (figure 3.8).

The fat-tree⁹ is a common default for ML clusters because a non-blocking design can provide full BW_{bisect} , a nonnegotiable requirement for the AllReduce collective, which demands simultaneous, all-to-all communication. The network is constructed in hierarchical tiers: Leaf switches (ToR) connect directly to servers, Spine switches interconnect all leaves within a locality domain known as a pod, and Core switches bind multiple pods together.

A fat-tree built from switches with radix¹⁰ k supports $N_{\text{hosts}} = k^3/4$ hosts at three tiers, and two distinct two-tier framings, which differ only in whether the upper tier is treated as the cluster's edge or as an aggregation layer below a future core. The first framing counts every switch in the two tiers as line-rate capacity for hosts. With radix-64 switches, the fabric spends half of each leaf's ports on hosts and half on spine uplinks, giving $k^2/2 = 2,048$ host ports across the pod. The second framing reserves the upper tier as aggregation that will later uplink to a core layer rather than terminating hosts: each leaf still provides $k/2$ host ports, but the pod now contains only $k/2$ leaves, so it reaches $(k/2)^2 = 1,024$ hosts per pod. The two counts are the same switches accounted differently: whether the upper tier terminates as the cluster spine or as a pod aggregation stage. Either framing comfortably accommodates our 1,024 reference cluster with only leaf and spine layers.

A concrete bisection estimate shows how quickly oversubscription turns into synchronization delay.

⁹ | **Fat-Tree (Clos Network):**

The underlying multi-stage switching theory was invented by Clos (1953) at Bell Labs to minimize the number of electromechanical crosspoints in telephone exchanges. Leiserson (1985) at MIT generalized the concept as the “fat-tree,” where the tree is “fat” because link bandwidth increases toward the root, proving it could emulate any network of equal hardware volume. The same cost-minimization logic that drove 1950s telephony now drives ML cluster design: minimize switch count while guaranteeing non-blocking connectivity for global AllReduce.

¹⁰ | **Switch Radix:**

High-end switches (for example, NVIDIA Quantum-2) can feature a radix of 64 ports, each at 400 Gb/s. This density allows a two-tier fat-tree to support up to 2,048 GPUs with only two switch hops. As model scale pushes toward 100,000 GPUs, increasing switch radix (to 128 or 256), grouping accelerators into larger local domains, or accepting topology constraints are the main ways to avoid adding more tiers and the resulting latency/cost explosion.

Figure 3.8: Non-Blocking Fat-Tree Topology: A three-tier Clos network built from radix- k switches. By ensuring that the number of uplinks at each level matches the number of downlinks, the topology provides full $BW_{\text{bisection}}$ between any two pods. The multiple parallel paths between leaf and spine enable hardware-based adaptive routing to spray packets and avoid congestion.

Napkin Math 3.3: Bisection bandwidth: The cost of oversubscription

Problem: A cluster designer is choosing between a “Non-blocking” (1:1) fat-tree and a “Cost-optimized” (4:1) spine for a cluster of 1024 GPUs. How much slower will a 100 GB-per-GPU AllReduce be on the cheaper network?

Math: Bisection bandwidth ($BW_{\text{bisection}}$) is the minimum pipe diameter between halves of the cluster.

1. **Non-blocking (1:1):** $BW_{\text{bisection}} = 512 \times 50 \text{ GB/s} = 25,600 \text{ GB/s}$ per direction.
 - Time: $51,200 \text{ GB} / 25,600 \text{ GB/s} \approx 2,000 \text{ ms}$.
2. **Oversubscribed (4:1):** $BW_{\text{bisection}} = 25,600 \text{ GB/s}$ divided by 4 = $6,400 \text{ GB/s}$ per direction.
 - Time: $51,200 \text{ GB} / 6,400 \text{ GB/s} \approx 8,000 \text{ ms}$.

Systems insight: Saving money on core switches creates a 4× bottleneck for global synchronization. On a \$300M supercomputer where training is 30 percent communication, that bottleneck wastes approximately \$142.1M in idle compute time, matching the bisection-bottleneck model in section 3.5.2. For training, network oversubscription is a false economy.

This oversubscription calculation turns the topology definition into a design rule: the subscription ratio at each tier determines whether a fat-tree can sustain global collectives.

Checkpoint 3.2: Fat-tree topologies

These questions check whether hierarchical switch-fabric trade-offs are clear:

- ☐ **Radix and scale:** Compute the maximum number of GPUs a Radix-64 two-tier fat-tree can connect without core switches.
- ☐ **Non-blocking ratio:** Explain why a Non-blocking fabric requires a 1:1 subscription ratio at every tier of the network.
- ☐ **Tier vs. latency:** Determine how α (**startup latency**) changes when moving from a two-tier to a three-tier fat-tree.
- ☐ **Aggregate vs. bisection:** Distinguish aggregate bandwidth from $BW_{\text{bisection}}$ and identify the metric that matters for AllReduce.

Scaling beyond this requires a three-tier architecture with core switches, enabling the fabric to reach 65,536 hosts, but the added scale carries both cost and latency. A non-blocking $k = 64$ three-tier tree requires roughly $5k^2/4 \approx 5,120$ switches across the core, aggregation, and edge layers; at \$10,000 to \$50,000 per switch, the switching layer alone represents \$50M to \$250M. Typical **hop counts** also rise from 2 for intra-pod traffic (leaf-spine-leaf) to 4 for inter-pod traffic (leaf-spine-core-spine-leaf), adding serialization delay and switch processing time to the α latency term across thousands of synchronization steps. Rail-optimized topologies respond to both pressures by matching the physical cabling pattern to the collective communication pattern.

3.5.3 Rail-optimized topology

Rail-optimized topology begins from the communication pattern rather than from a generic switch hierarchy. In dense accelerator nodes, GPUs can be grouped by local slot position into rails; figure 3.9 makes that physical cabling pattern concrete.

The wiring pattern connects corresponding GPUs across nodes (GPU 0 to GPU 0, GPU 1 to GPU 1) through dedicated rail switches rather than a shared ToR switch. This matters because data parallelism creates a deterministic and highly stratified communication pattern that standard topologies fail to exploit. When tensor-parallel groups stay inside each node, each replica assigns the corresponding model shard to the same local GPU rank. A rank is the worker or GPU index assigned by the distributed runtime, so GPU 0 on one node synchronizes that shard's gradients with GPU 0 on other nodes, but rarely with GPU 1. A **rail-optimized topology** physically hardwires this logic by isolating these same-rank communication paths into dedicated networks. Instead of connecting all 8 GPUs in a node to a single ToR switch, the network connects all GPU 0s across the entire cluster to a dedicated "Rail 0" switch fabric, all GPU 1s to "Rail 1," and so on. A simple hop-count estimate shows the payoff.

Napkin Math 3.4: The rail-optimized dividend

Problem: A team is synchronizing per-rank data-parallel gradients across 128 nodes. In a standard fat-tree, each message between same-rank GPUs traverses its source leaf switch, a spine switch, and the destination leaf switch (3 switch traversals). In a rail-optimized network, all corresponding GPUs sit on the same rail switch (one traversal). How much "Latency Dividend" does the rail design earn?

Math: Communication latency (α) is proportional to the number of switch traversals.

1. **Standard latency:** $3 \text{ traversals} \times 0.6 \mu\text{s} = 1.8 \mu\text{s}$.
2. **Rail-optimized:** $1 \text{ traversal} \times 0.6 \mu\text{s} = 0.6 \mu\text{s}$.
3. **Result:** $3\times$ lower latency.

Systems insight: For synchronous data-parallel AllReduce (which the training step waits on every iteration), a $3\times$ latency reduction is the difference between 80 percent and 95 percent scaling efficiency. The scaling efficiency bound (principle 8) explains why this matters: physically

Figure 3.9: Rail-Optimized Physical Wiring: In dense accelerator nodes (for example, DGX H100), GPUs are partitioned into ‘Rails’ corresponding to their PCIe slot position. GPU 0 in every node connects to Switch Rail 0, GPU 1 to Switch Rail 1, and so on. This architecture ensures that data-parallel AllReduce traffic—which synchronizes between corresponding GPUs—never competes for BW_{bisect} with other parallel groups, minimizing hop count and congestion for the most latency-sensitive traffic.

aligning the network to the model’s same-rank traffic pattern eliminates the “Spine Tax” for the most bandwidth-hungry communication. Archetype A clusters achieve their performance because they are structured, not merely large.

That same-rank latency dividend is why the rail pattern appears in large LLM training fleets rather than remaining a cabling optimization. Archetype A workloads exploit this structure directly, because 3D parallelism generates traffic patterns that align with the rail wiring.

 **Lighthouse 3.1: Archetype A (GPT-4/Llama-3): The rail-optimized fleet**

Archetype A’s use of 3D parallelism generates two distinct traffic patterns that pull in opposite directions: (1) massive, bandwidth-hungry gradient averaging for data parallelism, and (2) high-frequency, latency-sensitive activation exchanges for tensor parallelism. The rail-optimized design ensures that data-parallel traffic traverses only a single switch hop between nodes, minimizing the latency that would otherwise stall the synchronous training loop.

The engineering consequence of this alignment is measurable at cluster scale. Because each of the 8 GPU ranks in a node communicates only with the same rank on other nodes during data-parallel AllReduce, the rail topology partitions the cluster into 8 independent switch networks that can operate concurrently without contention.

For our cluster of 1,024 GPUs spanning 128 nodes, this creates 8 parallel networks of 128 GPUs each, allowing per-rank data-parallel AllReduce traffic to traverse a single switch hop rather than the multi-hop leaf-spine-leaf path required by a standard fat-tree. The latency benefit is significant for the frequent, bandwidth-hungry gradient exchanges that synchronous data parallelism demands. However, this architecture introduces a sharp trade-off: traffic that must reach GPUs of different ranks (such as expert routing in MoE, or pipeline-stage handoffs that do not align with the rail wiring) requires bridging across rails. Large clusters therefore often employ a hybrid approach, using rail-optimized leaves for same-rank data-parallel traffic while bridging the rails with a full fat-tree spine to support cross-rank communication patterns.

Checkpoint 3.3: Rail-optimized networks

These questions check whether workload-specific network-design trade-offs are clear:

- ☐ **Rail beneficiary:** Identify the dimension of 3D Parallelism (TP, PP, or DP) that benefits most from a Rail-Optimized design.
- ☐ **Switch hops:** Explain why a rail-optimized network reduces the number of switch hops for gradient exchanges compared to a standard fat-tree.
- ☐ **Traffic isolation:** Explain the “Traffic Isolation” benefit of placing all GPU 0s on one rail and all GPU 1s on another.
- ☐ **Core switch need:** Classify the claim as true or false: a rail-optimized network eliminates the need for high-bandwidth core switches connecting different rails.

3.5.4 Dragonfly and torus alternatives

¹¹ | **Dragonfly Topology:** Introduced by John Kim and William Dally at ISCA 2008, the dragonfly uses high-radix routers grouped into fully connected “super-nodes” to reduce global cabling by 52 percent compared to a folded Clos of equivalent scale. The cost savings are real but create a rigid scheduling constraint: any training job that crosses group boundaries hits the oversubscribed global links, making topology-aware placement mandatory rather than optional.

A **Dragonfly**¹¹ topology organizes switches into high-radix groups, where each group functions as a fully connected island. These groups connect to one another via global optical links. The hierarchical structure minimizes the number of expensive long-distance cables required to scale, reducing cabling cost by roughly 50 percent compared to a fat-tree. However, bandwidth within a group is non-blocking (100 percent), while bandwidth between groups is typically only 25–50 percent of the aggregate injection rate. For ML workloads, this oversubscription creates a binary performance cliff based on job placement. A training job that fits entirely within a single dragonfly group sees full line-rate performance; a job spanning multiple groups is throttled by the limited global bandwidth, potentially suffering a 2–4× slowdown. Dragonfly fabrics therefore require topology-aware schedulers that rigidly pack jobs into groups to avoid crossing the oversubscribed global links.

A **Torus** topology connects each node directly to its neighbors in a multidimensional grid, most commonly a 3D torus where every node links to its six adjacent peers (up/down, left/right, front/back). The design offers full local bandwidth with minimal switching hardware, as connections travel only 1–2 hops to reach neighbors. However, global communication requires traversing the diameter of the mesh ($\mathcal{O}(N^{1/3})$ hops), making latency scale poorly with cluster size. Google adopted this architecture for its Tensor Processing Unit (TPU) pods because Transformer training is dominated by data parallelism and pipeline parallelism, both of which use nearest-neighbor communication patterns that map naturally onto the physical grid. The limitation becomes apparent with Mixture-of-Experts (MoE), which relies on AllToAll communication patterns. On a torus, these random permutations congest the limited BW_{bisect} of the mesh, causing performance to degrade by 2–4× compared to a switch-based fat-tree.

The trade-offs between these topologies become stark when quantified for a large-scale deployment. Consider a 4,096-GPU cluster. A non-blocking fat-tree at this scale, built from the $k = 64$ switches assumed throughout this chapter, requires hundreds of switches (two 2,048-GPU pods plus a bridging core layer) and tens of thousands of optical cables to deliver 100 percent BW_{bisect} , enabling any GPU to communicate with any other at full speed. A 3D torus connecting the same nodes might use zero external switches (relying on direct host-to-host links) and only short copper cables, but offers only a fraction of BW_{bisect} (scaling with $N^{2/3}$). The architecture choice follows from workload regularity. Google’s TPU Pods have used torus topologies because their workloads,

primarily transformer training, are predictable and the structured grid efficiently supports collective communication algorithms (ring AllReduce, AllGather, ReduceScatter) that map onto the 3D mesh. General-purpose GPU clusters often favor fat-trees because their workloads are more diverse, ranging from recommendation systems to graph neural networks, and rely heavily on global AllReduce patterns that require the full $BW_{\text{bisection}}$ only a tree can provide. A torus saves millions in switch costs but rigidly constrains the software; a fat-tree costs more but provides the universality needed for general-purpose AI research.

Figure 3.10 quantifies the bandwidth and cost differences between these common families. The Butterfly bar represents a multistage low-diameter switching network: it uses fewer stages than a full fat-tree, but its structured paths offer less bisection bandwidth for arbitrary ML collectives.

Figure 3.10: Network Topologies for ML: Bandwidth vs. Cost: Bar chart comparing $BW_{\text{bisection}}$ (TB/s, left axis) and cost per Gb/s (right axis) for five topologies on a 1,024-GPU cluster: Fat-tree (25.6 TB/s, \$3.0/Gb/s), Dragonfly (20.0, \$4.0), Torus 3D (8.0, \$1.5), Rail-opt (12.8, \$2.0), Butterfly (6.4, \$5.0). Fat-tree provides full $BW_{\text{bisection}}$ but at $2\times$ the cost of Torus 3D per Gb/s.

Bisection analysis alone assumes a single workload type. In practice, clusters serve multiple workloads with different communication patterns, and topology selection must balance their competing demands.

Checkpoint 3.4: Topology selection for your workload

The choice of network topology dictates the upper bound of training efficiency. Warm up by matching each single-workload pattern to its ideal topology, then design a fabric that must serve several at once.

Single-workload picks

- ☐ **AllReduce bandwidth:** Select the topology that maximizes $BW_{\text{bisection}}$ for a standard data-parallel job dominated by AllReduce.
- ☐ **MoE traffic:** Select the topology that minimizes hop count while maintaining congestion control for a Mixture-of-Experts model with AllToAll-dominant, bursty, sparse communication.

- **Mesh locality:** Select the topology that offers the best locality for a 2D mesh computation by mapping physical neighbor links directly to hardware.

Designing for a mixed cluster

You are designing the network for a new ML cluster that will run two primary workloads: (1) training a 175B-parameter language model using 3D parallelism (tensor, pipeline, and data parallelism), and (2) serving a Mixture-of-Experts model that relies heavily on AllToAll communication to route tokens to the correct experts.

- **Training topology:** Select the topology (fat-tree, rail-optimized, or hybrid) that best matches tensor parallelism within groups of 8 GPUs and data parallelism across all nodes, then justify the choice.
- **MoE topology:** Revise the topology choice for unpredictable AllToAll traffic where any GPU may need to communicate with any other GPU.
- **Oversubscription risk:** Identify which workload suffers more under 2:1 spine-layer oversubscription and propose a scheduling strategy to mitigate the impact.

Topology provides the structural capacity for our cluster of 1,024 GPUs to communicate, but structure alone does not guarantee performance. When all 1,024 GPUs simultaneously inject 350 GB of gradient traffic into the fabric, that theoretical capacity collides with the reality of **Fabric Behavior**: congestion control and routing dynamics determine whether this traffic flows smoothly or gridlocks under the strict synchronization of the BSP model.

3.6 Level 4: Fabric Behavior (Congestion, Routing)

Real fabrics deviate from theoretical full $BW_{\text{bisection}}$ due to congestion, and the impact of this congestion is qualitatively different in ML clusters than in general-purpose networks. The BSP barrier introduced earlier is what makes the difference: web traffic is stochastic and asynchronous, so one user's 50 ms delay does not penalize the thousands of others, but under BSP the slowest flow in the fabric dictates the iteration time for the entire cluster. If a single link out of 10,000 becomes congested and doubles its latency, the effective throughput of the entire supercomputer drops for that step. In this synchronized regime, tail latency is the dominant performance constraint, not an outlier metric.

Definition 3.6: Bulk synchronous parallel (BSP)

Bulk Synchronous Parallel (BSP) is a parallel execution model in which every worker completes a local computation phase, exchanges data with all other workers, and then waits at a global barrier before any worker begins the next phase—making the slowest participant the pacing constraint for the entire cluster.

1. **Significance:** BSP makes system efficiency η_{scaling} directly proportional to the slowest worker: if one GPU in a 1,024-GPU cluster runs 10 percent slower due to thermal throttling or network jitter, the barrier stalls the remaining 1,023 GPUs for that fraction of the step, wasting effectively 102 GPU-steps of compute per iteration. At \$3/GPU-hour, a 5 percent straggler gap across a \$50M training run wastes roughly \$2.5M in idle accelerator time.
2. **Distinction:** Unlike asynchronous parallelism, which allows workers to proceed with stale weights from previous steps, BSP enforces a global state update at every barrier, providing mathematical equivalence to single-device training and predictable convergence behavior.
3. **Common pitfall:** A frequent misconception is that BSP is simply inefficient compared to async models. Asynchronous training often requires more total steps to converge because stale gradient updates introduce noise—in practice, BSP with careful straggler mitigation typically reaches the same loss in fewer wall-clock hours than async alternatives.

This is why **tail latency (P99)**, not average throughput, is the metric that governs a training fabric: one congested switch port stalls the barrier, and the barrier stalls the cluster. The mechanisms that keep tail latency bounded therefore become the central concern of fabric behavior.

3.6.1 Priority flow control (PFC)

The BSP weakest-link property means that even a single dropped packet can trigger a retransmission timeout that stalls the global barrier for milliseconds, an eternity in a training loop where each compute step finishes in tens of milliseconds. RoCEv2 fabrics mitigate this with priority flow control (PFC), operating in lossless mode: rather than allowing switch buffers to overflow and drop packets, the fabric uses a link-layer backpressure mechanism to pause upstream senders before any buffer saturates (Guo et al. 2016; Gangidi et al. 2024).

Definition 3.7: Priority flow control

Priority Flow Control (PFC) is a link-layer mechanism used by RoCEv2 ML cluster fabrics to prevent switch buffer overflow by sending PAUSE frames to an upstream sender when a port's queue depth crosses a configured threshold, throttling injection on a per-priority basis without dropping packets.

1. **Significance:** PFC is the foundation for lossless Ethernet required by RoCEv2 RDMA. A PFC PAUSE frame must reach the upstream sender within one round-trip time (roughly 1–5 μ s at switch-to-switch distances) before the buffer overflows. In a 1,000-node cluster, a single slow receiver can trigger PAUSE frames that propagate 3–5 hops upstream within 10–50 ms, halting gradient traffic across thousands of unrelated GPU pairs and collapsing cluster throughput to near zero.
2. **Distinction:** Unlike standard IEEE 802.3 flow control, which pauses all traffic classes on a link, PFC operates per priority class, allowing latency-sensitive control messages to continue flowing while only pausing the congested gradient data queue.
3. **Common pitfall:** A frequent misconception is that PFC solves congestion. It transforms packet loss into congestion spreading: a backpressure cascade can freeze the entire fabric within 200 ms of a single faulty transceiver, because no mechanism limits how far PAUSE frames propagate across the network.

The danger of PFC lies in its cascading nature. When a switch port's buffer fills, it sends a PAUSE frame upstream, which causes that switch's buffers to fill, which triggers another PAUSE frame further upstream. In theory, this backpressure should throttle the source. In practice, a single slow receiver can propagate pauses across the entire fabric in milliseconds, freezing links that have no direct relationship to the original congestion point. This cascading behavior, known as **congestion spreading** or **victim flows**, is the primary operational risk of PFC-based lossless Ethernet. The root cause is incast, a many-to-one traffic pattern inherent to distributed synchronization, as illustrated in figure 3.11; this deterministic overload is what triggers the PFC backpressure cascades.

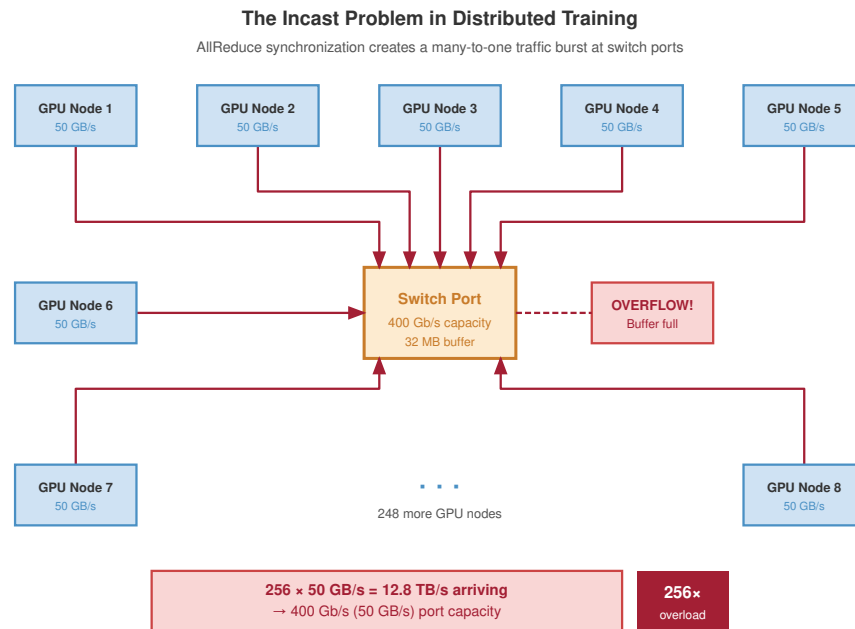

A production incident shows how this cascade can freeze a cluster.

War Story 3.1: Microsoft's PFC deadlock (2016)

Context: A team led by Chuanxiong Guo at Microsoft Research deployed RoCEv2 across Microsoft's data centers—a fleet operating at the scale of tens of thousands of servers—to support latency-sensitive services. RoCEv2 requires a lossless fabric, so the network used Priority Flow Control (PFC), and the team developed a DSCP-based PFC mechanism to extend the deployment beyond VLAN boundaries (Guo et al. 2016). DSCP marks packet priority, VLANs define layer-2 traffic boundaries, ARP resolves an IP address to a MAC address, and switches learn MAC-to-port forwarding entries.

Failure mode: PFC interacted with Ethernet flooding to create a cyclic buffer dependency. In Microsoft's reported example, a dead server with an incomplete ARP/MAC mapping caused

Incast is deterministic in BSP training: every AllReduce step concentrates line-rate traffic from all senders onto aggregation switch ports.

Figure 3.11: The Incast Problem in Distributed Training: During AllReduce synchronization, every GPU node sends line-rate traffic to a common aggregation switch port, producing a many-to-one traffic burst. The figure shows 256 GPU nodes each at 50 GB/s converging on a switch port with 400 Gb/s (50 GB/s) capacity and a 32 MB buffer: 12.8 TB/s of offered load against 50 GB/s of capacity oversubscribes the egress port by 256×. This deterministic overload is the root cause of the PFC backpressure cascades described later in this section.

upstream switches to flood lossless packets to every port; PFC PAUSE frames then propagated upstream in response to the flooded traffic, eventually forming a closed loop of paused buffers among switches.

Consequence: Once the PFC deadlock formed, restarting servers did not clear it. Microsoft's fix was architectural: block broadcast and multicast traffic from entering lossless traffic classes, and drop lossless packets when the corresponding ARP entry is incomplete rather than fall back to flooding.

Systems lesson: PFC congestion spreading is a structural vulnerability of lossless Ethernet at hyperscale. RoCE fabrics require packet-class discipline, PFC pause telemetry, and hardware-level safeguards because a mechanism designed to avoid packet loss can itself become the failure mode. ML training fabrics built on RoCE inherit this risk directly: a single stale ARP entry can cascade into a PFC storm that stalls a multi-thousand-GPU training run, with the cluster appearing healthy while no gradient flows between workers.

A simple probability calculation shows that such incidents are not rare edge cases but recurring operational risks at scale.

 Napkin Math 3.5: The probability of a PFC storm

Problem: A 4096-GPU RoCE cluster is in operation. If the probability of a single transceiver degrading and triggering PFC pauses is just 0.001 percent per day, what is the chance of a cluster-wide "PFC Storm" occurring in a given day?

Math: In a lossless Ethernet fabric, one bad link can pause its neighbor, which pauses its neighbor, eventually freezing the entire tree.

1. **Total exposure:** 4096×3 link tiers = 12,288 links, or 24,576 transceivers.
2. **Probability of zero transceiver failures:** $\Pr(\text{safe}) = (1 - 0.00001)^{24,576} \approx 0.782$.
3. **Probability of at least one storm:** $\Pr(\text{storm}) = 1 - 0.782 = 0.218$ (about 21.8 percent).

Systems insight: Even with “five-nines” reliable components, a large-scale RoCE cluster faces a 21.8 percent daily risk of a fabric-wide freeze. That is not guaranteed to happen every day, but it is frequent enough to be a weekly-scale operational concern. RoCE deployments therefore require aggressive PFC watchdogs and hardware-level telemetry, because at scale, “rare” link degradations become recurring operational realities that must be handled automatically.

3.6.2 Proactive congestion control: DCQCN and HPCC

To avoid the blunt instrument of PFC pauses, high-performance fabrics rely on proactive congestion control to modulate injection rates before buffers overflow. In BSP workloads, proactive control is a *latency requirement*, not an *optional throughput optimization*: if a single packet is delayed by a congested switch queue, the entire cluster must wait for that straggler to complete the synchronization step. The tail latency of the network effectively becomes the average step time of the training job.

The first widely deployed solution, **DCQCN**¹², operates as a reactive feedback loop using Explicit Congestion Notification (ECN) (Zhu et al. 2015). When a switch’s queue depth exceeds a configured threshold, it marks the ECN bit in the packet header. The receiver echoes this mark back to the sender via a Congestion Notification Packet (CNP), prompting the sender to reduce its injection rate using a multiplicative-decrease algorithm. DCQCN is widely supported, but production AI collectives expose a tuning problem: ECN thresholds and NIC firmware behavior can trade off PFC avoidance, throughput, visibility, and tail latency rather than offering one stable optimum (Gangidi et al. 2024).

A more precise alternative, **HPCC**¹³, addresses this opacity by using In-Network Telemetry (INT) (Li et al. 2019). Instead of a simple bit mark, switches append precise metadata to every packet header: current queue depth, link utilization, and timestamps. The sender receives a full dashboard of the network state, allowing it to calculate the exact allowable transmission rate within a single round-trip time. By reacting to precise telemetry rather than binary signals, HPCC reduces queue buildup and tail-latency variance in the evaluated incast-heavy workloads. The primary trade-off is hardware support: DCQCN functions on standard ECN-capable Ethernet switches, whereas HPCC requires programmable switches capable of pushing INT metadata at line rate.

3.6.3 Adaptive routing

Static routing protocols like ECMP¹⁴ (Equal-Cost Multi-Path) distribute traffic by hashing flow headers to fixed paths. While statistically sound for millions of small web requests, this approach fails for the elephant flows typical of ML training. Consider a scenario with 4 equal-cost paths and 8 large gradient flows. A perfect distribution would place 2 flows on each link. However, static hashing frequently results in collisions where one link carries 4 flows while another sits idle. In a synchronized training step, the completion time is dictated by the overloaded link, effectively halving the network’s useful bandwidth.

Adaptive routing mitigates this problem by allowing switches to dynamically select the output port based on real-time queue depth rather than a static hash. The implementation is protocol-dependent: InfiniBand fabrics perform packet-level adaptive routing, spraying¹⁵ individual packets across all available lanes because the hardware transport guarantees in-order delivery at the destination.

Ethernet fabrics typically employ *flowlet switching*, rerouting bursts of packets only when a sufficient time gap is detected, to avoid the performance penalties associated with packet reordering. This mechanism becomes essential for Mixture-of-Experts (MoE) models. Unlike the predictable Ring AllReduce pattern, MoE models use AllToAll communication, where every GPU sends data to every other GPU containing active experts. For a 175B-parameter model using expert parallelism with 64 experts, this generates a dense 64×64 traffic matrix—4,096 simultaneous flows. Under static

¹² | **DCQCN (Data Center Quantized Congestion Notification):** Introduced at SIGCOMM 2015 by Microsoft and Mellanox, DCQCN was designed for large-scale RDMA fabrics (Zhu et al. 2015). Its binary ECN/CNP feedback loop is simpler to deploy than telemetry-rich schemes, but it can become a tuning surface for training collectives: Meta’s SIGCOMM 2024 RoCE study reports that tighter ECN thresholds could reduce PFC in some settings while hurting collective completion time, and that 400G deployments exposed firmware and visibility issues (Gangidi et al. 2024).

¹³ | **HPCC (High Precision Congestion Control):** Developed by Alibaba and presented at SIGCOMM 2019, HPCC replaced binary ECN with per-packet in-network telemetry and reported large reductions in flow completion time under evaluated incast-heavy workloads. The trade-off is hardware dependency: HPCC requires programmable switch ASICs capable of appending telemetry metadata at line rate, limiting deployment to clusters with newer switching silicon (Li et al. 2019).

¹⁴ | **ECMP (Equal-Cost Multi-Path):** ECMP selects a path by hashing on the 5-tuple (source/destination IP, source/destination port, protocol), which means the same flow always takes the same path. This determinism is a feature for packet ordering but a liability for ML: because a single AllReduce ring produces a small number of persistent flows, hash collisions are not transient statistical events but permanent hot spots that persist for the entire training run.

¹⁵ | **Packet Spraying:** Unlike standard Ethernet (which hashes flows to single paths to avoid reordering), packet spraying sends individual packets of a single flow across multiple paths. This can improve BW_{bisect} for AllReduce elephant flows when the transport can tolerate or repair reordering. UEC's Ultra Ethernet Transport design explicitly includes multi-path packet spraying and flexible ordering to reduce the ECMP collision problem for AI/HPC traffic (Ultra Ethernet Consortium 2025).

ECMP, hash collisions are statistically guaranteed to create stragglers; adaptive routing is required to distribute this traffic evenly across the fabric's BW_{bisect} .

3.6.4 The incast problem in ML

Congestion control and adaptive routing manage flows that traverse the interior of the fabric. A different failure mode occurs at the edge, where the traffic pattern itself overwhelms a single port regardless of how much capacity the fabric interior provides.

Definition 3.8: Incast

Incast is a many-to-one ML cluster traffic pattern in which a large number of senders simultaneously transmit data to a single receiver port, concentrating line-rate traffic from multiple sources into a single switch queue and causing buffer overflow even when the rest of the fabric is uncongested.

1. **Significance:** In the reduce phase of AllReduce, every participating GPU simultaneously sends gradients toward the same aggregation points. With 256 senders each at 50 GB/s targeting one switch port, the instantaneous incast reaches 12.8 TB/s, orders of magnitude above a 400 Gb/s port's absorption capacity. A 32 MB switch buffer holds about 640 μs of one 400 Gb/s egress stream, but under $256\times$ incast the net fill rate is roughly 12.75 TB/s after subtracting the single 50 GB/s egress port, so overflow arrives in about 2.5 μs . That sudden overflow triggers either PFC cascade or packet drops that elevate L_{lat} cluster-wide.
2. **Distinction:** Unlike general congestion (which occurs on shared internal links when aggregate traffic exceeds link capacity), incast is an endpoint bottleneck: it occurs even if every internal spine and leaf link is completely uncongested, because the bottleneck is the single destination port, not the fabric interior.
3. **Common pitfall:** A frequent misconception is that incast is rare or unpredictable. Because ML training synchronizes all GPUs at each backward pass, incast is a deterministic event at the end of every layer's gradient computation—it occurs hundreds of times per training step and must be architecturally mitigated through layer-staggered AllReduce or tree-based collective algorithms, not treated as an edge case.

ML training is structurally susceptible to incast because of its synchronized communication patterns. When a layer finishes backward computation, thousands of nodes simultaneously initiate AllReduce, targeting the same switch ports. In our 175B model training across 1,024 GPUs, each AllReduce involves every node injecting data simultaneously, creating a burst that can momentarily exceed the fabric's capacity at specific switch ports. Production clusters mitigate this through three complementary techniques:

- **Layer-staggering:** Trigger each gradient bucket's AllReduce as soon as backpropagation produces it. Final-layer gradients reduce while earlier layers are still computing, so communication is staggered instead of released as one burst.
- **Algorithm selection:** Choose collectives that limit the fan-in at any single port. Hierarchical and rail-local reductions aggregate gradients in stages so that no switch port must absorb all senders at once, in contrast to a flat reduction in which every node targets one aggregation point. Bandwidth-optimal ring AllReduce is itself point-to-point and creates no single aggregation hotspot; the incast pressure comes from many such flows converging on oversubscribed ports, which topology-aware placement and rail-optimized wiring relieve.
- **Quality of Service (QoS) classification:** Tag gradient traffic with the highest service class so background storage or management traffic does not delay the synchronization path.

Together, these mitigations spread the burst in time, space, and priority, but they do not eliminate congestion or tail latency. The question becomes how to build end-to-end clusters that perform despite these realities.

3.7 Level 5: Cluster Design and Case Studies

The final level of the stack is cluster design, where wires, transport, topology, and congestion control combine into a coherent system. The goal of cluster design is to provide an end-to-end Gradient Bus that makes thousands of distributed GPUs feel like a single machine. At this level, the abstraction layers collapse into concrete engineering decisions: which cables to buy, how to wire the racks, which protocol to deploy, and how to validate that the resulting fabric actually delivers the bandwidth the training job expects. Two representative large-scale architectures, one built on InfiniBand and one on Ethernet, illuminate the trade-offs that define ML infrastructure (NVIDIA 2023; Meta Engineering 2024; Gangidi et al. 2024).

3.7.1 The GPU-to-GPU “gradient bus”

In a well-designed cluster, the network fabric acts as a scheduler-aware extension of the system bus, not a passive pipe. The intra-node (NVLink) bandwidth is $\sim 9\times$ higher than inter-node (InfiniBand/RoCE) bandwidth, and the primary mechanism for hiding this cliff is **communication-computation overlap**. During the backward pass, gradients for the final layers are computed first. Instead of waiting for the entire backward pass to finish, the system triggers an asynchronous AllReduce for these gradients immediately while the GPUs continue computing gradients for earlier layers. If the backward pass requires 500 ms of computation and the AllReduce takes 300 ms, perfect overlap masks the entire communication cost behind computation, reducing the effective overhead to $\max(0, 300 - 500) = 0$. In practice, dependency chains and resource contention limit this efficiency to 60–80 percent, leaving a **last-mile problem**: the gradients for the very first layer (computed last) have no subsequent computation to hide behind, exposing their raw transfer time to the critical path.

The bandwidth hierarchy plotted in figure 3.2 dictates the parallelism strategy to mitigate this cliff. Tensor parallelism, requiring massive bandwidth for frequent activation exchanges, is confined to the NVLink domain within a node. Pipeline parallelism, involving point-to-point transfers of activations between pipeline stages, spans the InfiniBand links between nodes. Data parallelism, tolerant of lower bandwidth through gradient accumulation and overlap, stretches across the full fabric.

3.7.2 Case study: NVIDIA DGX SuperPOD

The NVIDIA DGX SuperPOD architecture connects DGX H100 nodes using an NDR InfiniBand network, serving as a concrete implementation of the Gradient Bus concept (NVIDIA 2023). Each node acts as a dense compute island, with eight H100 GPUs connected via NVSwitch to provide 900 GB/s of internal bandwidth. Externally, each GPU pairs with a ConnectX-7 NIC delivering 400 Gb/s of injection bandwidth. Across a standard scalable unit of 32 nodes (256 GPUs), this yields an aggregate injection bandwidth of 12.8 TB/s (256×50 GB/s), ensuring the fabric can ingest gradients as fast as the accelerators produce them.

This architecture explicitly instantiates the five-level model constructed in this chapter. At Level 1, it minimizes latency by using passive copper (DAC) within the rack and active optics only for spine connections. At Level 2, it relies on InfiniBand’s native credit-based flow control to guarantee a lossless medium without the fragility of Ethernet PFC. Level 3 implements a rail-optimized fat-tree: GPU rails are aligned across a scalable unit so same-rail traffic stays close and cross-rail traffic traverses the spine layer. At Level 4, hardware-based adaptive routing can select among spine paths to improve bisection behavior for cross-rack communication. At Level 5, the design is modular: multiple SuperPOD scalable units connect through additional switching to form larger clusters (NVIDIA 2023). For our 175B-parameter model, the physical infrastructure would consist of approximately four SuperPOD scalable units wired together, allowing about 1,024 GPUs to function as a single synchronous instrument.

3.7.3 Case study: Meta Grand Teton

Meta disclosed two Grand Teton-based 24,576-H100 clusters: one using RoCE over an Arista/OCP Ethernet fabric and one using NVIDIA Quantum-2 InfiniBand, both with 400 Gb/s endpoints. Meta used both for Llama 3 training and reported ongoing Llama 3 training on the RoCE cluster (Meta Engineering 2024). The primary motivation for Ethernet is operational scale and supply chain

resilience: by using Ethernet, Meta can source switches from multiple vendors and use the same optical infrastructure and management tooling shared by their front-end serving fleet, avoiding the operational silo of a dedicated InfiniBand island.

Making Ethernet perform like a dedicated HPC fabric at this scale requires significant engineering at Level 4. Meta's RoCE study describes PFC watchdogs for long-duration pause events, iterative routing designs beyond plain ECMP, future-oriented flowlet switching experiments, and a 400G deployment experience in which DCQCN tuning proved difficult enough that Meta proceeded without DCQCN while relying on PFC plus higher-layer collective controls (Gangidi et al. 2024). While this architecture achieves high line-rate bandwidth for large gradient transfers, it accepts a trade-off: small-message latency can remain higher than InfiniBand because RoCE deployments rely on Ethernet buffering, QoS, PFC/ECN/DCQCN tuning, routing policy, and switch/NIC implementation choices rather than InfiniBand's native credit-based fabric semantics. For giant models where bandwidth dominates, this is an acceptable exchange; for latency-sensitive MoE routing, the penalty requires careful algorithmic compensation.

🔍 Systems Perspective 3.3: InfiniBand vs. RoCE: The industry verdict

The coexistence of InfiniBand (NVIDIA DGX SuperPOD) and RoCE (Meta Grand Teton, Google) in production reflects a genuine trade-off rather than a clear winner. InfiniBand can provide lower tail latency and simpler lossless configuration. RoCE can provide lower switch costs and multi-vendor flexibility. For *training runs* where iteration time is measured in seconds, the latency difference is often absorbed into the noise. For *inference serving* with tight SLOs, the latency difference may matter.

The design space is converging. NVIDIA's Spectrum-4 Ethernet switches incorporate InfiniBand-inspired adaptive routing and congestion control. Broadcom's Memory DCS chips add hardware support for RDMA-optimized switching. The distinction between the two ecosystems is narrowing, though it has not disappeared.

These case studies close the five-level stack by showing how the physical wire, transport protocol, topology, and congestion controls become one production fabric. The remaining operational problem is not how to build a single fast cluster, but how to share that expensive substrate across teams and workloads without sacrificing the predictable performance that training demands.

3.8 Network Virtualization

Production ML clusters are rarely dedicated to a single training job, creating a massive economic imperative for efficient multi-tenancy. A \$300 million supercomputer that sits 30 percent idle because it cannot securely isolate concurrent workloads represents a \$90 million waste of capital. To recover this utility, the network must support virtualization along three orthogonal dimensions: **bandwidth partitioning** (guaranteeing minimum throughput), **latency determinism** (preventing head-of-line blocking), and **security isolation** (preventing memory snooping between tenants). Technologies like SR-IOV (Single Root I/O Virtualization) and virtual lanes decouple the training job from the physical wire, much as hypervisors decoupled the operating system from the CPU. For our 175B model, this means the training job can reliably consume 80 percent of the cluster's BW_{bisect} while a high-priority inference service and a background data preprocessing job share the remaining 20 percent, with the fabric enforcing hard boundaries that prevent the preprocessor's bursty traffic from stalling gradient updates.

3.8.1 SR-IOV: Hardware NIC virtualization

Cloud providers can deliver near bare-metal RDMA performance to virtualized GPU instances through **Single Root I/O Virtualization (SR-IOV)**, a standard that allows a physical NIC to present itself as multiple independent **Virtual Functions (VFs)**. Each VF has its own hardware queues, doorbell registers, and DMA mappings. By assigning a dedicated VF to each VM or container, the hardware creates a direct path for DMA operations that bypasses the host kernel and hypervisor completely. The passthrough architecture is critical for ML training because it can reduce virtualization overhead to low levels, often within a few percent of bare metal when the NIC, hypervisor,

and placement policy are configured correctly. The cluster-management consequence is immediate: VFs become allocatable network resources, so placement logic must reserve NIC capacity and QoS policy alongside GPUs rather than treating the network as an unbounded shared pool.

However, hardware-level isolation still needs explicit bandwidth policy. SR-IOV exposes multiple VFs that share the NIC’s physical resources; administrators can add per-VF or per-group QoS policies to cap or guarantee bandwidth, such as assigning eight VFs 50 Gb/s each on a 400 Gb/s NIC. For our 175B-parameter model training on a multi-tenant cluster, that configured partitioning can prevent a neighboring tenant from stealing bandwidth, but it also enforces a hard ceiling on peak throughput. The training job must be architected to operate within this slice, as no amount of software optimization can burst beyond the configured VF limit.

3.8.2 Traffic isolation and quality of service

Consider a worst-case contention scenario on a shared cluster: our 175B model is midway through a latency-sensitive AllReduce operation when a neighboring job initiates a massive checkpoint save. Without strict isolation, a bursty 100 GB write (taking 2 seconds at full 400 Gb/s line rate) could saturate the shared spine links, introducing queuing delays that increase the AllReduce time by 50 percent or more. To prevent this noisy-neighbor effect, high-performance fabrics rely on **Quality of Service (QoS)** mechanisms that enforce fairness at the packet level.

The primary tool is the Virtual Lane (VL) in InfiniBand (or **Traffic Class** in RoCE), which provides up to 16 independent logical channels on a single physical link. By mapping different traffic types to separate VLs, the network ensures that a saturation event in one lane does not block progress in another. Each VL maintains its own independent credit-based flow control: if the storage traffic for the checkpoint fills up its buffer, the switch pauses only that specific lane. Gradient updates, tagged with a high-priority service level, continue to flow through their reserved lane unimpeded. On the Ethernet side, **Enhanced Transmission Selection (ETS)** provides analogous bandwidth guarantees per traffic class, while advanced switch ASICs can partition their forwarding tables and buffer pools into isolated **network slices**, ensuring that congestion in one tenant’s slice cannot trigger PFC pauses in another’s.

Virtualization solves the sharing problem but makes performance diagnosis harder. When a training job slows down on a multi-tenant cluster, the cause could be a physical link degradation, a noisy neighbor exceeding its bandwidth allocation, or a misconfigured QoS policy. Systematic monitoring is essential to distinguish these cases.

3.9 Monitoring and Debugging

Network performance problems in ML clusters are insidious because they manifest as **silent waste** rather than explicit failures. A degraded transceiver causing a 10 percent reduction in effective bandwidth might slow each training iteration by only 2–3 percent, a drift easily masked by the natural variance of checkpointing or data loading. Over a 30-day training run on 1,024 GPUs, this invisible drag accumulates to roughly 15,000–22,000 wasted GPU-hours, burning about \$45,000–\$66,000 at \$3/GPU-hour without triggering a single alarm. Traditional IT monitoring tools like SNMP or ICMP ping measure connectivity, not the sustained throughput required by RDMA. Effective observability requires a three-layer approach: **physical monitoring** (FEC errors, signal attenuation), **transport monitoring** (PFC pause frames, retransmission rates), and **application monitoring** (NCCL algorithmic bandwidth) (Jeauegy 2017; Gangidi et al. 2024). Only by correlating signals across these layers can operators detect that a “slow training run” is actually caused by a single degraded cable in one rack.

3.9.1 Link-level telemetry

At the physical layer, hardware counters answer whether the wire still behaves like the model assumed. Every RDMA NIC and switch maintains these counters, accessible via the `perfquery` utility (Linux man-pages project 2026). `PortXmitData` and `PortRcvData` provide the raw byte counts used to compute real-time link utilization, while `PortXmitDiscards` tracks packets dropped by the switch—in a properly configured lossless fabric, discards should be exactly zero. Physical signal integrity is tracked via the `SymbolErrorCounter`, which increments on bit-level errors caused by

loose cables or dirty optics, and the **LinkDownedCounter**, which logs link flaps often triggered by intermittent hardware faults or overheating transceivers.

These metrics are typically polled by a centralized monitoring system (for example, Prometheus with Grafana dashboards) at 10–30 second intervals to catch **silent degradation**. A common failure mode involves a QSFP56 cable negotiating at HDR speed (200 Gb/s) instead of NDR (400 Gb/s), or silently dropping from 4 lanes to 2 lanes due to a single bad connector pin. The link remains “up” and functional, but its bandwidth is halved. In a cluster of 1,024 GPUs with over 3,000 links, a 0.1 percent point-in-time component degradation rate implies about 3 degraded links in expectation, with a high probability that at least one link is degraded. Because distributed training algorithms like Ring AllReduce are synchronous, a single degraded link throttles the entire job to the speed of that straggler, transforming a minor hardware fault into a massive waste of idle compute cycles.

3.9.2 Bandwidth and latency validation

Once counters rule out visible link faults, validation must test the bandwidth and latency that the training job can actually use. A healthy NDR InfiniBand link can approach the raw 50 GB/s rate after encoding and protocol overheads, but the only useful number is the delivered payload bandwidth on the specific host pair. Operators rely on periodic health checks, often running perf test tools such as `ib_write_bw` between selected node pairs and assembling the results into an **all-pairs bandwidth matrix** (linux-rdma project 2026). This heatmap immediately visualizes cold spots in the fabric where specific spine switches or cable bundles are underperforming, allowing for targeted maintenance before jobs are scheduled.

For latency-sensitive synchronization, `ib_write_lat` measures round-trip times for small RDMA writes. Baseline NDR latency should remain below 2 μ s for directly connected nodes. Latencies exceeding 5 μ s suggest switch-buffer congestion or routing imbalances, while values spiking above 100 μ s usually indicate the RDMA path has fallen back to TCP/IP emulation—a catastrophic configuration error. Before launching a massive training job, robust validation includes application-level tests such as `nccl-tests`, which verify that the fabric can sustain the expected AllReduce bandwidth across the specific collective topology (ring or tree) used by the workload. This ensures that the physical network reality matches the theoretical design before expensive compute resources are allocated.

3.9.3 Systematic debugging workflow

When a training job reports lower-than-expected throughput, the diagnostic order should preserve the layer model rather than starting with cables. The following sequence moves from application symptoms toward physical causes:

1. **Check GPU utilization:** Rule out compute bottlenecks using `dcgmi` or `nvidia-smi`. If SM utilization is 100 percent, the network is not the bottleneck. Low utilization does not automatically implicate the fabric, however: a starved input pipeline (data loading or storage) produces the same symptom, so confirm the data path is keeping the accelerators fed before investigating the network.
2. **Inspect NCCL logs:** Set `NCCL_DEBUG=INFO` to reveal which network transport was selected, the detected bandwidth between nodes, and any fallbacks to slower protocols.
3. **Run point-to-point tests:** Use `ib_write_bw` between specific nodes in the job. A single degraded link can bottleneck the entire ring in a Ring AllReduce.
4. **Check PFC/ECN counters:** Inspect switch counters along the path. Sustained PFC activity indicates persistent congestion that should be investigated at the scheduler or routing level.
5. **Validate Physical Layer:** Check symbol errors and CRC counts to identify failing transceivers or cables.

The diagnostic sequence preserves the chapter’s layer model: application symptoms identify the failing path, transport counters show whether congestion or fallback is involved, and physical telemetry confirms whether the wire itself is degrading.

📌 Checkpoint 3.5: Diagnosing a training slowdown

Your 175B model training job has been running for 3 days on 512 GPUs. You notice that the iteration time has gradually increased from 4.2 seconds to 4.8 seconds (a 14 percent slowdown). The GPU utilization reported by `nvidia-smi` has dropped from 92 percent to 85 percent.

- ❑ **First diagnostic:** Choose the first diagnostic step, name the tool that confirms whether the bottleneck is communication-bound or compute-bound, and cite the evidence that distinguishes the two.
- ❑ **Physical layer:** Identify physical-layer causes that could explain a 50 percent bandwidth drop when `ib_write_bw` finds one node pair at 24 GB/s instead of the expected 48 GB/s, and verify them using switch counters.
- ❑ **Collective impact:** Estimate the impact on overall AllReduce time when the degraded link lies in the Ring AllReduce path, then evaluate whether switching to a Tree AllReduce algorithm helps.

3.10 Network Technologies That Move the Ceiling

Monitoring keeps deployed fabrics honest, but observability cannot push past a physical ceiling that copper approaches at high signaling rates. The physical ceiling that monitoring exposes is the reason new fabrics deserve attention: they matter only when they move a bound the synchronization backbone cannot cross. As clusters scale toward 100,000 nodes, the durable design variables are power per bit, reach, and the ratio of compute to memory to network capacity, not the product names attached to a particular roadmap.

3.10.1 Protocol convergence and link density

The first pressure point is reliability. The Ultra Ethernet Consortium (UEC) targets that constraint by trying to make Ethernet behave more like an HPC fabric without inheriting RoCEv2's PFC fragility. Its Ultra Ethernet Transport design combines packet spraying across multiple paths, flexible ordering, multiple transport delivery services, congestion-control changes, and telemetry intended for AI/HPC traffic (Ultra Ethernet Consortium 2025). The goal is to preserve Ethernet's ubiquity and multi-vendor economics while moving its failure behavior closer to InfiniBand's lossless fabric model. Specific mechanisms such as packet trimming or link-layer retry are implementation details of that broader direction, so they should be evaluated against the same durable criteria: whether the fabric can repair congestion locally before it becomes a synchronous-training straggler.

Higher port rates attack hop count as well as raw bandwidth. XDR InfiniBand pushes 800 Gb/s per port, and Ethernet roadmaps include 800GbE and 1.6TbE link speeds (NVIDIA 2026c; Ethernet Alliance 2025). Ethernet switch silicon with 1.6 Tb/s ports pushes aggregate capacity to 102.4 Tb/s in current Tomahawk 6-class designs (Broadcom Inc. 2025). A single 1.6 Tb/s port delivers the bandwidth of 4 400G ports. The increased density allows architects to flatten the topology: a cluster that previously required three tiers of switches may be served by two when radix, port rate, and placement constraints line up, halving the transceiver count and reducing tail latency by removing an entire hop of switching and FEC overhead.

3.10.2 Optical interconnects

Optical interconnects attack the power-per-bit and reach terms that copper makes worse as data rates increase. At 112 Gb/s per lane (the PAM-4 signaling rate used by NVLink 4.0 and InfiniBand NDR), copper SerDes transceivers consume approximately 7–10 pJ per bit and are limited to distances of 2–3 meters before signal integrity degrades beyond the point where equalization can recover the data.

The 224 Gb/s-per-lane class pushes copper even harder. At 224 Gb/s, the SerDes power consumption roughly doubles to 15–20 pJ per bit, and the reach shrinks to 1–1.5 meters over passive copper cables. Active electrical cables (which include retimer chips to regenerate the signal mid-cable) extend the reach but add latency and power.

Each extra meter pushes the fabric from copper toward optics.

Co-packaged optics (CPO) addresses these limitations by integrating optical transceivers directly into the switch or accelerator package, rather than placing them at the end of a pluggable cable module. In CPO, a silicon photonics chip sits on the same package substrate as the processor, converting electrical signals to light at the die boundary. The optical signal then travels through a fiber at the speed of light, with negligible attenuation over distances of tens of meters, and is converted back to electrical at the receiving package.

CPO changes the link budget through three independent physical effects:

- **Shorter electrical path:** Moving the optical transceiver from the switch faceplate to the package substrate reduces the SerDes-to-optics path from centimeters to millimeters, lowering the power consumed by electrical signal conditioning.
- **Distance-stable bandwidth:** Optical fiber has no distance-dependent bandwidth degradation over data center-relevant distances up to 100 meters, eliminating retimers and enabling more flexible physical layouts.
- **Lighter cable plant:** Fiber is lighter and thinner than copper cables, simplifying cable management in dense racks.

Together, these effects shift the fabric from a copper-limited layout problem toward an optics-limited packaging and power problem.

A quick estimate makes the power dividend concrete.

Napkin Math 3.6: The optical dividend

Problem: Calculate the power savings of moving a 51.2 Tb/s switch from pluggable transceivers to Co-Packaged Optics (CPO).

1. **Pluggable Architecture:** $128 \text{ ports} \times 20 \text{ W} = 2.56 \text{ kW}$ for optics alone.
2. **CPO Architecture:** $128 \text{ engines} \times 10 \text{ W} = 1.28 \text{ kW}$.
3. **Savings:** The savings reach 1.28 kW of power per switch.

Systems insight: In a cluster with 1,000 switches, pluggable optics consume 2.56 MW just to move light. CPO halves this “network tax,” saving 1.28 MW and redirecting enough power to fuel roughly 1,800 H100 GPUs. At the BW_{bisect} wall, sustainability is not a choice; it is an architectural requirement driven by the thermal limits of the faceplate.

For a 10,000-GPU cluster, eliminating pluggable modules could save more than a megawatt of power that can be redirected to computation. CPO also removes the transceiver as a discrete field-replaceable unit, eliminating a common point of mechanical failure.

For ML infrastructure, CPO could flatten the bandwidth hierarchy by narrowing the gap between intra-node and inter-node bandwidth. If inter-node links achieve bandwidth comparable to NVLink-class local fabrics (hundreds of GB/s per GPU), the constraint that confines tensor parallelism to within a single node would relax. This would enable new parallelism strategies where tensor parallelism spans two to four nodes rather than being confined to a single 8-GPU node, potentially improving scaling efficiency for very large models.

The product roadmap is less durable than the constraint it illustrates: as link speed rises, optics moves closer to silicon to control power and reach. Products that integrate optics into switch packages or accelerator packages are concrete attempts to pay less power and latency for the same physical distance. Whether a specific product generation succeeds is less important than the systems direction: the electrical path shrinks, the optical path begins closer to the die, and package-level thermals become part of network design.

However, CPO introduces new challenges. Optical components are sensitive to temperature (laser wavelength shifts with temperature, requiring active thermal management), and integrating photonics on the same package as a 1,000 W GPU creates a hostile thermal environment for the optical components. The manufacturing processes for silicon photonics and CMOS transistors are similar but not identical, requiring separate fabrication steps that increase package cost and complexity. These challenges are being addressed through hybrid integration approaches where the

photonics chiplet is placed on a cooler region of the package substrate, thermally isolated from the GPU die.

3.10.3 Disaggregated and composable architectures

The conventional node bundles a fixed ratio of compute, memory, and networking, and section 2.7.1 established why that ratio is wasteful when one workload needs more memory capacity per GPU and another needs more network bandwidth: CXL memory pooling lets a processor in one chassis reach memory in another with load/store semantics, and disaggregated designs decouple compute, memory, and networking into independently composable pools. The fabric-specific consequence is what concerns this chapter. Once memory pooling and resource composition cross the node boundary, the rigid distinction between intra-node NVLink domains and inter-node InfiniBand domains softens into a single memory fabric, and the synchronization backbone shifts from a fixed node boundary to a composable one.

That shift does not repeal the physics this chapter has developed. A composed virtual node still pays the same α - β costs on every cross-pool access, the same power-per-bit limits on the links that carry it, and the same observability requirements that keep an oversubscribed path from masquerading as slow accelerators. The systems lesson is the displacement of overhead: disaggregation relocates the synchronization backbone rather than eliminating it. Whether a composable fabric works is decided by the same fabric properties that decide whether a fixed-node fabric works.

3.11 Fallacies and Pitfalls

Designing and operating high-performance fabrics for ML requires unlearning assumptions from traditional data-center networking. The following fallacies and pitfalls capture the most common errors that stall training and degrade cluster productivity.

Fallacy: *More bandwidth always means faster training.*

Engineers assume upgrading from HDR (200 Gb/s) to NDR (400 Gb/s) will yield proportional gains, but the α - β model (section 3.4.4) reveals this is only true in the bandwidth-dominated regime. For small models or the small-message phases of pipeline parallelism, the latency term α , dominated by switch hops and FEC ($\sim 1 \mu\text{s}$), dictates performance. If a workload is latency-bound, a $2\times$ bandwidth increase may deliver only a small fraction of the line-rate gain while adding substantial power and transceiver cost.

Consider a 10 KB message (typical for control synchronization). On 200 Gb/s InfiniBand, it takes $1.90 \mu\text{s}$. Upgrading to 400 Gb/s reduces this to $1.70 \mu\text{s}$, a 10.5 percent improvement despite doubling the link rate.

Pitfall: *Treating InfiniBand as just fast Ethernet.*

Procurement teams compare InfiniBand and high-speed Ethernet on link rate alone and conclude they are equivalent at the same Gb/s. InfiniBand and Ethernet differ architecturally, not just in speed. InfiniBand provides kernel-bypass (RDMA), hardware-managed flow control, and credit-based congestion avoidance, all standardized and predictable. Ethernet relies on software-managed TCP/IP stacks with orders-of-magnitude higher latency and requires PFC/ECN approximations to behave losslessly under RDMA. The choice between InfiniBand and Ethernet is a system architecture decision, not a bandwidth selection: it determines whether failure modes are bounded by hardware credits or by software configuration discipline.

Fallacy: *Lossless Ethernet is as reliable as InfiniBand.*

RoCE over Ethernet can achieve throughput comparable to InfiniBand for large transfers, but the “lossless” property is an approximation maintained by PFC (section 3.6.1). A misconfigured switch or a firmware bug can trigger a **PFC storm**, where PAUSE frames propagate in a loop, freezing the entire fabric. InfiniBand’s credit-based flow control is inherently immune to such cascades because it operates on per-hop buffer availability rather than reactive signals. Teams deploying RoCE must invest substantially more engineering effort in fabric testing and monitoring to avoid multi-day outages caused by “lossless” deadlocks.

Pitfall: *Accepting oversubscription because most traffic is local.*

In general-purpose clouds, 4:1 or 8:1 oversubscription at the spine is common because traffic is stochastic. However, ML training is bulk synchronous. When an AllReduce starts, the barrier’s coordination forces every node to inject full bandwidth simultaneously. As shown in the bisection

bottleneck analysis (section 3.5.2), even a 4:1 oversubscription slows the entire synchronization by 4×. For a \$300M cluster where sync accounts for 30 percent of time, this “cost optimization” wastes over \$142.1M in idle GPU cycles.

Fallacy: *TCP bandwidth tests are sufficient for ML fabric validation.*

Standard benchmarks like `iperf` measure kernel-based TCP/IP performance. Because TCP requires CPU-managed buffer copies and context switches, it often caps at 20–40 Gb/s regardless of the wire speed. ML training uses RDMA, which bypasses the kernel entirely. A link that appears “broken” at 30 Gb/s in `iperf` might be perfectly healthy and deliver 390 Gb/s in `ib_write_bw`. Validation protocols must use RDMA-specific tools from the `perftest` suite to match the workload’s data path.

Pitfall: *Relying on adaptive routing instead of topology-aware placement.*

Adaptive routing distributes traffic across available paths, but it cannot create bandwidth that does not exist. If a scheduler places a 1,024-GPU job across two oversubscribed spine groups, adaptive routing will balance the traffic, but it will still be throttled by the group-to-group links. Topology-aware placement, discussed in section 8.3, and adaptive routing are complementary: the former ensures bandwidth exists, while the latter ensures it is used efficiently.

Fallacy: *Network fabric problems always appear as hard failures.*

Network performance issues in ML clusters often manifest as subtle training slowdowns rather than errors. A 10 percent reduction in throughput due to intermittent congestion can waste thousands of GPU-hours before being noticed, because jobs continue to run while gradients arrive late.

Pitfall: *Treating PFC and ECN counters as optional production details.*

Operators must alert on `PortXmitDiscards` and PFC Pause frame rates. A gradual increase in these counters is often the leading indicator for a failing transceiver or a routing imbalance that will eventually lead to a job failure.

3.12 Summary

The Five-Level Model shown in figure 3.1 structures our analysis of high-bandwidth fabrics, ascending from the physics of signal transmission to the architecture of warehouse-scale clusters. The framework reveals that network performance is the product of interactions between physical reach, transport protocols, topology, and congestion control, not link speed in isolation. Level 1 (Wire) established that PAM4 encoding and FEC impose irreducible latency floors constraining cluster diameter. At Level 2 (Transport), InfiniBand’s native credit-based flow control and RoCE’s reliance on PFC yield different reliability guarantees, and the α - β model quantifies the bandwidth-latency trade-offs inherent in distributed collectives.

Level 3 (Topology) demonstrated how non-blocking fat-trees and rail-optimized designs provide the structural $BW_{\text{bisection}}$ required by global AllReduce patterns. However, Level 4 (Behavior) showed that structure alone is insufficient: in the synchronous world of BSP training, tail latency is the dominant constraint, necessitating proactive congestion control mechanisms like DCQCN and HPCC to prevent incast-induced stalling. Level 5 (Cluster Design) integrated these layers into production architectures like the NVIDIA SuperPOD and Meta Grand Teton, illustrating how virtualization and multi-tenancy allow these massive instruments to be shared safely.

At the physical limit, the constraints of copper and the operational complexity of Ethernet drive new interconnect designs. Ultra Ethernet Consortium (UEC) standards, Co-Packaged Optics (CPO), and CXL memory pooling all aim to flatten topologies or reduce the power tax of moving data. Yet, as our monitoring workflow discussion emphasized, no technology eliminates the need for rigorous observability. Whether debugging a single degraded transceiver or optimizing a multi-tenant scheduler, the ability to correlate physical counters with application-level throughput remains the ultimate safeguard against silent waste in the machine learning fleet.

The practical value of this layered understanding is diagnostic precision. When a distributed training job underperforms, the complaint is invariably “the network is slow,” but slowness has many causes: a failing transceiver degrading a single link, a PFC storm cascading across a subnet, a topology bottleneck starving one communication pattern while adequately serving another. Engineers who understand the Five-Level Model can isolate the layer at fault, correlate physical counters with transport behavior, and distinguish a topology limitation from a congestion control misconfiguration.

This capacity to reason across abstraction layers, from SerDes signal integrity to cluster-wide $BW_{\text{bisection}}$, is what separates routine troubleshooting from genuine systems engineering.

Equally important, the α - β cost model provides a quantitative vocabulary for making architectural decisions before hardware is purchased and racks are wired. Choices between InfiniBand and RoCE, between fat-tree and rail-optimized topologies, and between 400G and 800G link speeds are all decisions with multi-million-dollar consequences that hinge on the interaction between message size distributions, collective algorithms, and physical link characteristics. The framework developed in this chapter equips practitioners to evaluate these trade-offs with analytical rigor rather than vendor benchmarks alone.

Key Takeaways: The fabric decides useful compute

- **Link speed is not fabric speed:** A global AllReduce is limited by the narrowest bisection cut, not the fastest advertised port. Topology decides how much purchased accelerator throughput becomes useful training throughput and how much becomes idle silicon.
- **Latency and bandwidth bind differently:** The α - β model separates startup cost from per-byte transfer cost, with $n^* = \alpha \cdot \beta$ marking the regime change. Message-size distributions, not vendor peak numbers, determine whether to optimize software latency or hardware bandwidth.
- **Losslessness moves the risk:** RDMA needs a lossless fabric to avoid expensive retransmission stalls. InfiniBand supplies this natively, while RoCE depends on PFC, ECN, DCQCN, and HPCC, trading hardware flexibility for tail-latency and operational complexity.
- **Topology must match traffic:** Fat-trees buy flexible bisection bandwidth, rail-optimized designs accelerate same-rank AllReduce, and dragonfly or torus designs trade cabling and locality differently. The right fabric depends on whether the workload stresses AllReduce, AllToAll, or multi-tenant sharing.
- **Telemetry saves GPU-hours:** PFC counters, link error rates, bandwidth baselines, and application throughput must be correlated across layers. Without that observability, a degraded transceiver or congestion storm silently converts a high-end fleet into a queue of waiting accelerators.

Link speed is the number everyone quotes and the wrong one to trust. What decides whether a fleet computes as one machine is bisection bandwidth, the rate at which one half of the cluster can talk to the other, because a global AllReduce is only as fast as the fabric's narrowest cut. A topology that starves that cut turns expensive silicon into idle silicon, waiting on gradients the wires cannot deliver in time. The α - β model puts a number on the waiting, separating the latency a message pays to *start* from the bandwidth it pays to *finish*. That is why this chapter treats the interconnect as part of the computer and not the plumbing between computers: at fleet scale, the fabric decides how much of the silicon was worth buying.

What's Next: From wires to data pipelines

The network fabric now binds compute nodes into a fleet, and every byte of gradient data and activation tensor flows through it. The fleet, however, also needs to move massive datasets and enormous checkpoints. Chapter 4 examines the parallel storage systems and data-loading architectures that keep the fleet supplied with data.

Research Questions: For further inquiry

- Why does bisection bandwidth, rather than advertised link speed, decide how much accelerator compute becomes useful?

- How should the α - β model change decisions about link upgrades, hop count, and topology?
- When is InfiniBand preferable to RoCE, and when might RoCE's operational flexibility justify its risks?
- How can one degraded link or congestion cascade silently waste an entire training fleet?

Purpose

Why does storage become the invisible bottleneck that prevents accelerators from reaching their potential?

Accelerators can compute faster than storage can feed them. A high-end accelerator processes data at terabytes per second internally, but individual local drives deliver gigabytes to low tens of gigabytes per second, and distributed storage systems add latency that compounds into idle accelerators waiting for data to arrive. This mismatch is invisible in benchmarks that measure accelerator performance in isolation but dominates real workloads where training data must stream continuously, checkpoints must be saved reliably, and model weights must be loaded at serving time. The gap between what accelerators can consume and what storage can deliver shapes system architecture at every level: it forces careful attention to data formats, caching strategies, and pipeline design that would be unnecessary if storage kept pace with compute. Organizations that optimize accelerator utilization without addressing storage discover that their expensive hardware runs at a fraction of capacity because nobody planned for the data path. In C^3 terms, data storage is a compute-communication co-design problem: the fastest compute in the fleet sits idle when the storage hierarchy cannot supply data at the rate the accelerators consume it.

Learning Objectives

- Explain how ML storage workloads invert database assumptions through streaming, checkpoint bursts, and metadata pressure
- Calculate required training bandwidth with the pipeline equation and target accelerator utilization
- Compare memory, flash, parallel file, object, and archive storage tiers by bandwidth, latency, capacity, and cost
- Design prefetching, sharding, caching, and locality strategies that prevent fleet-scale accelerator starvation
- Evaluate accelerator-direct and CPU-bypass storage paths for latency, augmentation, and locality bottlenecks
- Select checkpoint staging and replication strategies that balance pause time, recovery risk, and storage cost
- Assess retrieval indexes and synthetic-data pipelines as storage workloads with distinct latency, consistency, and governance constraints

4.1 The Fuel Line

DENSE accelerator nodes can pack eight GPUs delivering petaFLOP/s of aggregate compute, and InfiniBand fabrics can connect thousands of such nodes at hundreds of gigabits per second. Within the fleet stack shown in figure 1.13, data storage completes that physical foundation by providing the fuel supply: training data, model weights, optimizer state, and intermediate checkpoints staged at the right distance from the accelerator. An engine without fuel is expensive sculpture. The engineering question is how to deliver that fuel fast enough that 1,000 accelerators never starve.

Consider the running example for the storage analysis. A 175-billion parameter language model trains on 1.5 trillion tokens of text: roughly 3 TB in compressed source form, or 6 TB once represented as 4-byte token IDs. Each training epoch reads every token once, in a shuffled order determined by the random seed. There is no “hot” subset of data that dominates access; every byte is consumed exactly once per pass. Meanwhile, each accelerator processes its local batch in roughly 200 ms, then waits for the next. If storage cannot deliver data within that 200 ms window, the accelerator sits idle, and the organization pays for silicon that produces heat instead of gradients.

The problem is deceptive because storage technology has improved substantially. NVMe drives achieve 7 GB/s of sequential throughput, a figure that would have seemed out of reach a decade ago. The accelerators, however, improved faster. An H100 GPU consumes data from its HBM at 3.35 TB/s, roughly 478.6× faster than a single NVMe drive can feed it. The gap between storage delivery and accelerator consumption is the central storage tension, and it cannot be solved by any single technology. Instead, it requires a hierarchy of storage tiers, each carefully matched to a specific phase of the ML lifecycle, connected by pipelines that hide latency through prefetching and pipelining.

The storage problem is fundamentally one of physics meeting economics. Physics dictates that data closer to the accelerator (in both physical distance and interconnect hops) can be delivered faster but in smaller quantities. Economics dictates that cheaper storage can hold more data but at greater distance. The engineering art is constructing a pipeline that bridges these constraints, keeping the expensive top tier full by drawing from cheaper lower tiers fast enough that the accelerator never perceives the delay. The resulting design problem is quantitative: how fast each tier must be, how deep the pipeline must run, and which bytes are worth keeping close to the accelerator.

The canonical training-data footprint for this example is roughly 9 TB across the hierarchy, combining the compressed corpus and tokenized shards introduced above. Additional shuffled or packed variants can raise the staging footprint, but the per-epoch training read over 4-byte token IDs is 6 TB. The model generates roughly 1.75 TB checkpoints (1,750 GB total: 350 GB of weights plus 1.4 TB of Adam optimizer state) every 10 minutes. Over a 30-day training run on 256 nodes, the storage system must deliver 6 TB of tokenized training data per epoch, absorb 7.6 PB of checkpoint

Storage is the Infrastructure axis of the fleet stack.

Checkpoint writes dwarf training-data reads by about 1,000 times.

writes, and stage model weights for evaluation runs. These numbers anchor the sections that follow, grounding abstract principles in concrete engineering constraints.

Those numbers force the storage path. ML access patterns first invert the assumptions behind conventional storage systems; that inversion forces a hierarchy from HBM to cold archive; the hierarchy then requires pipeline equations, direct data paths, and economics that decide which bytes belong at each tier. Checkpoints, retrieval indexes, and synthetic-data provenance are variations on the same fuel-line problem: the storage system must place the right representation at the right distance before the accelerator asks for it.

4.2 How ML Workloads Invert Storage Assumptions

A database administrator moving to an ML infrastructure team would find that ML storage workloads invert nearly every storage design principle they relied on. The 175B running example makes the inversion concrete. Each training epoch reads every token, in shuffled order, exactly once. The next epoch shuffles again and reads them all once more. There is no “hot data” in the traditional sense and no 80/20 rule where a small fraction of data accounts for most accesses. The standard storage optimizations fail precisely because they assume the opposite.

Traditional storage systems evolved to serve transactional databases, workloads characterized by small random accesses, strong consistency, and moderate bandwidth. A database server might issue thousands of 4 KB reads per second to serve user queries. The industry optimized for this pattern over decades, developing sophisticated caching algorithms, write-ahead logs, and RAID¹ configurations tuned for small-block random access. Each optimization assumed that the most recently accessed data would likely be accessed again soon.

ML workloads systematically invert these assumptions. Training data access is predominantly sequential, streaming through datasets that span hundreds of terabytes. Individual accesses are large (megabytes rather than kilobytes) because models consume batches of images or text sequences. Consistency requirements are relaxed, since slightly stale features rarely affect model quality. Bandwidth demands, however, are extreme: hundreds of gigabytes per second, sustained for days or weeks. The mismatch between what storage was optimized for and what ML actually needs creates what we call the **I/O wall** (principle 6): when storage throughput cannot deliver training data as fast as accelerators consume it, GPUs idle regardless of their computational power. A storage system that was adequate for 8 GPUs becomes the bottleneck at 64, making the *data pipeline*, not the *model*, the limiting factor. Section B.5.2 classifies this wall as a constraint that lives at the intersection of Communication and Compute in the fleet-scale diagnostic framework, so a storage engineer can confirm that the cure is more bandwidth rather than faster accelerators.

A simple shard-assignment calculation shows how this bottleneck can emerge even when aggregate storage capacity looks ample.

¹ | **RAID (Redundant Array of Independent Disks):** A 1988 Berkeley taxonomy of drive-combining strategies, each trading redundancy against bandwidth (Patterson et al. 1988). ML training inverts the database-era default: RAID 0 (striping, no parity) maximizes sequential read throughput at the cost of zero fault tolerance, a safe trade-off[^fn-raid0-immutable] because training data is immutable and durably backed in object storage. Choosing RAID 5 or 6 instead wastes bandwidth on parity calculations that protect data already protected elsewhere.

Napkin Math 4.1: The thundering herd: Shard contention

Problem: A dataset is split into 1000 shards on a shared file system. If 32 workers each pick a shard at random to start their next epoch, what is the probability that at least two GPUs “collide” on the same storage server, causing a performance bottleneck?

Math: This is a variant of the “Birthday Problem” in probability.

1. **Probability of No Collision:** $\approx e^{-n^2_{\text{workers}}/(2K_{\text{shards}})} = e^{-32^2/2000} \approx 0.60$.
2. **Probability of Contention:** $1 - 0.60 = 40\%$.

Systems insight: Even with a large number of shards, the birthday-problem approximation $1 - e^{-n^2/(2k)}$ yields a 40.1 percent chance of storage shard contention with $n = 32$ workers and $k = 1,000$ shards: a “hot spot” where multiple workers land on the same storage server in the same epoch. In a distributed fleet, these collisions create tail latency: the entire cluster waits for the two GPUs sharing a disk to finish. To solve this, production data loaders use global shuffling and deterministic shard assignment to ensure that workers are perfectly distributed across the storage fabric, eliminating the “thundering herd” effect.

Shard collisions are one runtime symptom of the I/O wall; the hardware trend behind that wall is a widening gap between compute throughput and storage bandwidth.

🔍 Systems Perspective 4.1: The widening I/O wall

Between 2016 and 2024, advertised accelerator Tensor Core throughput grew sharply, but exact ratios depend on whether the comparison holds precision fixed or follows each generation's lowest supported training/inference precision. Over the same period, NVMe sequential bandwidth grew far more slowly, from roughly 3.5 GB/s to 14 GB/s per drive. The compute-to-storage bandwidth ratio has therefore worsened substantially. If that pattern continues, the storage hierarchy must add new tiers (persistent memory, Compute Express Link (CXL)-attached storage) or fundamentally change the data pipeline architecture (compute-near-storage, in-storage processing) to prevent the I/O wall from becoming the binding constraint on training throughput. The durable planning lesson is that compute improvements do not automatically carry the storage path with them.

Figure 4.1 makes this widening gap visually precise by tracking GPU throughput and storage bandwidth side by side on the same timescale.

Figure 4.1: The Storage-Compute Chasm: GPU peak FP16 throughput (blue, left axis) and NVMe sequential read bandwidth (orange, right axis) from 2016 to 2024, both on logarithmic scales. GPU throughput has grown 236× while storage bandwidth has grown only 4× over the same period. The shaded region highlights the widening gap that data pipeline engineering must bridge through prefetching, caching, and format optimization.

Figure 4.1 illustrates *why* the I/O wall is the defining constraint of this chapter. The nearly 60× ratio between GPU throughput growth (236×) and storage bandwidth growth (4×) means that every new GPU generation increases the pressure on the data pipeline. This growth divergence, how fast the gap has widened over the years, is distinct from the static tier-to-tier bandwidth cliffs that later sections quantify, which measure how steep the gap is at a single moment. Without a multi-tier storage hierarchy, prefetching, and format optimization, the expensive accelerators at the top of the stack would spend more time waiting for data than computing on it. The remainder of this chapter examines how each tier of the storage hierarchy addresses a different facet of this chasm.

The first inversion is **access pattern**. Where database workloads exhibit *random access patterns* that benefit from seek-time optimization, ML training performs massive *sequential scans*. A training epoch

reads every sample once, in whatever order the shuffling algorithm produces. This pattern resembles video streaming more than database queries. Storage systems optimized for random IOPS² waste their capabilities on ML workloads, while systems optimized for sequential throughput excel. The distinction is quantitatively dramatic: a Gen4/Gen5 NVMe drive delivers roughly 7–14 GB/s for sequential reads, while small 4 KB random reads can fall near 0.5 GB/s, an order-of-magnitude to 30× penalty for the wrong access pattern. The penalty is even more severe on hard drives, where mechanical seek times impose a 100× throughput reduction for random access compared to sequential.

The shuffling that ML training requires adds a complication rooted in the requirements of stochastic gradient descent. Stochastic gradient descent requires that each mini-batch be drawn approximately uniformly from the training distribution; presenting samples in a correlated order (all samples from the same document, all images from the same class) biases the gradient estimates and slows or destabilizes convergence. True global shuffling would satisfy this requirement perfectly, but it requires random access across the entire dataset, destroying the sequential access pattern that storage hardware demands. For a petabyte-scale corpus, random per-sample seeks are I/O-prohibitive: a dataset of 1 trillion 4-byte tokens stored as individual elements on NVMe, accessed at random, would take thousands of hours to read at the drive’s random-read IOPS rate rather than the few hours achievable with sequential streaming. The practical solution is therefore a compromise: shuffle the order of large data shards, then shuffle samples within each shard’s local buffer. This achieves sufficient randomness for training convergence while preserving the sequential I/O pattern that storage hardware demands. The shard size determines the trade-off: larger shards provide more within-shard shuffle diversity but require more memory for the shuffle buffer.

The second inversion is **working set size**. Traditional applications exhibit temporal locality: a web server repeatedly accesses popular pages, and a cache holding the top 10 percent of content serves 90 percent of requests. ML training datasets are accessed uniformly. Our 6 TB serialized corpus has no “popular” tokens; each is consumed once per epoch. A cache of any practical size holds only a tiny fraction of the dataset, and every sample is effectively “cold” when accessed. This lack of temporal locality renders traditional caching strategies ineffective. Even an LRU³ (Least Recently Used) cache, the workhorse of database systems, achieves a 0 percent hit rate on uniformly accessed data, because by the time a sample is accessed again in the next epoch, it has long been evicted to make room for other samples.

The exception to this uniformity is multi-task or curriculum learning, where certain subsets of the dataset are accessed more frequently during specific training phases. In curriculum learning, the trainer begins with “easy” examples and progressively introduces harder ones. This creates a temporary working set that does exhibit locality, and local caching at the NVMe tier can exploit this structure. For the majority of large-scale pretraining workloads, however, the access pattern is effectively uniform, and the storage system must be designed for full-dataset streaming rather than hot-subset caching.

The third inversion is **write pattern**. Transactional systems generate continuous streams of small writes, each immediately durable. ML systems generate occasional massive writes when saving checkpoints. A 175B parameter model checkpoint, including optimizer state, occupies roughly 1,750 GB. Saving it every 10 minutes generates concentrated bursts that saturate bandwidth for seconds, followed by long idle periods. Together, these bursts form a **checkpoint storm**: a synchronized checkpoint-write event that parallel file systems must absorb without disrupting ongoing training reads. The bursty write pattern is particularly challenging because all nodes in the cluster write their checkpoint shards simultaneously. If 128 nodes each write 14 GB, the parallel file system receives 1.8 TB of writes in a single burst, which must complete before the training pipeline can resume. Table 4.1 consolidates these inversions into the procurement rule: optimize for streaming and bursts, not database-style random IOPS.

² | **IOPS (Input/Output Operations Per Second)**: The metric that dominated storage procurement for decades because database workloads issue millions of small random reads. ML training inverts this priority: a pipeline streaming 256 MB shards sequentially needs sustained GB/s throughput, not per-operation speed. Provisioning storage by IOPS rating for an ML workload over-spends on random-access capability the pipeline never exercises.

³ | **LRU (Least Recently Used)**: LRU’s optimality proofs assume temporal locality, the property that recently accessed data will be accessed again soon. ML training’s uniform-access-per-epoch pattern violates this assumption maximally: every sample is accessed exactly once, making LRU’s eviction decisions no better than random. Teams that provision a large DRAM cache expecting database-like hit rates on training data discover 0 percent reuse, wasting memory that would be better allocated to prefetch buffers.

Table 4.1: ML Workloads Invert Traditional Storage Assumptions: Where databases optimize for random IOPS with cacheable working sets, ML training streams sequentially through datasets that exceed all cache levels.

Workload Pattern	Traditional Assumption	ML Reality
Access pattern	Random access	Sequential streaming

Workload Pattern	Traditional Assumption	ML Reality
Working set	Fits in cache	Exceeds all cache levels
Write pattern	Continuous small writes	Bursty large writes
Read/write ratio	Balanced	Phase-dependent (100:1 to 1:0)
Locality	Strong temporal locality	No locality (uniform sampling)

As table 4.1 shows, these inversions have a fourth, subtler dimension: the read/write ratio shifts dramatically by lifecycle phase. During training, reads dominate writes by 100:1 or more, as the system streams through data continuously and saves checkpoints occasionally. During checkpoint-heavy phases in fault-prone clusters, writes can briefly dominate. During data preprocessing, both reads and writes are heavy, and the access pattern more closely resembles a MapReduce job than a training loop: tokenization, deduplication, and shuffling scan the raw corpus once (large sequential reads), write intermediate artifacts (large sequential writes), and then scan those artifacts again for the next stage. A single 1 TB text corpus typically expands to 6 TB of tokenized shards before the first training epoch begins, loading each storage tier differently from the read-only training phase that follows. No single storage configuration optimizes for all phases, which is why ML systems require a multi-tier hierarchy rather than a single storage technology.

A fifth inversion emerges when comparing training and inference workloads. *Training* reads datasets sequentially and writes checkpoints in bursts. *Inference*, by contrast, reads model weights once at startup (a large sequential read of potentially hundreds of gigabytes), then performs no further storage I/O during normal operation because the model resides entirely in HBM. The storage challenge for inference is cold-start latency: the time required to load a model from storage to HBM when scaling up or recovering from failure. Because the model is read once and then resident, the binding constraint flips from sustained streaming throughput to a single bulk read whose duration depends entirely on which tier supplies the weights, with a parallel file system taking several times longer than local NVMe. Section 4.6.3 derives the concrete load times for a 175B model. For serving workloads with strict availability requirements, this cold-start time drives the design toward keeping warm replicas in host DRAM or using model sharding to parallelize the load across multiple storage devices.

When scaling from a single user to thousands of concurrent inference requests, the storage challenge shifts from a single-stream throughput problem to a massive fan-out distribution problem. A serving cluster with 100 replicas of our 175B parameter model requires 35 TB of model weights distributed across the cluster. When a new model version is deployed (a **model rollout**), all 100 replicas must be updated, triggering a 35 TB data distribution event that must complete within minutes to minimize serving disruption. This is analogous to the checkpoint storm in training but in reverse: Instead of many nodes *writing* to a central location simultaneously, many nodes are *reading* the same data simultaneously. The storage system must sustain this burst read bandwidth for model distribution while continuing to serve inference requests from the existing model version without degradation.

These inversions have direct consequences for system procurement and architecture. An organization provisioning storage for ML based on database-era heuristics will over-invest in random IOPS (which ML does not need), under-invest in sequential bandwidth (which ML desperately needs), and fail to account for the bursty write patterns that checkpointing creates.

Checkpoint 4.1: Storage workload analysis

You are designing the storage subsystem for a new ML training cluster with 512 GPUs. The primary workload will train large language models on a 10 TB text dataset.

- ☐ **Database heuristics:** Use the five storage workload inversions to name at least three database optimization strategies that would be counterproductive for this workload.

- ❑ **Epoch reads:** Calculate the total data volume read when each training epoch reads the full 10 TB dataset once and the cluster trains for 100 epochs, then compare it to a typical database workload.
- ❑ **Checkpoint bandwidth:** Calculate the minimum write bandwidth required when the model saves a 500 GB checkpoint every 15 minutes and each save must complete within 30 seconds.
- ❑ **Write duty cycle:** Calculate the percentage of time the storage system spends in “write mode” vs. “read mode” under bursty checkpoints every 15 minutes.

Understanding which storage tier can keep accelerators fed is essential to system design. Figure 4.2 plots the required I/O throughput to sustain full GPU utilization against model size, with horizontal ceilings for each storage tier overlaid. Below the NVMe ceiling, local SSDs can sustain the training feed; between NVMe and parallel-filesystem ceilings, only Lustre-class storage suffices; and beyond the parallel-filesystem ceiling, the workload enters the storage-bottleneck regime where no single tier can sustain the accelerators on its own.

Figure 4.2: The Storage Bottleneck Zone: Required I/O throughput (GB/s) for full GPU utilization vs. model size (parameters, 100M to 175B). The red curve shows storage demand growing with model size; horizontal dashed lines mark the ceilings for common storage tiers (NVMe at 7 GB/s, Object at 50 GB/s, Lustre at 100 GB/s). Between the Compute-Bound and Storage-Bottleneck regions lies the transition where storage, not compute, limits training throughput.

The storage-bottleneck region in figure 4.2 widens with model size: as parameter counts grow, the required throughput rises faster than commodity storage tiers can supply, pushing larger models into regimes where only parallel filesystems or sharded object storage can sustain the training feed. At small request sizes, the gap also widens between sequential and random access: at 4 KB, sequential reads outperform random reads by $10\times$. This is *why* datasets stored as millions of small files (the “small file problem”) perform catastrophically on ML workloads, even on high-bandwidth storage: the storage service spends its time on metadata rather than payload bytes, the same failure mode that large-scale file systems identify as a metadata bottleneck (Shvachko et al. 2010). The ML-specific response is to aggregate small samples into large sequential shards (Aizman et al. 2019).

The practical consequence for our running example is stark. The 1.5 trillion tokens of training data produce roughly 6 TB of sequential token-ID reads per epoch, even though the compressed source corpus is only 3 TB. If each token were stored as an individual file (as naive data collection might produce), the metadata overhead alone would throttle throughput to a fraction of what the storage hardware can deliver. Instead, the data must be preprocessed into large sequential shards so that each read operation amortizes the fixed overhead of file open, seek, and close across many tokens. This preprocessing step transforms the access pattern from metadata-heavy one-file-per-sample access to sequential shard reads (Aizman et al. 2019), keeping the workload below the storage ceiling shown in figure 4.2 and setting up the hierarchy that bridges accelerator appetite and storage capacity.

4.3 The ML Storage Hierarchy

A system architect must organize storage to serve workloads that simultaneously demand terabytes-per-second bandwidth for computation, petabyte-scale capacity for datasets, and extreme durability for checkpoints. No single technology satisfies all three requirements. HBM provides bandwidth but not capacity. Object storage provides capacity and durability but not bandwidth. The resolution is a multi-tier hierarchy that places small amounts of fast, expensive storage close to the accelerator and large amounts of slow, cheap storage at the periphery. Each tier exists because it resolves a specific tension between physics (bandwidth and latency are governed by distance from the accelerator) and economics (cost per bit decreases as capacity increases). The hierarchy extends the classic processor memory hierarchy (registers, L1/L2 cache, DRAM) that students encounter in computer architecture courses, adding tiers below DRAM that are unique to large-scale data systems. Table 4.2 reveals the extreme bandwidth disparities that ML systems must navigate.

Table 4.2: Extended Memory Hierarchy for ML Systems: The roughly $30\times$ aggregate-to-aggregate bandwidth gap between HBM and object storage (and a much larger per-client gap once a single inference instance pulls from a shared object endpoint) drives the need for sophisticated prefetching and caching across multiple levels.

Storage Tier	Typical Capacity	Bandwidth	Latency	Cost (\$/GB)
GPU HBM	80 GB	3.35 TB/s	~ 100 ns	~ 15.00
Host DRAM	512 GB–2 TB	200 GB/s	~ 100 ns	~ 3.00
Local NVMe SSD	4–30 TB	7–25 GB/s	~ 100 μ s	~ 0.10
Parallel File System	100+ PB	1+ TB/s aggregate	~ 1 ms	~ 0.03
Object Storage	Very large pool	100 GB/s aggregate	~ 50 ms	~ 0.02
Archive/Cold Storage	Very large pool	1 GB/s	Minutes to hours	~ 0.004

One reading of table 4.2 is worth flagging: HBM’s advantage over host DRAM is *bandwidth*, not *latency*. Random-access latency for both technologies sits in the ~ 80 – 150 ns range; HBM achieves its bandwidth lead (10 – $20\times$) through thousands of parallel traces on a silicon interposer and 3D stacking, not faster cells. The latency cliff between adjacent tiers only opens up at NVMe and below, where the physical distance from the accelerator grows from millimeters to meters.

The storage hierarchy principle (principle 7) governs every design decision in this chapter. Storage performance decreases and capacity increases as data moves further from the accelerator: each tier in table 4.2 drops bandwidth by 10 – $100\times$ while increasing capacity by 10 – $100\times$. Data format choices, caching strategies, prefetch buffer sizing, and tiering policies all exist to manage the movement of data upward through the hierarchy so that the accelerator never starves.

Figure 4.3 maps these six tiers into a spatial hierarchy, showing how bandwidth decreases and capacity increases at each step away from the accelerator.

The pyramid in figure 4.3 encodes a fundamental trade-off: every step down the hierarchy trades bandwidth for capacity and cost. This trade-off is not arbitrary; it reflects the physics of data proximity. HBM sits on the same silicon interposer as the accelerator, connected by thousands

Figure 4.3: ML Storage Hierarchy: Storage tiers grouped into Hot, Warm, and Cold bands, from GPU HBM (terabytes per second, gigabytes of capacity) down to tape archive (sub-gigabyte-per-second bandwidth, very large capacity), with cost per gigabyte changing inversely. The figure adds two tiers beyond the five-level model the prose develops, a legacy SATA SSD tier and the tape archive, to show the full span of the trade-off; the shared object storage and parallel file system tier is filled red because it is the bottleneck that starves a large cluster, the tier whose bandwidth cliff the rest of the chapter works to hide. The figure uses illustrative values to make the bandwidth-vs.-capacity trade-off visible at a glance; the canonical per-tier numbers used throughout this chapter come from table 4.2, which is the source of truth where the figure and the table disagree.

of parallel traces measured in millimeters. Host DRAM communicates over PCIe lanes spanning centimeters. NVMe reaches across a circuit board via a PCIe connector. The parallel file system traverses meters of cable and network switches. Object storage may span kilometers of fiber between data centers. At each level, the increasing physical distance translates directly into increased latency, decreased bandwidth per connection, and decreased cost per byte (because the same medium can store more data at lower density).

The engineering challenge is to ensure that data flows upward through the pyramid fast enough that the top tier (HBM) is never empty when the accelerator needs it. Return to our running example: the durable corpus lives in object storage (Tier 4) as a 3 TB compressed source copy plus 6 TB of tokenized training shards, but the accelerator needs each batch in HBM (Tier 0) within 200 ms. The data must be promoted through intermediate tiers, staged in progressively faster storage, so that by the time the accelerator requests a batch, it is already waiting in host DRAM, one PCIe transfer away from HBM.

4.3.1 Bandwidth cliffs between tiers

The bandwidth ratios between adjacent tiers reveal the severity of each transition in the hierarchy. Between HBM and host DRAM, the ratio is roughly 16.8× (3.35 TB/s vs. ~200 GB/s). Between host DRAM and NVMe, the ratio is roughly 7.1× (200 GB/s vs. ~28 GB/s from a 4-drive RAID-0). Between NVMe and a parallel file system, the ratio depends on the per-node allocation: if a 1 TB/s aggregate PFS serves 256 nodes, each node receives roughly 4 GB/s, a 7× reduction from local NVMe. Between the parallel file system and object storage, the ratio is typically 10× or more, depending on the number of concurrent clients and network bandwidth.

These bandwidth cliffs have a critical implication: the pipeline cannot simply “stream through” the hierarchy in real time. If the accelerator consumes data at 3.35 TB/s from HBM, and the next

tier down delivers only 200 GB/s, then HBM can be emptied in under 50 ms but takes 400 ms to refill from host DRAM. The only way the accelerator avoids stalling is if the batch it needs next is already in HBM before it finishes the current batch. This is *why* every tier in the hierarchy serves as a prefetch buffer for the tier above it: host DRAM buffers data for HBM, NVMe buffers data for host DRAM, the parallel file system buffers data for NVMe, and object storage is the ultimate source of truth. Each buffer must be deep enough to absorb the latency and bandwidth variance of the tier below it.

The bandwidth arithmetic also explains *why* increasing cluster size creates storage pressure. A single node with 8 GPUs needs roughly 4 to 40 GB/s of storage bandwidth (depending on workload). A cluster of 256 such nodes needs 1,000 to 10,000 GB/s. A cluster of 10,000 nodes needs 40 to 400 TB/s. At the upper end, even a world-class parallel file system with 1,000 object storage servers (the data-serving nodes introduced in the parallel file system tier below) delivering 1 TB/s aggregate cannot satisfy the demand, and the architecture must rely on local NVMe caching to reduce the load on shared storage. The severity of that cluster-level pressure depends sharply on the data modality.

Napkin Math 4.2: Text vs. image bandwidth

Problem: How much aggregate storage bandwidth does a 2,048-GPU cluster require for text training versus image training?

Setup: The bandwidth demand depends entirely on the data modality.

For **text training**, the demand is surprisingly low. With a typical batch size of 4,096 tokens per GPU and a 200 ms step time, the aggregate bandwidth is:

$$2,048 \text{ GPUs} \times 4,096 \text{ tokens/GPU} \times 4 \text{ bytes/token} \div 0.2\text{s} \approx \mathbf{167.8MB/s}$$

This is easily served by a single network-attached storage node.

For **image training**, the picture changes dramatically. Using a common batch size of 256 per GPU (ImageNet at 224×224 , roughly 150 KB/image), the aggregate bandwidth explodes:

$$2,048 \text{ GPUs} \times 256 \text{ images/GPU} \times 150 \text{ KB/image} \div 0.2\text{s} \approx \mathbf{393.2GB/s}$$

This is about 2,300× higher than the text workload and requires a high-performance parallel file system. This fundamental difference drives hierarchy design: text training is *volume-heavy* but *bandwidth-light*, bottlenecked by total dataset size and checkpointing; image training is *bandwidth-heavy*, bottlenecked by the storage system’s ability to feed the accelerators.

The bandwidth cliff between tiers also has implications for the data format at each level. At the HBM tier, data must be in the format the accelerator can directly compute on: float16 tensors, packed token IDs, or preprocessed feature vectors. At the NVMe tier, data can be in a more compact format (compressed JPEG, tokenized text with dictionary encoding) because the CPU has time to decode it while the accelerator processes the previous batch. At the object storage tier, maximum compression is desirable to minimize both storage cost and transfer time, even if decompression adds CPU overhead. The format transition from compressed storage to compute-ready tensors is part of the pipeline’s “value-added” work, transforming raw bytes into the representation that the accelerator needs. This transformation happens in host DRAM, which is *why* host DRAM serves as the critical staging area for the pipeline.

The format challenge intensifies for multi-modal training, which combines text, images, audio, and video in a single model. Each modality has a dramatically different data profile: a text token is 4 bytes, a high-resolution image is 150 KB, and a short video clip is 10 MB. They also have different compression characteristics and require different augmentation pipelines. A multi-modal training job must manage multiple parallel data streams, each with its own bandwidth profile and prefetch requirements. The storage hierarchy must be provisioned for the sum of all modalities’ bandwidth demands, not the dominant one alone. For a training job combining 3 TB of text with 50 TB of images and 200 TB of video, the video modality overwhelmingly dominates both storage capacity and I/O bandwidth requirements, even though the text modality may contribute more to model quality.

This asymmetry between storage cost and training value is a recurring challenge in multi-modal system design.

The descent starts where computation actually consumes bytes: HBM, the tier fast enough to keep accelerator arithmetic fed but far too scarce to hold the full training corpus.

4.3.2 Tier 0: GPU HBM

The most constrained resource in the entire system is also the most scarce. High Bandwidth Memory (HBM) is the only storage tier where weights and activations can reside during active computation. As established in section 2.3.1, HBM is a 3D-stacked memory technology that places DRAM dies vertically atop the accelerator, connected by thousands of through-silicon vias that provide aggregate bandwidth of 3.35 TB/s on an H100. This bandwidth is roughly $17\times$ higher than the chapter’s 200 GB/s host-DRAM figure and roughly $480\times$ higher than a single 7 GB/s NVMe drive. That bandwidth is what makes large-scale deep learning feasible: a matrix multiplication involving billions of parameters requires reading those parameters from memory every forward and backward pass.

The constraint at this tier is *capacity*, not *bandwidth*. An H100 provides 80 GB of HBM, enough to hold a 40-billion parameter model in FP16 (2 bytes per parameter), but nowhere near enough for the 175B parameter running example. To understand the severity of this constraint, consider the memory budget for training our 175B model. The model weights in FP16 consume 350 GB. The Adaptive Moment Estimation (Adam) optimizer maintains two additional states (momentum and variance) in FP32, consuming $175 \times 10^9 \times 4 \times 2 = 1,400$ GB. Activations for a single batch, depending on sequence length and batch size, can consume another 100 to 400 GB. The total memory footprint reaches roughly 1.85–2.15 TB depending on activation size, approaching or exceeding $25\times$ the capacity of a single H100’s HBM. That $25\times$ is the un-partitioned footprint, which is precisely why the partitioning in table 4.3 is mandatory. From the storage hierarchy perspective, HBM is the destination that every lower tier exists to serve. The data pipeline’s purpose is to ensure that the 80 GB of HBM always contains the data the accelerator needs *next*, not the data it needed *a second ago*.

Because HBM capacity is so limited relative to both model size and dataset size, the accelerator processes data in batches. Each batch occupies a fraction of HBM for the duration of one forward-backward pass, then is discarded to make room for the next. The rate at which batches must be supplied sets the bandwidth requirement for all lower tiers.

That batch lifecycle creates a “spill” dynamic down the hierarchy. When weights alone do not fit in one HBM pool, the system has only two basic choices: split the live weights across accelerators, or keep some state outside HBM and fetch it when needed. For our 175B parameter model, FP16 weights occupy 350 GB, requiring at least five 80 GB H100 accelerators just for weight storage, with no room left for activations or optimizer state. Adam’s FP32 momentum and variance add another 1.4 TB. Sharding this footprint across the cluster makes the run possible, but every shard creates more lower-tier traffic and more coordination. The storage point is that HBM scarcity is what forces the rest of the hierarchy to exist.

The razor-thin margin is a defining feature of large model training. Table 4.3 shows the HBM memory budget for training our 175B parameter model on a single H100 GPU with 80 GB of HBM. The table treats partitioning as a storage layout: model weights are split eight ways inside the node, while optimizer and gradient state are sharded across 256 nodes. The purpose is not to derive the partitioning algorithm, but to show the storage pressure HBM sees.

Table 4.3: HBM Memory Budget for 175B-Parameter Training: Per-GPU allocation when splitting a 175B model eight ways inside the node and sharding optimizer and gradient state across 256 nodes. The optimizer and gradient rows are per-GPU shards after both levels of partitioning. The resulting budget occupies most of a 80 GB HBM device, leaving limited buffer for the incoming data pipeline. Any delay in fetching the next batch from host memory risks starving the accelerator.

Component	Size per GPU
Model Weights (FP16, 8-way shard)	43.75 GB
Optimizer State (node-sharded)	0.7 GB
Activations (variable by sequence length)	10–20 GB
Gradient Buffers (FP16, node-sharded)	0.2 GB

Component	Size per GPU
Communication Buffers (NCCL)	2–4 GB
Total Occupied	56.6–68.6 GB

Even with aggressive partitioning, the total memory footprint reaches 56.6–68.6 GB on a decimal gigabyte basis—about 65.9–79.9 percent of the 80 GB HBM pool when measured against its binary capacity. This leaves a limited buffer for the incoming data pipeline, especially once fragmentation and framework workspaces are included. Any delay in fetching the next batch from host memory risks starving the accelerator, forcing it to sit idle while the most expensive resource in the system produces heat instead of gradients.

The batch lifecycle within HBM illustrates how transient storage at this tier truly is. When a new training batch arrives from host DRAM via PCIe, it is placed in a preallocated input buffer in HBM. The forward pass reads the input data, reads the model weights (which persist across batches), and writes activations to HBM. The backward pass reads the activations, computes gradients, and writes gradient updates. The optimizer step reads gradients and model weights, computes updated weights, and writes them back. After the optimizer step, the input batch and activations are no longer needed and their HBM regions are freed for the next batch. The entire lifecycle of an input batch in HBM, from arrival to deallocation, spans a single training step: typically 100 to 500 ms. Model weights and optimizer state, by contrast, persist in HBM for the entire training run, occupying a fixed allocation that cannot be reclaimed for batch data.

From the data pipeline’s perspective, Tier 0 is not a storage tier to be managed but a constraint to be satisfied. The pipeline’s purpose is to ensure that the batch the accelerator needs *next* is already resident in HBM before the *current* batch’s computation completes. If it arrives late, the accelerator stalls. If it arrives early, it consumes HBM that could hold activations. The tension between “just in time” and “just too late” defines the pipeline’s buffer management strategy, which we quantify in section 4.4.

4.3.3 Tier 1: Host DRAM

One level below HBM, host DRAM serves as the staging area for the data pipeline. Every byte of training data that reaches the accelerator passes through host DRAM first (unless GPUDirect Storage bypasses it, as described in section 4.5). A typical training node contains 512 GB to 2 TB of system memory shared across the host CPU and its peripherals. While the bandwidth between host DRAM and the accelerator is limited to what PCIe Gen 5 (about 64 GB/s per direction, 128 GB/s bidirectional) or NVLink (900 GB/s) can provide, host DRAM plays three critical roles in the ML storage hierarchy.

The data loader pipeline that runs in host DRAM follows four ordered stages:

1. **Read:** I/O threads read compressed data from NVMe or network storage into read buffers.
2. **Decode:** Decode threads decompress the data, such as JPEG decoding for images or decompression for text.
3. **Augment:** Augmentation threads apply transformations, including random cropping, flipping, and normalization for images or tokenization and sequence packing for text.
4. **Collate:** The collation stage assembles individual samples into batches and places them in **pinned memory** for efficient DMA transfer to the accelerator.

That final placement matters because pinned, or page-locked, memory (exposed in PyTorch as `pin_memory=True` on the `DataLoader`) prevents the operating system from paging out the buffer before the DMA transfer completes, allowing the NVMe controller to write directly into a physical address that the PCIe DMA engine can reach without an extra copy. Each stage runs concurrently, forming a pipeline that overlaps I/O, CPU computation, and data transfer. The efficiency of this pipeline determines whether host DRAM can keep up with the accelerator’s appetite.

Host DRAM’s most critical function is serving as a **prefetch buffer**. The CPU data loader reads data from lower tiers (NVMe or network storage), decodes compressed formats (JPEG, gzip), applies augmentations (random crops, flips, color jitter), and assembles tensors in host DRAM. By the time

the accelerator finishes processing batch i , batch $i + 1$ should already be assembled in host memory, ready for transfer to HBM. The depth of this prefetch buffer determines how much I/O variance the pipeline can absorb without stalling.

Recommendation workloads place a different demand on host DRAM: hosting **embedding tables** that can exceed 100 GB, far too large for HBM. These tables reside in host DRAM and are accessed through lookups that fetch only the rows needed for the current batch. The bandwidth between host DRAM and HBM becomes the critical bottleneck for these workloads, which is *why* some systems use CPU-side DRAM with RDMA to serve embedding lookups across the network.

Host DRAM also provides the **augmentation workspace** that the CPU pipeline requires. Data augmentation operations (resizing images, tokenizing text, applying noise) execute on the CPU and require temporary memory for intermediate results. A training pipeline that applies five augmentations to a 256-image batch at 150 KB per image needs tens of megabytes of working space for each augmentation stage. Although modest per-batch, this memory accumulates when multiple data loader workers run in parallel.

Some augmentation pipelines have moved from CPU to GPU execution, using libraries like NVIDIA Data Loading Library (DALI) to perform image decoding and augmentation on the accelerator itself. This approach eliminates the CPU augmentation bottleneck and reduces the host DRAM bandwidth demand, because compressed data (smaller) is transferred to the GPU instead of decoded data (larger). The trade-off is that augmentation on the GPU consumes HBM capacity and compute cycles that would otherwise be available for training. For *compute-bound* workloads (where the GPU is already saturated with matrix multiplications), GPU-based augmentation is counterproductive. For *I/O-bound* workloads (where the GPU waits for data), it can improve overall throughput by shifting work from the bottleneck (CPU) to the resource with spare capacity (GPU).

The three roles interact in subtle ways. The prefetch buffer and the augmentation workspace compete for the same physical DRAM, and embedding tables consume capacity that could otherwise serve as deeper prefetch queues. A node with 512 GB of DRAM hosting a 200 GB embedding table has only 312 GB remaining for prefetching and augmentation. If the data loader uses 8 workers, each maintaining a decode buffer of 1 GB, the effective prefetch capacity drops further. System architects must balance these competing demands by profiling the actual memory consumption of each pipeline stage and provisioning DRAM accordingly.

The physical layout of DRAM has performance implications that are invisible in single-socket benchmarks but critical at production scale. Multi-socket servers exhibit Non-Uniform Memory Access (NUMA) topology where each CPU socket has “local” DRAM that it can access at full bandwidth and “remote” DRAM attached to the other socket at roughly half bandwidth. In a dual-socket DGX node with eight GPUs split four per socket, a data loader thread running on socket 0 that allocates its prefetch buffer in socket 1’s DRAM pays a roughly $2\times$ bandwidth penalty on every buffer access. The fix is **NUMA-aware allocation**: pin each data loader worker to the same CPU socket (the same NUMA domain) as the GPUs it serves, and use `numactl` or `libnuma` to ensure memory allocation stays local. Proper NUMA pinning can improve data loading throughput by 30–50 percent on dual-socket systems, a gain that is invisible in development environments but essential when every percentage point of utilization translates to thousands of dollars per day.

The gap between host DRAM bandwidth and HBM bandwidth is the first major cliff in the hierarchy: roughly $16.8\times$ using the chapter’s 200 GB/s host-DRAM reference and 3.35 TB/s HBM figure. The host-to-GPU interconnect adds a separate cliff, with effective transfer bandwidth depending on whether the node uses PCIe or NVLink. Any failure to keep host DRAM populated from lower tiers cascades immediately to accelerator starvation, because the accelerator cannot fetch directly from NVMe or network storage. In our running example, the 256-node cluster requires each node’s host DRAM to sustain a continuous flow of decoded, augmented batches ready for PCIe transfer. If the NVMe-to-DRAM read pipeline falls behind by even a few hundred milliseconds, the prefetch buffer drains and the accelerator idles until the next batch arrives.

4.3.4 Tier 2: Local NVMe

When the working set exceeds host DRAM, the system falls to Tier 2: the local NVMe drives attached directly to the compute node. NVMe⁴ provides a high-performance protocol designed specifically for solid-state drives, achieving 7 GB/s of sequential throughput per drive. With four drives in a

4 | **NVMe (Non-Volatile Memory Express)**: A storage protocol designed for SSDs, connecting directly to the CPU via PCIe lanes. NVMe replaced Advanced Host Controller Interface (AHCI)’s single queue of 32 commands with 64K queues of 64K commands each, a 130-million-fold increase in maximum outstanding I/O. This deep queue parallelism is what allows a multi-worker ML data loader to saturate the drive’s bandwidth; with AHCI, 32 workers would serialize on the single command queue regardless of flash speed.

RAID-0 configuration, a single node can sustain roughly 28 GB/s of sequential reads before overhead, sufficient to stream the 6 TB serialized dataset from local disk in about 3.6 minutes under ideal sequential conditions.

In ML training, local NVMe acts as a **warm cache**, storing data shards fetched from distributed storage. This design allows workers to re-read samples across multiple epochs without re-traversing the network. For multi-epoch training on petabyte-scale datasets, the network egress cost of re-fetching from object storage each epoch would be prohibitive (as we quantify in section 4.6). Populating local NVMe from shared storage at job start and reading locally thereafter eliminates both cost and latency.

The warm cache pattern requires careful capacity planning. A training node with four 7.68 TB NVMe drives provides approximately 30.7 TB of local storage. For our running example, the 6 TB serialized dataset fits comfortably on a single node's local storage, with room for checkpoint staging and temporary augmentation buffers. A multi-modal training job combining 20 TB of images, 10 TB of text, and 5 TB of audio totals 35 TB, exceeding local capacity by about 4.3 TB and forcing the pipeline to stream from the parallel file system for at least part of the dataset. The design trade-off is between provisioning more local NVMe (which increases node cost) and accepting network-dependent reads (which risks latency spikes).

NVMe's internal parallelism is key to its throughput advantage over traditional storage. The NVMe specification supports up to 65,535 I/O queues, each with up to 65,536 outstanding commands. A data loader with 32 workers, each issuing asynchronous reads, can keep the NVMe controller's internal pipeline saturated. In contrast, the legacy AHCI protocol that NVMe replaced supported a single queue of 32 commands, throttling parallelism at the protocol level regardless of the underlying medium's capability. This architectural difference explains why NVMe delivers 10× to 50× the throughput of SATA SSDs with identical NAND flash, even though the storage medium is the same.

Data format design for sequential I/O

The choice of data format on local NVMe has a dramatic impact on effective throughput. Consider three approaches to storing a 1.28 million image dataset.

The first approach stores each image as a separate JPEG file in a directory hierarchy. This format is natural for data collection (download one image, save one file) but adversarial for training I/O. Each `open()` system call has a fixed overhead of roughly 10–50 μs in the kernel's Virtual File System (VFS) layer. At 8,000 images per second, the overhead alone consumes 80–400 ms of CPU time per second. Worse, the directory structure forces the file system to maintain an inode for each file, consuming metadata resources that would otherwise be available for data reads.

The second approach packs all images into a small number of large binary files (such as HDF5, LMDB, or raw concatenated tensors with an index file). Each file contains thousands of images stored contiguously, and a separate index maps sample IDs to byte offsets within the file. The data loader seeks to the desired offset and reads the sample directly. This eliminates the per-file metadata overhead and enables sequential access within each binary file. The disadvantage is that the dataset is no longer human-readable, and modifying a single sample requires rewriting the entire file.

The third approach uses the tar-based archive format popularized by WebDataset. Each sample is stored as a group of related files (image, label, metadata) within a standard POSIX tar archive. The tar format supports sequential iteration without a separate index, because each file's header contains its size, allowing the reader to skip forward to the next sample. This format combines the simplicity of individual files (each sample is self-describing) with the sequential I/O efficiency of large binary files. The tar archives are also valid HyperText Transfer Protocol (HTTP) byte-range targets, making them directly streamable from object storage without local staging.

For our running example, the 1.5 trillion token dataset is typically stored as a collection of 256 MB to 4 GB binary shards, each containing a contiguous sequence of tokenized text. The data loader opens a shard, reads it sequentially into a buffer, and iterates over tokens within the buffer. When the buffer is exhausted, the loader opens the next shard. The total number of `open()` calls per epoch is the number of shards (roughly 2,000 if the 6 TB serialized corpus is split into 3 GB shards), not the number of tokens (trillions). This approximately 750,000,000× reduction in metadata operations is what makes streaming from both local NVMe and remote storage feasible at training scale.

At the NVMe tier, compression represents a critical trade-off between I/O bandwidth and CPU cycles. An I/O-bound pipeline, where the NVMe drives cannot keep up with accelerator demand,

benefits from aggressive compression: zstd at level 9 achieves roughly 4:1 compression but decompresses at only 0.5 GB/s per CPU core. A CPU-bound pipeline, where decode and augmentation already saturate the host processor, prefers lighter compression: zstd at level 1 offers roughly 3:1 compression but decompresses at 1.5 GB/s per core. On a 28 GB/s four-drive NVMe RAID array, zstd-1 delivers an effective throughput of 84 GB/s of uncompressed data, while zstd-9 delivers 112 GB/s but requires $3\times$ more CPU cores dedicated to decompression. The optimal compression level is therefore not a property of the data but a property of the pipeline's bottleneck, and it can change when the cluster configuration changes (adding more GPUs shifts the bottleneck toward I/O, favoring heavier compression).

A standard ImageNet training pipeline makes the cost of the wrong format visible.

Napkin Math 4.3: The ImageNet bottleneck analysis

Problem: A ResNet-50 training job on ImageNet (1.28M, ~150 KB average) targets 1000 images/s. The question is whether to use individual JPEG files on an HDD or NVMe.

Math:

1. **Raw Bandwidth:** $1000 \text{ images/s} \times 150 \text{ KB} = 150 \text{ MB/s}$.
2. **HDD reality:** A 7200 RPM hard disk drive (HDD) delivers 100 IOPS at random reads. Sustaining 1000 images/s requires $10\times$ more IOPS than the disk provides.
3. **Result:** Shuffling individual files on an HDD will starve the GPU, capping utilization at about 10 percent before decode, seek, and file-system overheads.

Systems insight: The pipeline must either use NVMe ($\sim 100 \mu\text{s}$ random access, three orders of magnitude faster than object storage) or convert the dataset to a sequential format (TFRecord/WebDataset) to achieve sequential throughput.

The central challenge at this tier is the I/O wall: a single NVMe drive is roughly $500\times$ slower than HBM, and even a four-drive RAID-0 stripe remains roughly $120\times$ slower. Bridging this gap requires pipelining (overlap I/O with compute, detailed in section 4.4) and, increasingly, GPUDirect Storage (detailed in section 4.5) to bypass CPU overhead entirely. The I/O wall at this tier is particularly insidious because NVMe performance is excellent by historical standards. A storage engineer accustomed to HDD-era throughput of 100 MB/s might view 28 GB/s from a local RAID-0 stripe as superabundant. Relative to the accelerator's appetite, however, 28 GB/s is a trickle. The only way to bridge the gap is to overlap storage reads with computation so thoroughly that the accelerator never perceives the storage delay.

Local NVMe is also the primary tier for **local checkpoint staging**. When saving a model checkpoint, the fastest strategy is to write to local NVMe at full bandwidth (minimizing the time the training pipeline is paused), then asynchronously replicate to shared storage for durability, since a per-node shard written directly to a contended parallel file system takes several times longer than the same shard written to local drives. The optimal checkpoint frequency depends on cluster failure rates and checkpoint write time, but the storage-side design goal is already clear: minimize T_{write} through tiered staging by writing to local NVMe at full bandwidth, then background-copying to shared storage. Section 4.7 works the timings through in full.

The same local NVMe tier also pays for itself by recovering utilization lost to remote-read latency.

Napkin Math 4.4: ROI of local NVMe caching

Problem: A vision-model training pipeline runs each step in 800 ms. Fetching data from a shared Parallel File System adds 150 ms of I/O wait because of network congestion. How much does adding local NVMe SSDs to each node improve GPU utilization?

Math: GPU utilization (η_{hw}) is the fraction of step time spent in computation.

1. **Remote Only:** $800 \text{ ms} / (800 \text{ ms} + 150 \text{ ms}) \approx 84.2 \text{ percent}$.

2. **Local Cache:** Using prefetching into local NVMe reduces the exposed I/O wait to near zero.

- New Util: $800 \text{ ms} / (800 \text{ ms} + 10 \text{ ms}) \approx 98.8 \text{ percent}$.

Systems insight: Local storage is a *GPU utilization multiplier*. In this scenario, adding a \$500 NVMe drive to a \$30,000 GPU node recovers 14.6 percent of the GPU’s capacity that was previously wasted on I/O wait. Across a 1,024-GPU cluster, that utilization gain is equivalent to adding 149 GPUs worth of useful work without buying that many more accelerators. In ML infrastructure, local NVMe is not auxiliary; it is the physical buffer that decouples expensive compute from unpredictable shared storage.

A practical concern at this tier is **SSD endurance**. NAND flash memory can sustain a limited number of write-erase cycles before the cells degrade. Enterprise NVMe drives are rated for 1 to 3 Drive Writes Per Day (DWPD) over a 5-year lifespan. For a 7.68 TB drive at 1 DWPD, this means the drive can absorb 7.68 TB of writes per day, or roughly 14 PB total over its lifetime. ML training workloads are predominantly read-heavy (the dataset is written once and read many times), which is favorable for SSD endurance. However, checkpoint writes can be intensive: if each node saves a 4 GB checkpoint shard every 10 minutes, that is 576 GB per day of checkpoint writes, well within the 1 DWPD budget. The risk emerges when local NVMe is used as a staging buffer for both checkpoint writes and dataset caching: the combined write volume from initial dataset staging plus repeated checkpoint saves must remain within the drive’s endurance rating.

Local NVMe provides high bandwidth and low latency within a single node, but distributed training requires every node to access the same datasets and see the same checkpoints. This shared-namespace requirement cannot be satisfied by node-local storage alone and motivates the next tier in the hierarchy.

4.3.5 Tier 3: Parallel file systems

Beyond the single node, the workload requires a shared namespace where all workers can access the same datasets and where durable checkpoints are globally visible. This is the role of the parallel file system (PFS).⁵

⁵ | **PFS (Parallel File System):**

A family of distributed file systems (Lustre, GPFS/Spectrum Scale, BeeGFS, WekaFS) whose defining property is that a single client reads from multiple storage servers simultaneously, aggregating their bandwidth into one logical stream. For ML training, this means a single data shard striped across 100 servers can deliver 100× the bandwidth of any individual server, the architectural feature that makes petabyte-scale dataset access feasible within training-iteration time budgets.

Definition 4.1: Parallel file system

Parallel File System (PFS) is a distributed storage architecture for ML training clusters that stripes data across many storage servers to provide aggregate throughput exceeding the capacity of any single device.

1. **Significance:** A PFS aggregates BW_{io} linearly with the number of storage servers (Object Storage Servers). A Lustre cluster with 20 OSS nodes each delivering 10 GB/s provides 200 GB/s aggregate, vs. a single NAS server capped at 10 GB/s, enabling a training job to load a 10 GB striped shard in about 50 ms rather than 1 second. This aggregate bandwidth directly reduces the D_{vol}/BW term in the iron law.
2. **Distinction:** Unlike Network Attached Storage (NAS), where every I/O request routes through a single server, a PFS client receives stripe location metadata from a dedicated Metadata Server (MDS) and then reads data directly from multiple OSS nodes in parallel: the MDS and OSS paths are architecturally separated, so data bandwidth scales with OSS count while metadata operations scale with MDS count.
3. **Common pitfall:** A frequent misconception is that a PFS has unlimited throughput if enough OSS nodes are added. In reality, a Lustre MDS handles roughly 100,000–300,000 metadata operations per second; at 10,000 workers each opening one small file, the MDS saturates in under 1 second and becomes the serialization point that idles the entire cluster regardless of how many OSS nodes are present.

The architecture of a Lustre-style parallel file system separates two concerns that traditional file systems handle together (Schwan 2003). **Metadata Servers (MDS)** manage the namespace: file creation, directory listings, permission checks, and lock management. **Object Storage Servers (OSS)**⁶ manage the actual data blocks, each serving a stripe of every large file. When a client opens a 10 GB training shard, the MDS tells the client which OSS nodes hold which stripes, and the client reads from all of them in parallel. A Lustre⁷ deployment with 100 OSS nodes, each providing 10 GB/s, delivers an aggregate 1 TB/s.

This abstract architecture has concrete implications for performance tuning. When a training job creates a new dataset directory on Lustre, the administrator configures the **stripe count** (the number of OSS nodes a file is spread across) and **stripe size** (the chunk size written to each OSS) for that directory (Lustre Wiki 2017). For large sequential-read training shards, administrators may choose wider striping and multi-megabyte stripe sizes so a single file can draw bandwidth from multiple OSS nodes; Lustre’s striping guide treats wide striping as useful for very large files or files accessed by many clients, while smaller files often use fewer stripes to reduce overhead (Lustre Wiki 2019). A 4 GB data shard striped across 100 OSS nodes with 4 MB stripes places roughly 10 stripes on each OSS. When a data loader reads large contiguous ranges, the Lustre client can issue parallel read requests to the OSS nodes holding those stripes, aggregating their bandwidth. The client also maintains its own read-ahead buffer, prefetching the next several stripes while the application processes the current ones. This file-system-level read-ahead is distinct from the data loader’s application-level prefetch buffer; the two layers of prefetching compound to provide deep latency hiding, making the physical distance to the OSS nodes nearly transparent to the training process.

The separation between metadata and data paths is what enables the aggregate bandwidth that ML workloads demand. In GPFS⁸ (IBM Spectrum Scale), the architecture takes a different approach: it stripes data and metadata across shared disks and coordinates concurrent access through token-based distributed locking (Schmuck and Haskin 2002). The result is not a simple MDS/OSS split; it is a shared-disk design whose metadata and data placement can be distributed while the lock protocol preserves consistency across clients. The trade-off is greater complexity in lock management, which must scale to thousands of nodes.

This separation creates a critical bottleneck: the small file problem. If a dataset consists of millions of 10 KB images stored as individual files, the metadata load overwhelms the MDS long before the data links saturate. Each `open()` system call requires a metadata lookup, lock acquisition, and attribute fetch. With 10,000 workers simultaneously calling `open()` on different files, the MDS becomes the serialization point. The throughput of the storage system collapses to the rate at which the MDS can process metadata operations, typically a few hundred thousand per second, far below what the data path could deliver.

Definition 4.2: Small file problem

Small File Problem is an ML data-loading pathology where millions of individually small files overwhelm the metadata server of a storage system.

1. **Significance:** It reduces effective I/O Bandwidth (BW_{io}) to a fraction of its theoretical rating because each file requires its own metadata operations (`open`, `stat`, `close`). With 10,000 workers simultaneously accessing small files, the metadata server becomes a Serialization Point that idles the entire cluster.
2. **Distinction:** Unlike bulk data throughput (which measures bit-rate), the small file problem is a metadata latency (L_{lat}) issue: the bottleneck is the frequency of requests, not the size of the data.
3. **Common pitfall:** A frequent misconception is that this is “fixed” by buying faster SSDs. In reality, it is a Format Problem: the fix is to pack samples into large sequential containers (for example, TFRecord, Parquet) to Amortize metadata operations across thousands of samples.

At production scale, the metadata bottleneck can collapse an otherwise high-bandwidth file system.

6 | **OSS (Object Storage Server):** In parallel file system terminology, “object” means a chunk of striped file data managed by an Object Storage Target (OST), a usage that predates cloud object storage (S3, GCS) by over a decade. Confusing the two is a common source of miscommunication: when a Lustre administrator says “add more OSS nodes,” they mean adding data-serving capacity to the parallel file system, not provisioning cloud buckets.

7 | **Lustre:** A portmanteau of “Linux” and “cluster,” developed at Carnegie Mellon University and first deployed in production in 2003. Lustre is common in HPC and ML infrastructure because its architecture scales aggregate bandwidth linearly with the number of OSS nodes, the same property that makes it a natural choice for training clusters where a single job may demand hundreds of GB/s of sustained read throughput.

8 | **GPFS (General Parallel File System):** Developed by IBM Research starting in 1998, now marketed as IBM Spectrum Scale. Unlike Lustre’s dedicated metadata-server/object-server organization, GPFS is a shared-disk parallel file system that can stripe data and metadata and uses token-based locking to coordinate concurrent client access. For ML checkpoint writes, this distributed coordination model can reduce reliance on a single dedicated metadata path, but it also makes lock behavior part of the performance envelope.

Example 4.1: The metadata meltdown

Scenario: A large-scale training cluster migrates from a preprocessed sequential dataset to raw images stored as individual files.

Setup: The parallel file system is provisioned for 500 GB/s of aggregate data bandwidth, but it delivers less than 1 percent of rated throughput because the metadata servers cannot sustain the millions of `stat()` and `open()` calls per second generated by ML data loaders. Converting the 200-million-image dataset into 50,000 large tar files reduces metadata operations by four orders of magnitude.

Systems lesson: At scale, metadata operations can become the first bottleneck even when the storage fabric has ample data bandwidth.

The design response to the small file problem is **striping** and **aggregation**. Striping distributes a single large file across multiple OSS nodes so that a client can read from all of them in parallel. The stripe size (typically 1 to 4 MB per OSS) determines the granularity: a 4 GB file striped at 1 MB across 100 OSS nodes places 40 MB on each node, and a sequential read saturates all 100 data paths simultaneously. The stripe count (how many OSS nodes participate) can be configured per-file or per-directory, allowing administrators to tune bandwidth for different access patterns. Training data shards benefit from maximum striping; small configuration files benefit from minimal striping to avoid the overhead of coordinating across many nodes.

The interaction between stripe size and workload access pattern determines realized throughput. If the training data loader reads sequentially through a shard, the PFS client reads stripe 1 from OSS-A, stripe 2 from OSS-B, stripe 3 from OSS-C, and so on, naturally distributing the load across all OSS nodes that hold stripes of that file. If the read size is smaller than the stripe size, each read is served by a single OSS node, and the client does not benefit from parallel reads. If the read size spans multiple stripes, the client issues parallel reads to multiple OSS nodes simultaneously. For ML workloads that read multi-megabyte chunks (an entire batch of images, or a 4 MB block of tokenized text), the read size typically exceeds the stripe size, achieving full bandwidth aggregation.

Aggregation complements striping by reducing the number of files that the MDS must track. Small samples are bundled into large sequential files (such as WebDataset⁹ tar archives or TFRecord sequences) to amortize metadata costs across thousands of samples. A single `open()` on a 4 GB tar file gives access to 40,000 samples, reducing metadata load by 40,000× compared to individual files.

Parallel file systems provide the coordinated shared namespace and lock management required for reliable checkpoints (Schmuck and Haskin 2002). When a checkpoint save completes, every node that subsequently reads that checkpoint must see the same completed state. This guarantee is essential for fault recovery: if a node fails and restarts, it must read the checkpoint that the surviving nodes wrote, not a partially flushed version. Achieving this consistency at scale requires careful coordination between the MDS lock manager and the distributed OSS write paths, which is one reason that checkpoint writes are more expensive than training reads.

The consistency model has subtleties that matter for ML workloads. For training data reads, strong consistency is unnecessary because the data is immutable: once a dataset is preprocessed and uploaded to the parallel file system, it is never modified. Multiple workers reading the same shard simultaneously can do so without locking, because there are no concurrent writers to create conflicts. This read-only access pattern allows the PFS to serve training data at near-theoretical bandwidth. Checkpoint writes, by contrast, require exclusive locks to prevent partial reads during the write, and the lock acquisition and release add latency to every checkpoint operation. Some systems mitigate this by writing checkpoints to a new file rather than overwriting the previous one, trading storage space for reduced lock contention.

The performance of a parallel file system depends not only on the *number* of OSS nodes but also on the *balance* of load across them. If a training job reads a single large shard that is striped across 10 OSS nodes while the remaining 90 nodes are idle, the job achieves only 10 percent of the system's aggregate bandwidth. Conversely, if 100 training jobs each read different shards striped across all 100 OSS nodes, the aggregate bandwidth approaches the theoretical maximum. The scheduling of

⁹ | **WebDataset:** A data format that repurposes standard POSIX tar archives for ML training. The design insight is that tar's sequential header-then-data layout, invented in 1979 for tape backup, maps perfectly onto the streaming access pattern that ML data loaders need. Because tar archives are valid HTTP byte-range targets, a data loader can stream training samples directly from object storage without local staging, reducing the I/O path from five tiers to two.

data access patterns across the cluster is therefore a system-level optimization opportunity that can dramatically affect realized throughput.

At the scale of thousands of nodes, tail latency (Dean and Barroso 2013) dominates system performance. The mathematics is sobering. If a training step requires data from 100 storage servers and each has a 1 percent chance of being slow (due to background maintenance, garbage collection, or network jitter), the probability that all 100 respond quickly is $0.99^{100} = 0.366$, meaning over 63 percent of training steps will experience at least one slow response. The slowest response determines the step's completion time, because data-parallel training requires all workers to complete their batch before the collective communication phase begins.

Systems mitigate tail latency through **hedged requests**: after waiting for a configurable timeout (typically the median response time), the client issues a redundant read to a different replica of the same data stripe. The first response to arrive is used; the second is discarded. If the storage system replicates each stripe across two OSS nodes, the probability that both replicas are slow is $0.01^2 = 0.0001$, reducing the fraction of slow steps from 63 percent to less than 1 percent. The cost of the redundant request, one additional network read, is negligible compared to the cost of an idle accelerator consuming hundreds of watts while waiting.

The effectiveness of hedged requests depends on the replicated data layout. If both replicas reside on OSS nodes that share the same network switch, a switch failure makes both copies simultaneously unavailable. Effective hedging requires **failure-domain-aware placement**: replicas should reside in different racks, connected through different top-of-rack switches, so that the failure of any single component affects at most one replica.

In production clusters, the parallel file system is a shared utility, simultaneously servicing dozens of concurrent training jobs with different I/O patterns. At any given moment, a large language model job might be streaming sequentially through text shards, a computer vision job might be reading random image shards, and a checkpoint storm from a third job could be saturating write bandwidth. This concurrency gives rise to the **noisy neighbor problem**, where one job's I/O pattern severely degrades performance for all other jobs. A checkpoint save that consumes a disproportionate share of the PFS's internal network bandwidth causes read latency for other jobs to spike, potentially stalling their training pipelines. PFS administrators mitigate this through I/O scheduling policies (quality-of-service tiers, bandwidth quotas per job), but these policies add administrative complexity and can reduce peak single-job throughput.

A related challenge is **namespace isolation**. Different teams and workloads require different storage configurations. A team training on millions of 100 KB images needs a directory with high stripe count and small stripe size to maximize metadata performance. A team working with large video files needs fewer, larger stripes to optimize for sequential bandwidth. Misconfigured striping for one team's workload can create hotspots that degrade performance for the entire shared file system. The impact of sharing is easy to quantify: a PFS with 1 TB/s aggregate bandwidth, shared across 10 concurrent training jobs, provides only 100 GB/s per job on average. If one job's checkpoint storm consumes 400 GB/s for 10 seconds, the remaining nine jobs share 600 GB/s, a 33 percent reduction that can trigger data stalls in their accelerator pipelines.

Checkpoint 4.2: Parallel file system design

Consider a training cluster with 512 nodes, each running 8 GPUs. The training job requires 400 GB/s of aggregate read bandwidth.

- ☐ **OSS count:** Calculate the number of OSS nodes required when each Lustre OSS delivers 10 GB/s.
- ☐ **Metadata cost:** Calculate the time required to open 200 million 150 KB image files sequentially when each `open()` call takes 50 μ s on the MDS, then state the practical implication.
- ☐ **Shard count:** Calculate the number of metadata operations needed to read the full dataset when images are bundled into 4 GB tar files.

Parallel file systems solve the shared-namespace problem for active training clusters, but their cost per byte is too high for the organization’s complete data holdings. The petabytes of raw training data, historical checkpoints, and preprocessed datasets that an ML organization accumulates over years require a tier optimized for capacity and durability rather than bandwidth.

4.3.6 Tier 4: Object storage

At the scale of petabytes, object storage provides the durable, cost-effective foundation of the hierarchy. Services like Amazon S3 and Google Cloud Storage organize data in object namespaces where objects are retrieved by keys rather than by POSIX directory paths (Amazon Web Services 2026c; Google Cloud 2026). Unlike file systems, which organize data in hierarchical directories with metadata-rich operations (rename, link, permission inheritance), object storage treats each object as an opaque blob identified by a unique key. This simplification eliminates the metadata complexity that plagues parallel file systems at scale and enables horizontal scaling to very large capacity pools.

Object storage targets “eleven nines”¹⁰ of durability (99.99999999 percent) through erasure coding¹¹ and geographic replication. That target makes object storage the natural source-of-truth tier for training data and checkpoint archives, while still requiring versioning, lifecycle policy, access control, and recovery testing for operational failures outside the storage service’s durability model.

Definition 4.3: Erasure coding

Erasure Coding is a storage protection scheme for ML datasets and checkpoint archives that fragments an object into k data and m parity blocks, ensuring the original is recoverable from any k remaining fragments.

1. **Significance:** It achieves extreme data durability (for example, “eleven nines”) with significantly lower storage overhead than replication. For example, a 4+2 code stores four data fragments and two parity fragments, so it tolerates two unavailable fragments at $1.5\times$ storage overhead instead of the $3\times$ overhead of triple replication.
2. **Distinction:** Unlike replication (which stores complete copies), erasure coding uses mathematical encoding (for example, Reed-Solomon) to distribute redundant information across different failure domains (disks, racks, or sites).
3. **Common pitfall:** A frequent misconception is that erasure coding is “free durability.” In reality, it is a latency-compute trade-off: reconstructing data after a failure requires additional CPU cycles and increases the tail latency (L_{lat}) of the storage read.

The engineering behind erasure coding illustrates a recurring theme in storage systems: achieving extreme durability through redundancy that is invisible to the application. When an ML training job reads a shard from object storage, the storage service transparently reads k fragments from available nodes, reconstructs the original shard, and returns it to the client. If one fragment is on a failed disk, the service reads additional coded fragments and reconstructs the missing data. The client never observes the failure, but the storage system pays extra I/O, network, and decoding work, which contributes to the higher tail latency of object storage compared to local NVMe.

The cost advantage of object storage is significant: at a representative \$0.02/GB/month, it is $750\times$ cheaper per byte than HBM and $5\times$ cheaper than local NVMe. For a 100 TB training dataset, object storage costs roughly \$24,000 per year under that price assumption, compared to \$120,000 for local NVMe. This cost advantage makes object storage a common home for the organization’s training data lake, where raw data, preprocessed datasets, and archived model artifacts can reside durably.

The latency disadvantage is equally significant. A GET request to object storage can incur tens of milliseconds of latency; the design examples in this chapter use 50 to 100 ms as a representative planning range rather than a universal service guarantee. That latency is a consequence of the multi-layer indirection that provides durability. When a client requests an object, the storage service must look up the object’s location in a distributed metadata index, identify which erasure-coded fragments to read, retrieve fragments from potentially different storage nodes, and reconstruct the original object. This overhead is invisible for large objects (where transfer time dominates) but catastrophic for small ones (where per-request latency dominates).

¹⁰ | **Eleven Nines (99.99999999 Percent Durability):** A design target of 11 nines annual durability corresponds to an expected loss probability of about 10^{-11} per object-year; for one million objects, that is about one expected object loss per 100,000 years. This extreme durability is why object storage is the only tier where training data and checkpoint archives can be treated as permanent. The same service indirection, erasure coding, replication, and metadata lookup that support durability also make object storage a higher-latency tier than local NVMe or a warm parallel file system, so real-time data pipelines need prefetch buffering.

¹¹ | **Erasure Coding:** Built on Reed-Solomon codes (Reed and Solomon 1960), which use maximum-distance-separable coding to recover the original data from any sufficient subset of encoded fragments. In storage systems, Reed-Solomon-style codes and later local-reconstruction variants trade storage overhead against repair bandwidth and degraded-read cost (Plank 1997; Huang et al. 2012). For ML storage, the trade-off is concrete: a 4+2 code tolerates two missing fragments at $1.5\times$ storage overhead, while triple replication costs $3\times$; degraded reads then pay extra network I/O and reconstruction work when fragments are unavailable.

The solution is the same aggregation pattern used in parallel file systems: samples are bundled into multi-gigabyte shards using formats like WebDataset (Aizman et al. 2019) or Mosaic Streaming (Databricks 2026) that transform high-latency random access into high-bandwidth sequential streaming. Rather than issuing billions of small GET requests, the data loader issues hundreds of large reads in parallel, each fetching an entire shard that contains thousands of samples. With sufficient parallelism and colocated network capacity, object storage can sustain high aggregate throughput, enough to feed large training clusters for some workloads. The streaming pattern works by assigning each data loader worker a subset of shards and having it read them sequentially. Within each shard, samples are stored contiguously, so the worker decodes them in order and shuffles them in a local buffer. This approach achieves pseudo-random access across the dataset while maintaining sequential I/O at the storage level.

The architecture of a streaming data loader for object storage differs from a local-storage loader in important ways. A local-storage loader can use memory-mapped I/O to treat the dataset as a virtual memory region, relying on the operating system’s page fault mechanism to load data on demand. This approach is elegant but incompatible with object storage, which does not support the POSIX file system interface that memory mapping requires. Instead, an object-storage loader must explicitly manage HTTP connections, issue ranged GET requests for specific byte ranges within shards, handle retries on transient failures, and manage a local buffer pool for decoded samples. Libraries like WebDataset and Mosaic Streaming encapsulate this complexity, presenting a simple iterator interface to the training loop while managing the HTTP transport and buffering internally.

Applying this streaming architecture to our running example makes the design concrete. The tokenized training set is stored in an S3-like object store as roughly 2,000 shards of 3 GB each. The streaming architecture assigns each of the 256 compute nodes a unique subset of roughly 8 shards. Within each node, 8 data loader worker processes issue concurrent HTTP Range requests to fetch 256 MB chunks from their assigned shards. Across the cluster, this results in 2,048 concurrent requests, allowing aggregate throughput in the 50–100 GB/s range when the object store and network path are provisioned for it, easily saturating the roughly 167.8 MB/s required for text model training. In this regime, the bottleneck often shifts from the object store’s bandwidth to the network bandwidth between the compute VPC and the object-storage endpoint. Organizations that co-locate compute and storage in the same cloud availability zone can reduce cross-network latency, directly reducing the required prefetch buffer depth and improving overall pipeline efficiency.

Object storage exposes large request parallelism. Each GET request is independent and can be served by a different storage node within the cloud provider’s infrastructure. A training cluster with 1,024 nodes, each running 8 data loader workers issuing concurrent requests, generates 8,192 simultaneous GET requests. If each request fetches a 256 MB shard, the aggregate throughput depends on the cloud provider’s network capacity, internal bandwidth, and request-rate quotas. The practical limit is often the network bandwidth between the compute cluster and the object storage service, not the storage service’s internal media bandwidth.

Many object storage services provide strong read-after-write consistency, which means that once a checkpoint is written to object storage, a subsequent read sees the complete data. This was not always the case: until December 2020, Amazon S3 provided eventual consistency for overwrite PUTs and DELETes, meaning a read immediately after updating or deleting an existing object might return stale data. New-object PUTs were always strongly consistent, but checkpoint workflows that update a “latest” pointer or overwrite an existing artifact were vulnerable: a node recovering from failure might read a stale checkpoint and corrupt the training state. The December 2020 transition to strong read-after-write consistency for all operations on Amazon S3 closed this gap for S3-style checkpoint retention (Amazon Web Services 2020), while the broader design lesson is to verify the consistency semantics of the object store used by the pipeline. This consistency property makes object storage suitable for both training data source (the original dataset) and long-term checkpoint retention (the archival copy after local NVMe staging), provided the pipeline validates the service semantics it relies on.

The immense scale of ML datasets makes them vulnerable to **silent data corruption**: subtle bit flips in the storage medium or during network transfer that can introduce training artifacts nearly impossible to diagnose. Object storage services provide per-object checksums that verify integrity on upload, copy, or download; Amazon S3, for example, documents checksum options including

CRC-family and cryptographic hashes (Amazon Web Services 2026a). Parallel file systems often rely on underlying RAID or erasure coding for physical integrity but may not provide end-to-end checksums visible to the application. A robust large-scale ML pipeline computes and stores a checksum for each data shard during preprocessing and verifies it when the shard is first loaded by a training worker. The verification overhead is negligible compared to the cost of training on corrupted data. For model checkpoints, integrity verification is even more critical: a single bit flip in a weight or optimizer state can corrupt the model, causing training to diverge silently after recovery. Frameworks and checkpoint libraries can include integrity verification, but the pipeline should not assume it without testing the checkpoint format.

Storage security is a first-class concern in production ML infrastructure. Training datasets often contain sensitive information (personally identifiable data, proprietary text, licensed images) that requires access control. Object storage provides fine-grained security policies through Identity and Access Management (IAM) roles, per-bucket policies, and integrated encryption for data at rest and in transit. Parallel file systems provide POSIX permissions and access-control lists (ACLs) but often lack the audit logging that compliance requires. For organizations subject to data protection regulations such as the General Data Protection Regulation (GDPR) and the California Consumer Privacy Act (CCPA), the storage architecture must ensure that data access is logged, that deletion requests can be honored (a task complicated by immutable preprocessed shards), and that model checkpoints do not inadvertently memorize protected information. Storage design therefore has to preserve both throughput and governance metadata.

The transition from Tier 4 to Tier 5 is driven primarily by economics: data that is accessed rarely should move to archive storage when retrieval latency and governance requirements allow it, because the storage cost can be an order of magnitude lower.

4.3.7 Tier 5: Archive and cold storage

The final tier provides long-term preservation for compliance and auditability. Archive services (such as S3 Glacier) are designed for data that is rarely accessed: training logs from previous years, superseded model checkpoints, audit trails for regulatory compliance. At a representative \$0.004/GB/month, archive storage costs roughly \$4,800 per year for 100 TB, which is $5\times$ cheaper than the \$0.02/GB/month object-storage assumption used above. The trade-off is retrieval latency measured in minutes to hours, making this tier unsuitable for operational access.

The primary value of archive storage is organizational memory. When a model trained two years ago produces unexpected behavior in production, the ability to recover the exact training data, hyperparameters, and intermediate checkpoints for forensic analysis depends on archive storage. Organizations that aggressively purge old data to save costs discover, often at the worst possible moment, that they cannot reproduce or explain the behavior of deployed models.

Automated **lifecycle policies** govern the transition of data between tiers based on access recency. As one illustration of how such automation is expressed, a time-based rule for ML infrastructure might move checkpoints as follows: the most recent three checkpoints remain on the parallel file system for fast recovery; checkpoints older than 72 hours are transitioned to object storage; checkpoints older than 90 days are transitioned to archive storage; and checkpoints older than two years are deleted unless flagged for regulatory retention. S3 Lifecycle rules provide the same general transition/archive/delete mechanism for object lifetimes (Amazon Web Services 2026b). The running example later adopts a count-based variant of the same idea (section 4.7), where the transition rule keys on checkpoint count rather than age. Without automation, teams either hoard data on expensive tiers (wasting budget) or delete data too aggressively (losing reproducibility). The lifecycle policy encodes the organization's cost-recovery trade-off in a declarative rule that requires no manual intervention.

For our 175B model training run, the archive tier holds the complete training lineage: the raw 3 TB compressed source corpus, the 6 TB serialized shard set, all preprocessing scripts, the final checkpoint, and a sampled subset of intermediate checkpoints. If the organization budgets a conservative 100 TB for this retained lineage, the two-year archive cost is roughly \$9,600 ($100\text{ TB at } \$0.004/\text{GB}/\text{month} \times 24\text{ months}$), well under one day of GPU time on the training cluster. The asymmetry between archive cost and compute cost makes retention inexpensive relative to the run

it documents; failures to archive usually reflect missing lifecycle ownership, unclear retention policy, or retrieval-process neglect rather than raw capacity cost.

Archive storage services offer multiple retrieval speed tiers, each with different pricing. In an S3 Glacier-style service, standard retrieval may complete within hours at moderate cost, expedited retrieval may complete within minutes at a higher cost, and bulk retrieval may trade still more latency for the lowest retrieval price (Amazon Web Services 2026d). The choice of retrieval tier depends on the urgency of the use case. Forensic analysis of a production incident warrants faster retrieval; annual compliance audits can use slower bulk retrieval. Designing the lifecycle policy requires understanding the storage cost, the expected retrieval frequency, and the urgency for each class of data.

Compliance requirements can require organizations to retain training data provenance records for deployed models. The EU AI Act, for instance, requires documentation for high-risk AI systems, including information about training data composition and preprocessing. Archive storage is usually the economically viable tier for retaining the complete lineage of a model, from raw data through preprocessing to the final checkpoint, for a required retention period. The cost of compliance storage is often small compared to the operational and legal cost of insufficient documentation.

4.3.8 Data format landscape

Data format choices determine whether the storage hierarchy delivers its theoretical bandwidth or collapses under metadata overhead. The same multi-terabyte dataset stored in different formats can yield I/O throughput that differs by over $100\times$ on identical hardware. For large-scale machine learning, data must be structured for high-throughput sequential access, not for human readability or transactional convenience.

The useful design question is which access cost the workload must pay: per-file metadata, unnecessary feature reads, or sequential shard traversal. **Row-oriented formats**, such as CSV, JavaScript Object Notation (JSON) lines, or a directory of individual image files (JPEG, PNG), are the most intuitive and human-readable. They are easy to inspect and debug, making them suitable for initial data exploration or for datasets small enough to fit entirely in memory (typically under 10 GB). For training at scale, they are catastrophic for I/O performance. Each sample is a separate file, requiring a distinct file system operation (`open`, `stat`, `read`, `close`) that incurs significant per-sample overhead, often dominating the actual time spent reading data.

A second choice solves a different storage problem: **columnar formats** like Apache Parquet and Apache Arrow avoid unnecessary reads when tabular features can be selected before transfer. They organize data by column rather than by row, which allows for excellent compression as data within a column is typically of the same type and has lower entropy. This structure also enables **predicate pushdown**, where the storage engine reads only the specific columns (features) required by a query, avoiding unnecessary I/O. These formats are well-suited for tabular ML tasks and feature engineering but are less natural for unstructured data like images or audio, which are treated as atomic blobs.

A third choice addresses the training access pattern directly: **sequential streaming formats** reduce per-sample metadata to the cost of opening a shard. TFRecord, Mosaic’s StreamingDataset format (Databricks 2026), and WebDataset (based on standard `tar` archives) group many samples into large, contiguous binary files called shards. This amortizes the cost of opening a file over thousands of samples. A data loader opens a single shard and streams its contents sequentially, maximizing bandwidth. The `tar`-based formats have the added advantage of being valid targets for HTTP byte-range requests, making them ideal for streaming data directly from object storage without downloading the entire file first.

A key trade-off within streaming formats is the presence of an **index**. TFRecord and HDF5 often use a separate index file to record the byte offset of each sample within a shard. This enables efficient random access within a shard but introduces a metadata dependency: the index must be read and held in memory. WebDataset is indexless: each record in the `tar` archive contains its own header specifying its size, allowing for purely sequential streaming without any external metadata. The trade-off is that indexless formats cannot efficiently seek to an arbitrary sample within a shard, a capability that matters for curriculum learning or active learning workloads that require nonsequential data access.

Compression integration also varies across formats. Parquet integrates compression at the column level, exploiting type homogeneity for high ratios. WebDataset and TFRecord typically leave compression to the individual sample: a WebDataset of images stores already-compressed JPEG files, while a text dataset might apply zstd compression per shard. This choice affects the CPU-I/O trade-off discussed in the context of NVMe reads, as per-sample decompression must be handled by the host CPU.

For our running example, the 1.5 trillion token dataset is stored as roughly 2,000 shards of approximately 3 GB each in a custom binary format. Each shard contains a small header (token count, vocabulary size, byte order) followed by a contiguous array of 4-byte token IDs. When staged on POSIX storage such as local NVMe or a parallel file system, the data loader memory-maps the shard and indexes directly into the token array by position, achieving near-peak read bandwidth with zero per-sample metadata overhead. When the same shards are read directly from object storage, the loader uses HTTP ranged GET streaming and an explicit local buffer rather than memory mapping. Table 4.4 compares the format choices by the access cost they impose on the storage path.

Table 4.4: Data Format Comparison for ML Training: Per-sample overhead determines whether the storage hardware’s bandwidth is realized or wasted on metadata operations.

Format	Overhead/Sample	Random Access	Streaming	Compression
Individual files	~50 μ s (open/stat/close)	Yes	Poor	Per-file
Parquet	~1 μ s (row group seek)	Yes (row group)	Good	Column-level
TFRecord	~0.1 μ s (index lookup)	With index	Excellent	Per-record
WebDataset (tar)	~0 (sequential)	No	Excellent	Per-sample
Raw binary (tokens)	0	Yes (byte offset)	Excellent	None needed

The comparison in table 4.4 sets the data-volume term in the pipeline equation, turning format selection into a bandwidth-sizing problem.

4.4 The Data Pipeline Equation

Every training job eventually raises a concrete sizing question: how much storage bandwidth must the pipeline deliver before accelerators begin to stall? The required rate depends on the training configuration, and getting it wrong in either direction is expensive. Under-provisioning storage bandwidth starves accelerators. Over-provisioning wastes budget on storage capacity that sits partially idle. The **data pipeline throughput equation** in equation 4.1 quantifies the bandwidth the pipeline must sustain so that accelerators never wait for data:

$$BW_{\text{required}} = N_{\text{GPU}} \times \eta_{\text{target}} \times \frac{D_{\text{vol, batch}}}{T_{\text{iteration}}} \quad (4.1)$$

where N_{GPU} is the number of accelerators, η_{target} is the target utilization (typically 0.8 to 0.95), $D_{\text{vol, batch}}$ is the size of one local batch in bytes, and $T_{\text{iteration}}$ is the time for one forward-backward pass.

The equation reveals four levers for controlling storage demand:

- **Accelerator count:** Reducing N_{GPU} directly reduces bandwidth requirements, but fewer accelerators also reduce training throughput.
- **Target utilization:** Lowering η_{target} reduces the bandwidth needed, but accepting lower utilization wastes expensive hardware.
- **Batch volume:** Decreasing $D_{\text{vol, batch}}$ reduces per-iteration data volume, but smaller batches may harm model convergence.
- **Iteration time:** Increasing $T_{\text{iteration}}$ gives storage more time to deliver each batch, but slower iterations extend total training time.

In practice, none of these levers is free; the pipeline must be engineered to deliver the bandwidth that the training configuration demands.

As a separate image-training example, consider 256 GPUs training with ImageNet-scale images, 200 ms iterations, and 80 percent target utilization. This configuration requires 39.3 GB/s of aggregate storage throughput. The bandwidth must be sustained continuously for the duration of training, which may last days or weeks. If at any point the storage system delivers less than 39.3 GB/s, accelerators begin to idle. For the chapter's 175B language-model running example, tokenized text has a much lower per-batch bandwidth demand, but the total data volume and checkpoint traffic over the run are much larger, shifting the bottleneck from peak training-data bandwidth to sustained throughput and checkpoint movement over weeks.

The consequences of falling short are captured by the **data stall ratio**, defined in equation 4.2 as the fraction of each training step where the accelerator waits for data:

$$\text{Data Stall \%} = \frac{T_{\text{step}} - T_{\text{compute}}}{T_{\text{step}}} \times 100 \quad (4.2)$$

where $T_{\text{step}} = T_{\text{compute}} + T_{\text{I/O}}$ when I/O and compute are not overlapped, or $T_{\text{step}} = \max(T_{\text{compute}}, T_{\text{I/O}}) = T_{\text{compute}} + \max(0, T_{\text{I/O}} - T_{\text{compute}})$ with pipelining.

Napkin Math 4.5: The data stall ratio

Problem: A GPU processes a batch in 200 ms, but storage takes 250 ms to deliver the next batch. What fraction of each training step is the accelerator idle, and how much does pipelining I/O with compute reduce that stall?

Without pipelining (sequential I/O then compute):

$$T_{\text{step}} = T_{\text{I/O}} + T_{\text{compute}} = 250 + 200 = 450 \text{ ms}$$

$$\text{Stall \%} = \frac{250}{450} = 55.6\%$$

With pipelining (I/O overlapped with compute):

$$T_{\text{step}} = \max(200, 250) = 250 \text{ ms}$$

$$\text{Stall \%} = \frac{250 - 200}{250} = 20\%$$

Systems insight: Even with pipelining, the accelerator is idle 20 percent of the time. To eliminate the stall entirely, the next batch must arrive within the 200 ms compute window, either by increasing effective storage bandwidth, hiding tail latency with deeper prefetch buffers, or using more parallel I/O streams.

The data stall ratio provides a diagnostic metric that storage engineers can use to identify whether a training job is compute bound or I/O bound. A stall ratio below 2 percent indicates that the storage pipeline is healthy: the accelerator spends virtually all its time computing. A stall ratio between 2 percent and 10 percent suggests that the pipeline is marginally adequate but will degrade if the training configuration changes (more GPUs, smaller batches, faster model). A stall ratio above 10 percent indicates a clear storage bottleneck that wastes significant compute budget. Section B.5.1 maps these same green, yellow, and red bands onto the broader fleet diagnosis, so a storage engineer can read a high stall ratio as a red-light signal that computation is sitting idle and place storage alongside the other axes that starve an accelerator. Profiling tools like PyTorch's DataLoader profiler and NVIDIA Nsight Systems can measure data stall ratio directly by comparing the time the accelerator spends waiting for data vs. computing.

A storage system cannot be a "fire-and-forget" component; it requires continuous monitoring to prevent silent bottlenecks from eroding training efficiency. Key metrics to track in real time include per-tier bandwidth utilization (NVMe, network, object storage), prefetch buffer depth (how many batches are queued and ready), the data stall ratio per GPU, the parallel file system's metadata operation rate, and NVMe drive health indicators (wear level, temperature, error counts). Alert

thresholds should trigger before stalls become visible in training loss curves. An undetected 5 percent increase in data stall ratio across a 1,000-GPU cluster for just one week wastes over \$16,800 in idle compute ($1,000 \text{ GPUs} \times \$2/\text{GPU-hour} \times 168 \text{ hours} \times 5 \text{ percent}$), making comprehensive storage monitoring a first-order economic concern rather than an operational nicety.

This high-level monitoring must be complemented by fine-grained profiling to pinpoint the exact source of a bottleneck. Profiling occurs at three levels. At the application level, NVIDIA Nsight Systems provides a timeline view that shows exactly when and for how long the accelerator is idle waiting for data, with microsecond precision. At the pipeline level, PyTorch’s built-in `DataLoader` profiler reports per-worker throughput, batch processing times, and data queue depth, identifying slow workers or insufficient prefetching. At the device level, `iostat` and `nvme-cli` provide raw hardware bandwidth and latency metrics. For parallel file systems, Lustre’s `lctl get_param` and GPFS’s `mmpmon` give real-time statistics on storage server utilization, metadata operation rates, and client-side cache hit ratios. The most effective debugging approach combines all three levels: correlating an application-level accelerator stall with a specific pipeline worker and a saturated underlying storage device identifies the bottleneck tier and guides optimization effort to where it will have the greatest impact.

A common and costly failure mode is to develop and test a data pipeline on a small local dataset (1 GB) and only discover at full production scale (1 TB+) that the pipeline cannot sustain the required throughput. The root cause is often a bottleneck invisible at small scale but crippling under load: a Python Global Interpreter Lock (GIL) contention in a data augmentation function, a file descriptor leak that accumulates over millions of samples, or a memory fragmentation issue that causes the prefetch buffer to slow down after hours of continuous operation. Robust teams benchmark the data pipeline in isolation, measuring sustained throughput over at least 10 to 20 minutes at the target data volume, before connecting it to the training loop. This **pipeline stress test** catches system-level bottlenecks that would otherwise manifest as mysterious training slowdowns days into a production run.

Different ML workloads have dramatically different bandwidth profiles, even when using the same cluster. Image classification with ResNet-50 on ImageNet produces a high bandwidth demand because each batch contains hundreds of large images (150 KB each) and iteration times are short (100 to 200 ms). Language model pretraining produces a lower per-batch bandwidth demand because tokenized text is compact (each token is a 4-byte integer, and a batch of 4,096 tokens occupies only 16 KB per sequence), but the total data volume over the training run is enormous (trillions of tokens). Recommendation model training produces a mixed bandwidth demand: embedding lookups require high-IOPS random access to the embedding table, while the dense layers consume standard sequential training data. Each workload’s bandwidth profile determines which storage tier is the bottleneck and where optimization effort should focus.

Figure 4.4 visualizes this relationship between storage bandwidth and GPU utilization. The S-curve reveals a sharp transition: below the stall threshold, even modest bandwidth shortfalls cause dramatic utilization drops, while above it, additional bandwidth yields diminishing returns. The plotted technologies show why no single tier suffices: a hard disk and a network file system sit deep in the stall zone, a single NVMe drive lands almost exactly at the knee where utilization is still rising steeply, and only an NVMe RAID array clears the threshold into the compute-saturated regime. This spread is why tiered storage architectures are essential, because no single tier provides both the capacity and bandwidth needed to keep a large cluster saturated.

The pipeline equation also reveals a scaling challenge that worsens with cluster size. As N_{GPU} increases, the required bandwidth BW_{required} increases linearly, but the storage system’s aggregate bandwidth does not automatically scale to match. Adding more compute nodes to a cluster that shares a parallel file system increases the demand on a fixed storage resource. Eventually, the storage system saturates and every additional GPU beyond the saturation point contributes zero additional training throughput while increasing cost. This saturation point is the practical upper limit on cluster scaling for a given storage configuration, and identifying it quantitatively requires applying equation 4.1 to the specific storage system’s measured bandwidth.

Figure 4.4: The Data Stall Frontier: GPU utilization follows a steep S-curve as a function of storage bandwidth. Around the stall threshold (~ 10 GB/s for a typical 8-GPU node), utilization crosses from waiting-dominated to compute-dominated. The position of common storage technologies on this curve explains why tiered architectures are essential.

Example 4.2: The metadata tax

Scenario: A large GPU training cluster has enough raw storage bandwidth on paper, but measured Model FLOPs Utilization (MFU) remains far below target.

Failure mode: Profiling reveals that GPUs are frequently idle even though network and storage bandwidth metrics look healthy. A common root cause is metadata amplification: the data loader issues a `stat()` system call for each file before opening it, multiplying metadata-server load across thousands of workers.

Consequence: Across thousands of workers, per-file metadata checks can generate millions of metadata requests per minute, overwhelming the parallel file system’s metadata server. GPUs then stall on file-open operations, a delay invisible to standard I/O bandwidth counters.

Systems insight: Precompute a file manifest at job start and have loaders read it once, eliminating per-file metadata checks on the hot path. Storage bottlenecks are often metadata bottlenecks, not byte-throughput bottlenecks.

4.4.1 Pipelining and prefetching

The primary weapon against data stalls is **pipelining**: the CPU prepares batch $i + 1$ while the GPU processes batch i . Figure 4.5 illustrates this overlap. When I/O time is less than compute time, pipelining hides the storage latency entirely, and the accelerator never stalls.

The key insight from figure 4.5 is that pipelining converts a sequential bottleneck into a parallel overlap, but only when the prefetch buffer is deep enough to absorb variance in I/O latency. Pipelining works perfectly when I/O times are consistent. In practice, they are not. Storage systems exhibit **I/O jitter**: variation in read latency caused by a multitude of factors. NVMe drives experience occasional latency spikes during internal garbage collection (when the controller reorganizes NAND flash blocks) or wear-leveling operations. Parallel file systems exhibit latency spikes when multiple training jobs contend for the same OSS nodes, when the MDS processes a burst of metadata operations, or when background scrubbing detects and repairs bit errors. Object storage latency can spike during cross-region replication, garbage collection of versioned objects, or load-balancer rebalancing.

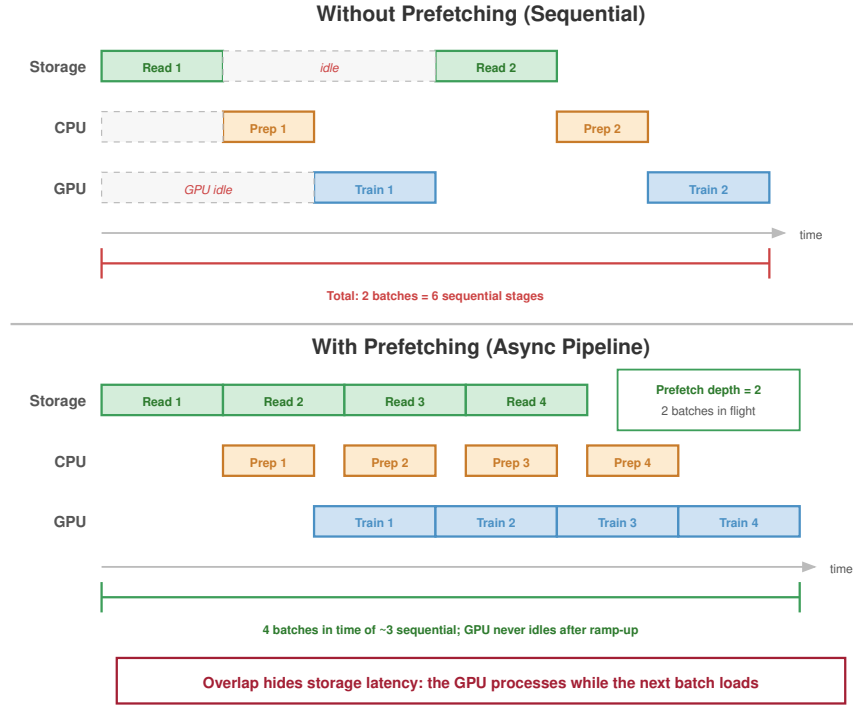

Figure 4.5: Pipelined Data Loading: The CPU prepares Batch $i + 1$ while the GPU processes Batch i . Pipelining hides storage latency, but only if the prefetch buffer is deep enough to absorb variance.

A single slow I/O can create a “bubble” in the pipeline that propagates forward, stalling the accelerator. If the CPU was preparing batch $i + 1$ and the read took twice as long as expected, batch $i + 1$ is not ready when the GPU finishes batch i . The GPU idles until the read completes, and the pipeline falls one batch behind. If subsequent reads are also slow, the pipeline never recovers. The defense is a prefetch buffer: rather than preparing just one batch ahead, the CPU maintains a queue of Q_{prefetch} preloaded batches.

The minimum buffer depth Q_{prefetch} must absorb the worst-case I/O latency without the queue draining:

$$Q_{\text{prefetch,min}} = \left\lceil \frac{T_{\text{I/O,P99}}}{T_{\text{compute}}} \right\rceil \quad (4.3)$$

The prefetch depth equation in equation 4.3 tells us how many batches must be in flight simultaneously to hide I/O latency behind computation. The equation assumes that the long-run data supply rate is at least as high as the accelerator’s consumption rate; prefetching absorbs latency variance, not a sustained bandwidth deficit. When average throughput is sufficient but P99 latency exceeds compute time, deeper prefetching prevents stalls. When sustained I/O throughput is lower than demand, the fix is faster storage, more parallel streams, smaller batches, or local staging. The equation uses P99 I/O latency rather than average latency because a single slow read can drain the buffer and stall the accelerator; sizing for the average guarantees frequent stalls at scale.

If I/O at the 99th percentile takes 500 ms and compute takes 200 ms, then $Q_{\text{prefetch,min}} = 3$ batches, with a safety margin of 5. In practice, data loaders like PyTorch’s `DataLoader` use `prefetch_factor` and `num_workers` parameters to control this depth. Setting `prefetch_factor=2` with 4 workers creates a buffer of 8 batches, which is typically sufficient for NVMe-backed pipelines but may be inadequate for object-storage-backed pipelines where P99 latency can exceed 500 ms.

P99 I/O latency sets the required prefetch depth.

To illustrate the memory cost of prefetch buffer depth, consider a large-batch text pipeline where each GPU processes a packed token batch in roughly 200 ms and the collated batch occupies about 40 MB per GPU. Reading from local NVMe, the P99 I/O latency for that batch is approximately 50 ms. The minimum prefetch depth is $\lceil 50/200 \rceil = 1$ batch, and a safety margin of 2 is adequate. Reading from a parallel file system, the P99 I/O latency rises to roughly 200 ms due to network jitter and contention, requiring a minimum depth of $\lceil 200/200 \rceil = 1$, with a safety margin of 3 to account for occasional multi-hundred-millisecond outliers. Reading from object storage, the P99 latency can exceed 500 ms, requiring a depth of at least 3, with a safety margin of 5 or more. These numbers translate directly into host DRAM consumption: at 40 MB per batch, a depth-5 prefetch buffer per GPU consumes 200 MB, and 8 GPUs per node consume 1.6 GB. At 40 MB per batch with a depth of 1, the same node needs only 320 MB. The storage tier directly determines the memory cost of the prefetch buffer.

The cost of deep prefetching is memory: each buffered batch occupies host DRAM. A batch of 256 images at $224 \times 224 \times 3$ bytes (after decoding) occupies roughly 37 MB. A prefetch buffer of 8 such batches consumes 300 MB, which is negligible for a node with 512 GB of DRAM. For large-batch language model training where each batch contains millions of tokens, however, the prefetch buffer can grow to several gigabytes, competing with embedding tables and other DRAM consumers.

The interaction between prefetching and the storage hierarchy creates a layered defense against stalls. The first layer is the prefetch buffer in host DRAM, absorbing I/O variance from NVMe reads. The second layer is the local NVMe warm cache, absorbing network variance from the parallel file system. The third layer is the parallel file system read-ahead cache, absorbing variance from disk seeks across the OSS cluster. Each layer adds latency tolerance at the cost of memory or storage capacity. The system designer's task is to ensure that the combined depth of all layers exceeds the worst-case latency spike at the lowest tier in regular use. For our running example, if the parallel file system occasionally exhibits a 500 ms latency spike and compute takes 200 ms per batch, the NVMe warm cache eliminates this risk entirely by serving reads locally, so the prefetch buffer only needs to absorb the much smaller NVMe latency variance of microseconds rather than milliseconds.

Checkpoint 4.3: Data pipeline design

A training cluster runs 1,024 GPUs with 128-image batches (150 KB per image after compression, 150 ms per iteration).

- ☐ **Bandwidth requirement:** Using equation 4.1, calculate the required aggregate storage bandwidth at 90 percent target utilization.
- ☐ **Checkpoint contention:** Determine whether 800 GB/s aggregate parallel-file-system bandwidth is sufficient, then recalculate when checkpoint writes consume 20 percent of that bandwidth.
- ☐ **Prefetch depth:** Calculate the minimum prefetch buffer depth in batches needed to absorb 300 ms P99 object-storage latency.
- ☐ **Host memory:** Calculate total prefetch buffer memory when each decoded batch occupies 10 MB in host DRAM at the depth calculated in (3).

4.4.2 Multi-worker data loading

A single CPU core cannot keep a high-throughput accelerator fed, even when the storage hardware is fast enough, because of the CPU work required between the storage read and the GPU transfer. Consider the throughput required for image training: decoding a 150 KB JPEG image into a $224 \times 224 \times 3$ raw tensor requires entropy decoding of Huffman-coded coefficients, inverse discrete cosine transform (DCT), chroma upsampling, and pixel-format conversion. This process takes roughly 1 to 5 ms per image on a server CPU core. After decoding, augmentation adds further CPU work: a random crop requires computing crop coordinates and copying the sub-region; horizontal flip requires copying with reversed column order; color jitter requires per-pixel multiplication and addition. Each augmentation adds 0.5 to 2 ms per image.

At 1,000 images per second per GPU and 8 GPUs per node, a single core would need to decode and augment 8,000 images per second, a throughput $10\times$ to $40\times$ beyond what a single core can sustain. The solution is **multi-worker data loading**, where W worker processes each read from storage, decode, augment, and enqueue batches independently. The effective I/O throughput scales approximately linearly with W until one of three bottlenecks is reached: the storage device's bandwidth saturates, the PCIe bus between host and device saturates, or the workers exhaust host CPU cycles.

In PyTorch's `DataLoader`, each worker is a separate process with its own file descriptors and memory space. The `num_workers` parameter controls W . Setting W too low leaves the GPU starved; setting W too high wastes CPU resources on context switching and contention. A good heuristic is to start with $W = 4 \times G$, where G is the number of GPUs per node, and profile the data stall ratio, adjusting until stalls are below 2 percent. For a node with 8 GPUs, this yields 32 workers, which on a system with 64 CPU cores leaves 32 cores for the PyTorch runtime, GPU-to-GPU communication threads, and operating system overhead. The division of CPU resources between data loading and training orchestration is itself a capacity planning exercise.

The interaction between multi-worker loading and the storage hierarchy matters. When reading from local NVMe, workers can issue concurrent reads to the same RAID array without contention, because NVMe's deep command queues (up to 64K outstanding commands) handle parallelism in hardware. When reading from a parallel file system, workers distribute their reads across different OSS nodes, naturally aggregating bandwidth. When reading from object storage, workers issue concurrent GET requests, each to a different shard, achieving parallelism at the HTTP level.

A subtle pitfall in multi-worker loading is **shuffle quality vs. I/O efficiency**. Perfect shuffling requires that each batch contain samples drawn uniformly from the entire dataset, which implies random access across all shards. Random access, however, defeats the sequential I/O patterns that storage systems optimize for. The practical compromise is *shard-level shuffling* combined with *within-shard shuffling*: the loader shuffles the list of shards at epoch start, assigns contiguous groups of shards to each worker, and then shuffles samples within each shard's local buffer. This approach provides sufficient randomness for training convergence while maintaining sequential I/O at the storage level. Empirical studies confirm that shard-level shuffling produces training loss curves indistinguishable from full random shuffling for most workloads, as long as the shard size is large enough (typically 256 MB or more) to provide adequate within-shard diversity.

The shuffle buffer size creates a memory-randomness trade-off. A larger buffer provides better randomness (because samples are drawn from a larger pool) but consumes more host DRAM. For our running example with text data, a shuffle buffer of 10,000 sequences at 2,048 tokens each, with each token represented as a 4-byte integer, consumes roughly 80 MB. This is negligible relative to the 512 GB of host DRAM. For image data, where each decoded image occupies 150 KB, a shuffle buffer of 10,000 images consumes 1.5 GB, still manageable but a nontrivial fraction of the prefetch budget. The data loader designer must balance shuffle buffer size against prefetch depth, since both compete for the same host DRAM capacity.

The data loading pipeline, from storage read through decode, augmentation, and transfer to accelerator, represents the complete fuel delivery system for the training engine. When any stage becomes the bottleneck, the accelerator starves.

4.4.3 Data locality and placement

In a distributed training cluster, the placement of data shards across the storage hierarchy determines pipeline performance. Each training worker needs efficient access to its assigned portion of the dataset. The core trade-off is between the flexibility of shared storage and the raw speed of local storage. Reads from a node's local NVMe drives are typically $10\text{--}100\times$ faster and have lower latency than reads that must traverse the network to a parallel file system or object store.

The simplest strategy is **static placement**. At the beginning of a training job, the orchestrator assigns a fixed subset of data shards to each node. The node stages this data by copying its shards from the shared PFS to local NVMe drives. For the remainder of the training run, all data reads are local, maximizing I/O bandwidth. This approach is highly effective for single-dataset training runs but introduces inflexibility: if the dataset changes or the job requires a different subset of data, the shards must be re-staged.

The alternative is **dynamic placement**, where shards are fetched on demand from shared storage as needed. This provides maximum flexibility, as any node can access any shard at any time. Dynamic placement is essential when the total dataset size exceeds the aggregate local NVMe storage of the cluster, or when the job involves data sampling strategies that change the active subset over time. The cost is performance: every read incurs network latency and consumes shared storage bandwidth.

A more advanced approach is **locality-aware scheduling**. The scheduler keeps track of which data shards are cached on which nodes' local NVMe drives. When it starts a new job or replaces a failed node, it prefers a node that already has the required data cached, rather than treating all nodes as interchangeable. This uses the principle of data gravity¹², co-locating compute with data to minimize transfer times. The storage point is simple: cached data only saves time if the placement system knows where the cache is. For teams running repeated experiments on the same dataset, locality-aware scheduling reduces staging time from minutes to zero.

For our 6 TB serialized dataset distributed across 256 nodes, each node is responsible for approximately 23.4 GB of data. If a node fails, its replacement must stage that shard subset from the PFS. At an uncontended PFS read speed of 4 GB/s, this staging takes about 5.9 seconds; under recovery contention, an effective 400 MB/s per-node rate stretches the same copy to about 58.6 seconds. If the orchestrator can instead schedule the replacement workload on an idle node that already has the data cached from a previous run, staging time is zero and training resumes instantly. At scale, this optimization compounds: in a 10,000-node cluster experiencing 10 node failures per day, locality-aware scheduling can save roughly a minute of staging time per failure, or about 10 minutes per day of aggregate cluster idle time, in the contended case.

4.4.4 Data versioning and pipeline orchestration at scale

Knowing where data lives is only half the story; at scale we must also pin which version of the data each run uses and how it flows through the pipeline. Versioning turns the storage hierarchy into a reproducibility system: the fleet must know not only which bytes it read, but which preprocessing code, shuffle seed, schema, and integrity checks produced those bytes before the run began.

Lighthouse 4.1: Archetype B (DLRM at scale): feature store latency

While Archetype A (GPT-4) deals with static, versioned datasets of trillions of tokens, Archetype B (DLRM at Scale), the DLRM workload, deals with dynamic, high-velocity feature streams. For a recommendation system, the “ground truth” changes every second as users click and interact. This forces a move from simple file-based storage to a feature store architecture that must solve the point-in-time correctness problem: ensuring that the features retrieved for training exactly match what the model would have seen at the moment of inference, without “leaking” future information.

That same reproducibility requirement becomes harder when the inputs are live features rather than immutable text shards. Feature store architectures address point-in-time correctness¹³ by maintaining an immutable feature ledger or a “time-travel” query engine, significantly increasing storage complexity.

At the 10,000-GPU scale, the dataset is no longer a *static collection of files* but a *dynamic stream* that must be captured with absolute precision. Foundation-model runs can last weeks or months; in our 30-day running example, the data seen near the end of the run must be identical in composition and order to the data seen on day 1. Otherwise, we cannot distinguish between a model regression and a silent change in the input distribution. Dataset versioning provides the necessary “Git for data” capability by snapshotting the cryptographic hashes¹⁴ of every data shard, the exact preprocessing code used for tokenization, and the random seeds governing the global shuffle. This level of rigor is essential for audit trails and for debugging the subtle “loss spikes” that characterize large-scale training, where we must be able to replay the exact batch that caused a divergence to determine if the cause was a corrupted data sample or a numerical instability in the optimizer.

At petabyte scale, the data pipeline has to make every transformation reproducible. Raw documents are cleaned, tokenized, packed into training examples, and sharded across storage tiers. Each

12 | **Data Gravity:** A metaphor treating large datasets as massive objects that attract compute. The gravitational analogy is apt: moving a 100 TB dataset across cloud regions costs over \$9,000 in egress fees and takes hours, while launching compute next to the data is near-instantaneous. In ML fleet design, data gravity means the storage location of the training dataset often dictates the physical placement of the entire training cluster.

13 | **Point-in-Time Correctness:** In recommendation systems, features (for example, user click history) must be retrieved exactly as they existed at the moment of the historical interaction. Retrieving current features for a past event – a “temporal leakage” – inflates training accuracy but causes the model to fail in production. Solving this at petabyte scale requires an immutable feature ledger or a “time-travel” query engine, significantly increasing storage complexity.

14 | **Hash Cost (SHA-256):** Verifying the integrity of a 100 TB dataset using SHA-256 consumes approximately 1,501.5 CPU-core hours under a pipeline-level throughput assumption of 18.5 MB/s per core. For a 30-day foundation model training run, this metadata validation step must be pipelined or performed during ingestion to avoid stalling the fleet’s startup phase.

stage writes an immutable artifact, and each artifact records the input version, code version, schema, and statistical checks it satisfied. Once those dependencies are explicit, the pipeline forms a Directed Acyclic Graph (DAG): later artifacts depend on earlier artifacts, and no stage is allowed to rewrite its own history. When a training job starts, the cluster manager verifies that each worker's local NVMe shards match the data snapshot declared for the run. By treating the data pipeline as a graph of versioned artifacts rather than a simple file transfer, the system eliminates the silent data drift that is a primary source of failure in foundation model training.

Beyond pipeline orchestration, a hardware optimization eliminates one of the most common bottlenecks: the CPU's role as intermediary between storage and accelerator.

4.5 GPUDirect Storage and the CPU Bypass

The storage hierarchy can provide enough aggregate bandwidth and still leave GPUs waiting when the CPU mediates thousands of small transfers. In the traditional path, every shard read bounces through host DRAM and software layers before reaching GPU HBM; GPUDirect Storage (GDS) removes that CPU-mediated path when local or RDMA-attached NVMe is the bottleneck. Understanding the traditional path first makes the GDS optimization clear.

The traditional data path for loading training data follows three hops: storage → host DRAM → GPU HBM. Data is first read from NVMe into a kernel buffer in host DRAM (via a DMA transfer initiated by the NVMe controller), then copied to a user-space buffer (the data loader's tensor, via a `memcpy` that the CPU executes), and finally transferred to GPU memory via the PCIe bus (using a `cudaMemcpy` or `cudaMemcpyAsync` call that programs the GPU's DMA engine). Each hop adds latency and consumes CPU resources. The CPU must orchestrate every transfer, manage buffer allocation, and handle interrupts from both the storage device and the GPU. For a single transfer, this overhead is negligible. When eight GPUs each demand thousands of small transfers per second, however, the aggregate CPU load for data movement alone can saturate multiple cores, leaving insufficient CPU capacity for the data augmentation that is also essential to the pipeline.¹⁵

¹⁵ | **GDS (GPUDirect Storage):** Part of NVIDIA's GPUDirect family, which also includes GPUDirect RDMA (network adapters writing directly to GPU memory) and GPUDirect Peer-to-Peer (inter-GPU memory access). GDS extends this CPU-bypass philosophy to NVMe storage via the `cuFile` API. The combined effect of RDMA and GDS is that data can traverse the path remote storage → network → GPU memory without a single CPU instruction on the critical path, freeing the host processor entirely for augmentation and pipeline orchestration.

Definition 4.4: GPUDirect Storage

GPUDirect Storage (GDS) is a technology that enables a direct DMA path between NVMe storage devices and GPU memory, bypassing the host CPU and system DRAM.

1. **Significance:** It eliminates the “Bounce Buffer” through system memory. In the small-transfer model below, this reduces per-transfer latency by 75 percent and makes the local transfer path 4× faster. It allows the GPU to saturate the NVMe link speed (for example, 7 GB/s) while reducing CPU utilization for I/O.
2. **Distinction:** Unlike Traditional I/O, where every byte must be processed by the CPU and stored in kernel buffers, GDS provides Direct Memory Access between the storage controller and the accelerator.
3. **Common pitfall:** A frequent misconception is that GDS makes all storage “faster.” In reality, it only accelerates Local or RDMA-attached NVMe; it does not eliminate the physical latency of network-attached file systems or object storage.

The software layers in the traditional I/O path contribute to the latency overhead. When a data loader calls `read()` on an NVMe-backed file, the call traverses the application's runtime, the Python/C++ boundary, the operating system's Virtual File System (VFS) layer, the file system driver (ext4, XFS), the block layer, and finally the NVMe driver. Each layer adds a few microseconds of overhead for parameter validation, lock acquisition, and buffer management. On the return path, the NVMe controller raises an interrupt, the interrupt handler wakes the blocked thread, and the data is copied from the kernel buffer to user space. The total round-trip overhead for a small read is 10–50 μs, dominated by the context switches and buffer copies rather than the actual NVMe access time.

GDS eliminates these software layers for the data path. The `cuFile` API registers a GPU memory region with the NVMe controller, establishing a direct DMA mapping. Subsequent reads transfer data from NVMe to GPU memory without traversing the kernel's file system or block layers. The CPU's

role is reduced to issuing the DMA command and checking for completion, a few microseconds of work compared to the 50+ microseconds of the traditional path.

The latency reduction from GDS matters most when the training pipeline is already optimized and the remaining bottleneck is the CPU’s ability to mediate transfers. In a node with 8 GPUs, each running a data loader with 4 workers, the CPU must manage 32 concurrent I/O streams. At 120 μ s per transfer, the CPU spends significant time in interrupt handling and buffer management. GDS offloads this work to hardware DMA engines, freeing CPU cores for data augmentation and other preprocessing tasks. Figure 4.6 contrasts the two data paths side by side, showing where GDS eliminates the CPU-mediated copies that dominate per-transfer overhead.

Figure 4.6: Traditional vs. GPUDirect Storage Path: The traditional path (top) requires two copies and CPU involvement. The GDS path (bottom) uses DMA to transfer data directly from NVMe to GPU memory, eliminating the CPU as a bottleneck.

As figure 4.6 illustrates, the throughput improvement from GDS is most pronounced for workloads that read many small objects (such as decoded image patches) where per-transfer overhead dominates. For large sequential reads (such as streaming a multi-gigabyte training shard), the throughput improvement is more modest because the transfer time dominates the setup overhead. The general principle is that GDS removes a constant overhead per transfer, so workloads with many transfers per second benefit most.

 Napkin Math 4.6: The CPU bypass dividend

Problem: A training node with 8 GPUs loads 150 KB at 8,000 images/s per GPU (64,000 images/s total). Compare the CPU load under traditional I/O vs. GDS.

Traditional path: Each image requires a DMA from NVMe to DRAM, a host copy from kernel to user space, and a PCIe transfer to GPU. At 64,000 images/s with 120 μ s of CPU time per

image, the CPU spends 7.68 seconds of CPU time per wall-clock second, consuming roughly 8 cores worth of processing just for data movement.

GDS path: Each image is DMA'd directly from NVMe to GPU. At 30 μ s of CPU time per image (for initiating the DMA), the CPU spends 1.92 seconds of CPU time per wall-clock second, freeing roughly 6 cores for data augmentation.

Systems insight: GDS reduces latency and, more importantly, shifts CPU utilization from data copying (which adds no value) to data augmentation (which improves model quality).

GDS has practical limitations. Not all NVMe controllers support peer-to-peer PCIe transfers. The data must be in a format that the GPU can consume directly, which means it must already be decoded or GPU-decodable (raw pixel values, token IDs, or formats handled by GPU decoders, not arbitrary compressed JPEG or gzip streams). In practice, many pipelines use a hybrid approach: CPU-side decoding for compressed formats followed by a normal pinned-memory GPU transfer, while GDS is reserved for direct reads of GPU-consumable data from supported local or remote storage.

The architectural evolution from CPU-mediated I/O to direct storage access reflects a broader trend in ML systems: removing the CPU from the critical data path wherever possible. Section 3.4.1 described RDMA, which removes the CPU from network data transfers. GDS does the same for storage transfers. The combined effect of RDMA and GDS is that data can flow from remote storage, through the network fabric, and into GPU memory without a single CPU instruction on the critical path. The CPU is freed to perform the tasks where it adds unique value: data augmentation, pipeline orchestration, and error handling.

The GDS design principle also extends to checkpoint writes. In the traditional path, checkpoint data flows from GPU HBM through host DRAM (via PCIe) to NVMe (via CPU-mediated write). With GDS, the checkpoint can be written directly from GPU HBM to NVMe, eliminating the host DRAM copy. For a 1,750 GB checkpoint, this removes one full data copy and reduces the CPU's involvement in the write path, lowering T_{write} further.

4.5.1 The complete data path

Combining GDS with the multi-tier hierarchy, we can now trace the complete data path for our running example. At the beginning of the training job, the 6 TB serialized shard set, derived from the 3 TB compressed source corpus, is staged from object storage into the cluster's local NVMe caches, with each node receiving its assigned shard subset during setup. The data loader workers read tokenized shards from NVMe, assemble packed sequences in pinned host DRAM, and transfer those batches to the accelerator. With GDS enabled, token IDs that are already in a GPU-consumable layout can be loaded directly into GPU memory without CPU involvement; compressed formats still require CPU or GPU decompression before use.

During training, the pipeline operates in steady state. The CPU data loader workers continuously read from local NVMe, filling a prefetch queue in host DRAM. The GPU pulls batches from this queue via PCIe DMA. The compute phase (forward pass, backward pass, optimizer step) consumes the batch and updates the model weights in HBM. Every 10 minutes, the training framework initiates a checkpoint: model weights and optimizer state are written from GPU HBM to local NVMe (either through host DRAM or via GDS), and a background thread asynchronously copies the local checkpoint to the parallel file system.

At the end of the training job, the final model checkpoint is promoted from the parallel file system to object storage for long-term retention. The local NVMe copies are deleted during job cleanup. If the model is deployed for inference, it is loaded from object storage into the serving cluster's HBM, completing the lifecycle of data movement through the hierarchy.

The total number of data copies in this lifecycle is instructive. Each training sample traverses: object storage $\rightarrow$ NVMe (staging), NVMe $\rightarrow$ host DRAM (read), host DRAM $\rightarrow$ GPU HBM (transfer). Each checkpoint traverses: GPU HBM $\rightarrow$ NVMe (local save), NVMe $\rightarrow$ parallel file system (async copy), parallel file system $\rightarrow$ object storage (long-term retention). Every copy consumes bandwidth and contributes latency. The engineering goal is to minimize copies on the critical path (the training loop) and tolerate additional copies on noncritical paths (staging and archival).

The volume of data moved during a 30-day training run reveals a counterintuitive reality. A single staging copy of the 6 TB serialized dataset from object storage to local NVMe accounts for a modest transfer. The checkpointing process, however, generates a vastly larger data stream. With a roughly 1,750 GB checkpoint created every 10 minutes across 256 nodes for 30 days, the system produces approximately 4,320 checkpoints, totaling roughly 7.6 PB of state that must traverse the storage hierarchy. Checkpoint data movement dwarfs training data movement for large models: while the 6 TB training dataset might be read a handful of times (once per epoch), the 7.6 PB of checkpoint data is generated anew, making checkpoint I/O the dominant storage workload. This insight explains why checkpoint staging strategy (write locally, replicate asynchronously) can have a larger impact on overall storage design than training data pipeline optimization for large-model runs. The physical data path dictates where bytes move; the remaining question is what each movement costs.

4.6 Storage Economics

A 100 TB training dataset can reside on any tier of the hierarchy, but the cost differs by orders of magnitude depending on which tier is chosen and how the data is accessed. ML storage economics is not simply about choosing the cheapest tier; it is about minimizing **total cost of data delivery**, which includes storage costs, transfer costs, and the opportunity cost of idle accelerators.

Consider storing a 100 TB training dataset. The annual storage cost varies enormously by tier:

- **Object storage (S3 Standard):** \$24,000/year
- **Local NVMe (provisioned):** \$120,000/year
- **Archive (Glacier):** \$4,800/year
- **HBM equivalent** (hypothetically storing 100 TB in GPU memory at \$15/GB): \$1,500,000 in hardware amortization

The 5× cost difference between local NVMe and object storage (with the full HBM-to-archive span exceeding 3,000×) explains why the hierarchy exists: data must live at the cheapest tier possible, migrating upward only when needed and returning downward when done. This cost gradient reflects the underlying physics. Faster storage requires more expensive materials (HBM uses 3D-stacked silicon with through-silicon vias), more energy per bit accessed, and more physical proximity to the accelerator (which limits the amount that can be provisioned per node). Cheaper storage uses commodity components (standard hard drives for archive), consumes minimal energy when idle, and can be located anywhere with network connectivity.

Storage cost, however, is only part of the equation. **Data transfer costs** can dominate, especially in cloud environments. Under the representative cross-boundary egress assumption used here, reading the 100 TB dataset from object storage to compute instances incurs a transfer charge of \$9,000. For multi-epoch training that reads the dataset 10 times, the egress cost alone exceeds \$90,000, more than the annual storage cost. This inversion, where *reading* data costs more than *storing* it, drives the architecture decision to cache data on local NVMe rather than streaming from object storage each epoch.

The economic analysis changes further when accounting for the opportunity cost of accelerator idle time. A 1,000 GPUs cluster at \$2/GPU-hour costs \$48,000 per day. If an undersized storage system reduces accelerator utilization from 90 percent to 70 percent, the organization loses \$9,600 per day in wasted compute. Over a 30 days training run, this amounts to \$288,000 of lost compute value, an amount that would easily fund a parallel file system upgrade or additional NVMe capacity. The economically rational approach treats storage investment not as an expense but as an enabler of compute utilization: every dollar spent improving storage throughput returns several dollars of increased accelerator productivity.

Repeated egress, not storage, dominates cloud cost.

🔍 Systems Perspective 4.2: The storage cost iceberg

The visible cost of storage (\$/GB/month) is the tip of the iceberg. Below the surface lie costs that often exceed the storage cost itself:

- **Egress fees:** A representative cross-boundary egress charge of \$0.09/GB makes a 100 TB dataset read once per epoch across 10 epochs cost \$90,000 in egress alone.

- **IOPS charges:** Object storage charges per-request fees. S3 Standard GET requests cost about \$0.0004 per 1,000 requests, so a dataset of 100M individual files, read once, costs about \$40 in GET request fees before data transfer or retrieval charges, even though the storage cost is \$2,300/month.
- **Idle accelerator cost:** If storage stalls reduce GPU utilization from 90 percent to 70 percent on a 1,000 GPUs cluster at \$2/GPU-hour, the lost compute costs \$9,600/day (20 percent of \$48,000 daily spend), dwarfing any storage savings.
- **Retrieval fees:** Archive storage charges retrieval fees (\$0.02/GB for Glacier) in addition to egress. Restoring a 100 TB dataset from Glacier costs \$2,000 in retrieval fees plus \$9,000 in egress.

The economically rational strategy often invests more in storage (local NVMe caching, parallel file system capacity) to reduce transfer costs and prevent accelerator stalls.

The cost iceberg reveals that raw storage capacity can account for less than half of the total expenditure; replication, metadata operations, API calls, and cross-region transfers can collectively dominate the bill at scale. Among those hidden line items, egress is the one that often flips the architecture decision. Unlike capacity charges, which scale with the volume of data stored, egress charges scale with the volume of data read, and ML training reads the full dataset on every epoch.

Napkin Math 4.7: The egress tax

Problem: A team trains a vision model on a 50 TB image dataset stored in S3. Training runs for 20 epochs. The decision is whether to stream from S3 each epoch or stage to local NVMe.

Option A: Stream from S3

- Storage: $50 \text{ TB} \times \$0.023/\text{GB}/\text{month} \times 12 \text{ months} = \$13,800/\text{year}$
- Egress: $50 \text{ TB} \times 20 \text{ epochs} \times \$0.09/\text{GB} = \$90,000 \text{ per training run}$
- Total for 4 training runs/year: $\$13,800 + \$360,000 = \$373,800/\text{year}$

Option B: Stage to local NVMe

- Storage (S3 source of truth): $\$13,800/\text{year}$
- NVMe capacity (50 TB across cluster): $50 \text{ TB} \times \$0.10/\text{GB}/\text{month} \times 12 = \$60,000/\text{year}$
- Egress (stage once per training run): $50 \text{ TB} \times 4 \text{ runs} \times \$0.09/\text{GB} = \$18,000/\text{year}$
- Total: $\$13,800 + \$60,000 + \$18,000 = \$91,800/\text{year}$

Systems insight: Local NVMe caching saves \$282,000/year at 20 epochs per run, enough to fund 9 additional H100 GPUs at list price. Including the \$60,000/year provisioned NVMe cost and the once-per-run staging egress, the break-even point is just over 4 epochs per run; by the fifth epoch, local caching is cheaper than streaming from S3 every epoch.

The notebook turns the iceberg into a decision rule: the cheapest storage tier is not always the cheapest delivery path. Object storage can remain the source of truth, but repeated reads make egress, request overhead, and idle-accelerator cost part of the storage design. Multi-epoch vision training may justify staging on local NVMe by the fifth epoch, while single-epoch language-model pretraining may leave the corpus in object storage and optimize the streaming path instead. The architecture is therefore chosen from access pattern, read count, and latency sensitivity rather than from \$/GB/month alone.

The cost analysis extends to the parallel file system tier, which occupies a middle ground between NVMe and object storage in both performance and price. A parallel file system capable of delivering 1 TB/s aggregate bandwidth requires roughly 100 OSS nodes, each with multiple NVMe drives and high-bandwidth network connections. The capital and operational cost of such a system can exceed \$10 million per year. This expense is justified only if the alternative, streaming from object storage and paying egress fees, is even more expensive, or if the latency requirements of checkpoint

writes cannot be met by object storage alone. The break-even analysis depends on the organization's workload mix: a team running a single long training job may find that staging data on local NVMe and bypassing the parallel file system entirely is the cheapest option, while a team running many concurrent short jobs benefits from the shared namespace that a parallel file system provides.

The decision to **build vs. buy** storage infrastructure hinges on the trade-off between the high capital expenditure of an on-premises parallel file system and the recurring operational expenditure of cloud object storage. A 1-petabyte Lustre deployment costs roughly \$3–5 million in hardware, plus an additional \$500,000 per year in operational overhead for power, cooling, and engineering support. Storing 1 PB in a cloud object store at \$0.02/GB/month costs \$240,000 per year for storage alone. However, egress fees for accessing the data dominate the total cost: reading that petabyte at 10 reads/year adds \$900,000 in data transfer fees. Under these assumptions, annual cloud delivery costs \$1,140,000; after subtracting \$500,000 of on-premises operations, the net savings are \$640,000 per year. The resulting hardware break-even is roughly 4.7–7.8 years, not 18 to 24 months. Reaching an 18- to 24-month payback requires a hotter workload with many more full-dataset reads per year, lower capital expense, or non-egress drivers such as checkpoint latency and shared-namespace requirements. For our running example, the 6 TB serialized corpus is much smaller than 1 PB, so the local-storage case is driven more by latency, repeated experiments, and checkpoint staging than by one-year egress savings alone.

Hardware degradation introduces the need for a **storage refresh cycle**. NVMe drives are rated for a specific write endurance, measured in Drive Writes Per Day (DWPD) over a typical five-year warranty period. Many large-scale ML training workloads are predominantly read-heavy once the initial dataset is ingested, so drives in a training cluster can last beyond their rated write lifespan. The primary driver for a refresh cycle may therefore be density rather than wear: newer drives often provide more capacity at a similar price point. Refreshing a cluster from 7.68 TB to 15.36 TB NVMe drives doubles the local cache capacity, enabling larger datasets to be staged directly on compute nodes and reducing dependence on the parallel file system for steady-state reads.

4.6.1 Tiering strategies

The cost structure described earlier turns tiering into a placement policy: keep data only as close to the accelerator as its access frequency and latency requirement justify. A **tiering strategy** encodes that policy across the hierarchy.

The fastest and most expensive layer is the **hot tier** (local NVMe + host DRAM), which holds data being actively consumed by the running training job. Datasets are staged from shared storage to local NVMe at job start. This tier is provisioned per-node and is not shared across the cluster, so data that multiple jobs or teams need simultaneously cannot live here alone.

That shared-access requirement is what justifies the **warm tier** (parallel file system), which holds datasets accessed by multiple jobs or teams, shared checkpoints for fault recovery, and model artifacts under active development. The parallel file system provides the shared namespace necessary for multi-tenant access with strong consistency.

Below the warm tier sits the **cold tier** (object storage), which serves as the canonical repository for all organizational training data. Datasets are authored and versioned in object storage, then promoted to warmer tiers when needed for training. Object storage also serves as the durable backup for checkpoints after they are staged from local NVMe through the parallel file system.

Data that must be retained for compliance or reproducibility but is not expected to be accessed during normal operations drops to the **archive tier** (Glacier or equivalent). Lifecycle policies automatically transition data from cold to archive after a configurable period, typically 90 to 365 days since last access.

The movement of data between tiers should be automated through lifecycle policies. A well-designed tiering system automatically promotes data from cold to warm when a training job requests it, and demotes data from warm to cold when no job has accessed it for a configurable period. Manual tiering introduces operational burden and inevitably leads to either over-provisioning (data left on expensive tiers) or under-provisioning (data unavailable when needed).

Return to our running example to see tiering in action. The 3 TB source corpus and 6 TB serialized training shards live permanently in object storage (cold tier). When a training job is scheduled, the orchestration system triggers a “data staging” phase that copies the tokenized shards to the parallel

file system (warm tier) before the first training node boots. Each node's data loader then copies its assigned shards to local NVMe (hot tier) during the first epoch. Subsequent epochs read entirely from local NVMe, incurring no network traffic. When the job completes, a cleanup process deletes the local NVMe copies and, after a configurable grace period, purges the parallel file system copy. The entire lifecycle, from staging through training to cleanup, is managed by policy rather than by the training engineer.

The economic benefit of automated tiering compounds over time. An organization running 50 concurrent training jobs, each using 10 TB of data, would need 500 TB of parallel file system capacity if all data were left in place. Automated demotion after job completion might reduce the steady-state parallel file system usage to 100 TB, saving \$144,000 per year at the parallel file system's per-TB rate. These savings are invisible in any single experiment but substantial when accumulated across the fleet.

Data staging patterns

The staging decision determines where the job pays for movement: before training starts, during the first epoch, or on every epoch. Three common patterns address different trade-offs between startup latency and steady-state throughput:

- **Prestaging:** Copy the entire dataset from object storage to local NVMe before the first training iteration begins. This gives the best steady-state performance because all reads are local, but it creates the worst job start time; staging a 10 TB dataset across 256 nodes at 500 MB/s per node takes roughly 80 seconds per node, and shared parallel file system bandwidth can extend that delay to several minutes.
- **On-demand staging:** Copy shards to local NVMe only when the data loader first accesses them. This removes the startup delay but makes the first epoch pay the full network-read cost, which works best for multi-epoch training where later local reads amortize the initial staging cost.
- **Streaming:** Keep data off local storage and read from the parallel file system or object storage every epoch. This has zero startup delay and zero local storage requirement, but every epoch pays the full network-read cost, making it appropriate for single-epoch pretraining or datasets too large for local NVMe.

Tiering is a placement policy, so the next question is where the tier boundaries can move. Emerging devices shift the boundary between DRAM, NVMe, and archival storage, while inference workloads reuse the same hierarchy for a different objective: reducing cold-start latency and managing serving-time working sets rather than maximizing epoch throughput.

4.6.2 Storage technologies that move tiers

While the six-tier hierarchy represents a common production baseline, memory and storage technologies can fill the bandwidth gaps between existing tiers, reshaping effective storage architecture for large-scale ML. The widest unfilled gap in the hierarchy sits between host DRAM and local NVMe. Compute Express Link (CXL), an open standard interconnect that allows CPUs, accelerators, and memory devices to share memory with cache-coherent semantics, targets exactly this gap. CXL-attached memory provides bandwidth between that of local DRAM and NVMe (roughly 30–60 GB/s) at latencies that are also intermediate (200–500 ns). For ML workloads, CXL memory could serve as a “Tier 1.5” between host DRAM and local NVMe, creating a massive capacity pool for embedding tables and prefetch buffers without the latency penalty of NVMe. For our running example, CXL-attached memory could expand the effective host memory tier from 512 GB to over 4 TB per node, large enough to hold the compressed source corpus or a large local shard cache, though still short of the full 6 TB serialized training copy on one node.

A different bottleneck appears when CPU-side decoding, not storage bandwidth, throttles the pipeline. The **Computational Storage Drive (CSD)** closes that gap by embedding processing elements (FPGAs or simple CPU cores) directly on the SSD controller, enabling decompression, filtering, or format conversion to happen at the storage device rather than consuming host CPU cycles. For ML pipelines where CPU-side decoding is the bottleneck, computational storage could eliminate the CPU from the data path entirely, complementing GDS by offloading work that direct DMA cannot address.

Checkpoint writes remain throttled by SSD write latency, the T_{write} term the Young-Daly formula penalizes. **Persistent memory**, despite market shifts such as the discontinuation of Intel Optane, remains the architectural idea that attacks that term directly. Byte-addressable non-volatile memory that sits between DRAM and NVMe in both latency and capacity could transform checkpoint storage: the durability of an SSD with write latencies approaching DRAM would reduce T_{write} from milliseconds to microseconds, making frequent, low-overhead checkpointing more practical.

These technologies are not yet broadly deployed at the scale of the largest ML clusters, but they illustrate the direction of the storage hierarchy's evolution. The fundamental principle remains unchanged: faster, more expensive storage closer to the accelerator, with slower, cheaper storage at the periphery. What changes is the *granularity* of the tiers and the *size of the gaps* between them.

4.6.3 Storage for inference workloads

The storage requirements for inference differ fundamentally from training. Training reads datasets continuously and writes checkpoints in bursts. Inference reads model weights once at startup and performs no further storage I/O during normal operation. For inference serving, the dataset is replaced by a stream of incoming user requests, and the primary storage challenge shifts from sustained throughput for large datasets to latency for loading the model itself.

The most critical metric for inference storage is **model loading latency**, often called cold-start time: the duration required to load a model from storage into the accelerator's HBM. For our 175B parameter language model, the weights alone occupy 350 GB in FP16 format. Loading this sequentially from a single high-performance NVMe drive at 14 GB/s takes 25 seconds, an unacceptable delay for a user-facing application. Loading from a shared PFS at a per-node rate of 4 GB/s takes nearly 88 seconds. From object storage at 1 GB/s, the delay approaches six minutes.

To reduce cold-start time, the model is sharded and loaded in parallel. If the 350 GB model is striped across 8 NVMe drives, each loading a 43.75 GB shard at 7 GB/s, the total load time drops to roughly 6 seconds. When using tensor parallelism across 8 GPUs, each GPU loads only its 43.75 GB shard, which can be accomplished in under 4 seconds by reading from host DRAM. For the most latency-sensitive applications, organizations maintain **warm replicas**: one or more copies of the model weights kept preloaded in host DRAM, ready to be transferred to HBM in under two seconds. This trades DRAM capacity for near-instantaneous cold-start times.

During autoregressive generation, the server keeps a per-request record of the attention keys and values produced by earlier tokens so it can generate the next token without recomputing the entire prefix. This record, called the **KV cache**, grows with sequence length and can consume significant HBM. For long sequences (128K tokens or more), KV cache offloading to host DRAM or NVMe extends the effective context window at the cost of increased latency per generated token, because cache blocks must be moved back into HBM before attention can use them. The storage lesson is that inference has its own working set, not just a model-loading problem.

While model serving dictates its own economic calculus, the training phase introduces an entirely different, burst-heavy I/O challenge: the preservation of model state through checkpoint storage.

4.7 Checkpoint Storage

After a thousand GPUs have been training for six hours, a power supply failure turns checkpoint storage into the difference between resuming quickly and repeating hours of work. The decisive storage questions are how quickly the most recent checkpoint was saved, where it resides, and whether it can be read back. Checkpoints are the most demanding write workload in the storage hierarchy. They are also among the most consequential: a lost checkpoint after a hardware failure means repeating hours or days of training. The storage architecture must therefore minimize T_{write} , the time the training pipeline pauses to save a checkpoint.

A 175B parameter model with Adam optimizer generates checkpoints of approximately 1,750 GB. The checkpoint includes 350 GB of FP16 model weights, 1,400 GB of FP32 optimizer state for momentum and variance, learning rate scheduler state, random number generator state, and the current data loader position. Every GPU in the cluster saves its shard of the checkpoint simultaneously, creating a checkpoint storm that the storage system must absorb without disrupting ongoing training reads.

Sharding turns replicated checkpoint storms into sharded writes.

 Definition 4.5: Checkpoint storm

Checkpoint Storm is a burst of synchronized network and storage traffic that occurs when all nodes in an ML training fleet save model state simultaneously.

1. **Significance:** The storm magnitude scales as $T_{\text{write}} = R \times \text{per-replica state} / \text{BW}_{\text{fabric}}$, where R is the number of replicas writing at once. For a 70B-parameter model, each replica holds 140 GB FP16 weights, 140 GB gradients, and 840 GB optimizer state. With vanilla data parallelism across 1,024 replicas, a naive checkpoint of that full per-replica state generates 1146.9 TB of simultaneous writes. At 100 GB/s fabric bandwidth, that write takes roughly 11,468.8 seconds, or over 191.1 minutes of training stall per checkpoint event. ZeRO-3, an optimizer-state-sharding scheme in which each node stores only its $1/N$ slice of the state rather than a full replica, collapses the written state to roughly 1.12 TB total (140 GB weights + 140 GB gradients + 840 GB optimizer state, split across 1,024 replicas), bringing T_{write} down to roughly 11.2 seconds. This stall is the checkpoint T_{write} term and can dwarf the compute time between checkpoints when the sharding optimization is omitted.
2. **Distinction:** Unlike general I/O contention (which is stochastic and unpredictable), a Checkpoint Storm is synchronous and periodic: every node writes at the same moment because the training orchestrator triggers checkpoint after a fixed step count. Its predictability makes it both more damaging (all nodes compete simultaneously) and more tractable (it can be prevented by design through staggered scheduling or asynchronous serialization).
3. **Common pitfall:** A frequent misconception is that checkpointing every 100 steps is “low overhead.” At 70B scale, this assumption is catastrophically wrong: if each training step takes 10 seconds and a checkpoint storm takes 11,468.8 seconds, checkpointing every 100 steps means spending most of the run on checkpoint I/O rather than useful training.

The severity of a checkpoint storm depends on two factors: the per-node shard size, determined by the model size and the sharding strategy, and the throughput of the first write tier, typically local NVMe. A concrete 175B example shows why the local-write phase, rather than the durable copy to the parallel file system, governs the exposed training pause.

 Napkin Math 4.8: Tiered checkpoint staging

Problem: A 256-node cluster saves a 175B-parameter checkpoint every 10 minutes. Each checkpoint totals 1,750 GB. With ZeRO-3, each node saves roughly 6.8 GB.

1. **Per-node write to local NVMe** (4 drives at 7 GB/s each = 28 GB/s): $6.8 \text{ GB} \div 28 \text{ GB/s} \approx 0.24 \text{ seconds}$.
2. **Async copy to PFS:** $256 \times 6.8 \text{ GB} \approx 1.8 \text{ TB}$ total. If the PFS provides 1 TB/s aggregate, the storm completes in roughly 1.8 seconds.
3. **Per-node PFS bandwidth:** If all 256 write simultaneously, each gets $1000 \text{ GB/s} \div 256 = 3.9 \text{ GB/s}$.
4. **Training pause:** only about 0.24 seconds (the local NVMe write). The PFS copy overlaps with the next training iteration.
5. **Overhead:** 0.24 seconds pause every 600 seconds ≈ 0.04 percent training time lost to checkpointing.

Systems insight: Under these 1 TB/s aggregate-PFS assumptions, tiered staging reduces checkpoint overhead from about a 1.8 seconds PFS-direct write to a sub-second local write. The key insight is that T_{write} for the training pipeline is the *local* write time, not the *durable* write time.

The **tiered staging** strategy minimizes T_{write} by writing in two phases. In the first phase, each node writes its checkpoint shard to local NVMe at full bandwidth. With 4 NVMe drives providing 28 GB/s aggregate, a per-node shard of roughly 6.8 GB (a 256-node ZeRO-3 split of the 1,750 GB total checkpoint) completes in roughly 0.24 seconds. The training pipeline can resume immediately after the local write completes.

In the second phase, a background process asynchronously copies the local checkpoint to the parallel file system for durability. This copy can overlap with the next training iteration, so it does not block the pipeline. The risk is that if the node fails before the async copy completes, the local checkpoint is lost. The mitigation is to replicate checkpoints to at least two peer nodes' NVMe drives before declaring the save complete, providing durability even if one node fails.

The total storage consumed by checkpoints over the life of a training run is substantial. A 175B parameter model checkpointed every 10 minutes over a 30-day training run generates roughly 4,320 checkpoints, each 1,750 GB, for a total of approximately 7.6 PB of checkpoint data. Retaining all of them is neither necessary nor economical. The retention policy this run adopts keeps the three most recent checkpoints on the parallel file system for fast recovery, copies every 100th checkpoint to object storage for long-term auditability, and deletes the rest. This policy reduces the parallel file system checkpoint footprint from 7.6 PB to roughly 5.25 TB (three live full checkpoints) while preserving 43 historical snapshots in object storage for posttraining analysis.

Incremental checkpointing offers a further optimization for reducing T_{write} . Rather than saving the entire model state every checkpoint, an incremental checkpoint saves only the parameters that changed since the last full checkpoint. For models where a large fraction of parameters are frozen (such as fine-tuning scenarios where only the last few layers are updated), incremental checkpoints can be orders of magnitude smaller than full checkpoints. The trade-off is recovery complexity: restoring from an incremental checkpoint requires applying a chain of incremental updates to a base checkpoint, which extends recovery time. Most production systems use a hybrid approach, saving incremental checkpoints frequently and full checkpoints periodically (every 10th to 100th increment).

Checkpoint storage interacts directly with the system's failure model. From the storage perspective, the design goal is to minimize T_{write} (the time the training pipeline pauses) while ensuring that at least one durable copy of the checkpoint exists before the next failure window opens. Reducing T_{write} through tiered staging makes more frequent checkpoints affordable. Minimizing T_{write} , however, only matters if the checkpoint can actually be read back; the costlier failure is a checkpoint that was written but never verified as restorable.

War Story 4.1: The backup that had not been restored

Context: On January 31, 2017, around 23:30 UTC, a GitLab.com site reliability engineer working a database replication incident wiped what they believed was the secondary PostgreSQL data directory but had switched terminals to the production primary (GitLab 2017). The restored snapshot later returned the database to its state at about 17:20 UTC, which is why roughly six hours of writes were unrecoverable.

Failure mode: GitLab.com depended on five layered recovery paths: pg_dump backups to S3, LVM snapshots, Azure disk snapshots, PostgreSQL replication, and WAL archiving. All five failed or were absent. The S3 dumps were silently empty due to a PostgreSQL 9.2/9.6 version mismatch; Azure snapshots were not enabled for database servers; replication was the very procedure that had broken; LVM snapshots existed but were six hours stale; WAL archiving had never been implemented.

Consequence: Roughly six hours of recent commits and database state were unrecoverable. GitLab livestreamed the recovery on YouTube to about five thousand concurrent viewers and published a public Google document tracking progress, restoring service after about eighteen hours from a stale staging-environment snapshot.

Systems lesson: Storage reliability is a restore property, not a backup property. A checkpoint, replica, or dump only counts if the team regularly proves that it can be located, validated, and restored under incident conditions.

That incident turns checkpoint storage from a capacity question into a restore-design question.

Checkpoint 4.4: Checkpoint storage design

A training cluster of 128 nodes saves a 175B-parameter model checkpoint every 10 minutes. Each checkpoint is 1,750 GB total, distributed across all nodes.

- ☐ **Per-node state:** Calculate the per-node checkpoint size.
- ☐ **Local write:** Calculate T_{write} for the local write when each node writes to local NVMe at 28 GB/s.
- ☐ **Async copy:** Calculate the per-node write bandwidth and async-copy time when the parallel file system provides 1 TB/s aggregate and all 128 nodes write simultaneously.
- ☐ **Tiered staging:** Explain why tiered staging (local NVMe first, then async PFS copy) is faster than writing directly to PFS.

4.7.1 Distributed checkpoint coordination

In a sharded training setup with 128 nodes, no single node necessarily holds the complete training state. One node may hold a shard of the optimizer state, while other model-partitioning strategies split the weights themselves across devices. A complete checkpoint therefore requires every node to save its shard, and the checkpoint is only complete when all shards have been durably written. This creates a coordination problem: the system must confirm that all 128 nodes have finished writing before training can resume.

The simplest approach is a synchronous barrier: all nodes pause training, write their shards to local NVMe, then run a cluster-wide acknowledgement operation to confirm completion. Only when every node has acknowledged its write does training resume. This approach minimizes the risk of inconsistent checkpoints, where some shards are from step i and others from step $i + 1$, but it maximizes the training pause because the slowest node determines the barrier time.

Asynchronous checkpointing reduces the training pause by writing in the background. Each node snapshots its shard to a pinned memory buffer (a fast copy within DRAM), resumes training immediately, and writes the buffer to NVMe in a background thread. The snapshot captures a consistent point-in-time view of the model state. The risk is that if a node fails during the asynchronous write, the local NVMe may contain an incomplete shard. The mitigation requires either waiting for the async write to complete before considering the checkpoint durable, or replicating the in-memory snapshot to a peer node before allowing the next training step to overwrite the snapshot buffer.

The choice between synchronous and asynchronous checkpointing depends on the ratio of T_{write} to $T_{\text{iteration}}$. If T_{write} is small relative to $T_{\text{iteration}}$ (for example, 1 second vs. 200 ms per iteration, meaning the checkpoint pause costs 5 iterations), synchronous checkpointing is acceptable. If T_{write} is large (for example, 30 seconds for a 500B+ parameter model), the training pause is prohibitive, and asynchronous checkpointing becomes essential.

Beyond the choice of synchronous or asynchronous methods, **checkpoint format optimization** reduces the per-node I/O volume. In the simplest data-parallel setup, every node holds an identical copy of the model weights, so a naive checkpoint would redundantly save the same data from every node. Sharded checkpoint protocols avoid that redundancy by saving shards instead of full replicas. DeepSpeed's **zero-redundancy checkpointing** uses its ZeRO optimizer-state partitioning: each of the H nodes saves only its $1/H$ shard of the optimizer state, and the system saves one consolidated copy of the weights. PyTorch's **Distributed Checkpoint (DCP)** protocol follows the same storage principle by writing each rank's sharded data to a distinct file. For our 175B model using ZeRO-3 across 256 nodes, the result is concrete: each node writes only its roughly 6.8 GB shard of the total 1,750 GB state, reducing the local write from minutes to around a second on one NVMe drive, or well below a second on a local stripe. The tiered-staging derivation in section 4.7 already threaded these per-node shard sizes and write times through the running example, and the same arithmetic governs distributed coordination: the exposed pipeline pause is the local NVMe write, while the durable copy to the parallel file system overlaps with subsequent training.

With the checkpoint accounting now derived in full, the running example’s storage demands can be consolidated against the same hierarchy, so the training dataset, checkpoints, and archive lineage are visible side by side.

Systems Perspective 4.3: The 175B model’s storage footprint

Table 4.5 assembles the complete storage picture for our running example, a 30-day training run of a 175B-parameter model on 256 nodes.

Table 4.5: 175B-parameter training storage footprint: Volume and primary storage tier for each data category in a 30-day, 256-node training run.

Category	Volume	Primary Tier
Training dataset (compressed source)	3 TB	Object Storage
Training dataset (tokenized, per epoch)	6 TB	Object Storage → NVMe cache → Host DRAM
Model weights (FP16)	350 GB	GPU HBM (distributed)
Optimizer state (FP32)	1,400 GB	GPU HBM (ZeRO-partitioned)
Single checkpoint (full)	1,750 GB	NVMe → PFS → Object Storage
All checkpoints (30 days, 10-min interval)	7.6 PB	NVMe (transient) → PFS (recent) → Object (archive)
Archive (retained checkpoints + dataset)	~84.2 TB	Glacier

The total data moved through the hierarchy is approximately 7.6 PB of checkpoint data plus 6 TB per 1 epoch of training data reads. For a single-epoch language model training run, checkpoint I/O dominates data loading I/O by a factor of over 1,260.

Feature stores and model registries, the operational systems that manage feature serving and model versioning, are also built on top of this storage hierarchy, depending on the same tiering, durability, and latency boundaries introduced here. Training streams its fuel sequentially and writes checkpoints in bursts; retrieval-augmented inference reverses that access pattern, replacing sequential streaming with random graph traversal, so the same hierarchy must now serve a workload it was not tuned for. Vector databases, specialized storage systems for approximate nearest-neighbor search in embedding spaces, serve the retrieval-augmented generation pipeline by making that reversed access pattern operational.

4.8 Retrieval Infrastructure: Vector Indexes

The storage hierarchy so far has optimized the training fuel line: large shards, sequential reads, and checkpoint bursts. Retrieval-augmented inference adds a storage workload that belongs in the same chapter because it reverses the access pattern again. A retrieval system first converts documents into vectors that represent semantic meaning, then serves an inference request by finding nearby vectors and returning their source documents as context. Instead of streaming sequential blobs via formats like TFRecord or Parquet, the storage system now traverses high-dimensional vector graphs.

Systems Perspective 4.4: The IOPS bottleneck in high-dimensional search

This architectural pattern shifts the primary storage bottleneck from **sequential read bandwidth** to **random-access IOPS**. Vector databases must traverse high-dimensional graph indexes to find approximate nearest neighbors across billions of embeddings. The performance is governed by a strict physical constraint: the **Recall vs. Latency vs. Capacity** trade-off. Maximizing recall requires traversing a larger portion of the index, driving up IOPS and latency. The index is

large because each embedded document chunk occupies substantial storage: a 1,536-dimension embedding in FP32 (4 bytes per value) consumes approximately 6.1 KB per vector, so a billion-document corpus requires roughly 6.1 TB of raw vector storage before the graph adjacency lists that enable fast navigation. If those adjacency lists add 50 to 100 bytes per node, they add roughly 50 GB to 100 GB, making raw vectors plus minimal graph metadata about 6.2 TB at the high end for a billion-entry corpus. Full production indexes can be larger once identifiers, graph levels, allocator overhead, deleted-entry slack, and replication are included, but those are implementation overheads rather than the raw vector-plus-adjacency footprint. At that scale, the index no longer fits in DRAM, which is the design pressure that motivates disk-backed alternatives. In-memory hierarchical navigable small world (HNSW) graph indexes make the same graph-navigation idea fast when the index fits in DRAM (Malkov and Yashunin 2020), while hybrid search combines vector similarity with lexical or metadata filters and therefore stresses both random vector traversal and document fetches. Disk-backed graph indexes such as DiskANN show how billion-scale search can trade DRAM footprint against SSD-backed graph traversal while targeting high recall and low query latency (Subramanya et al. 2019).

This makes retrieval infrastructure a useful counterexample to the training fuel line. The same hierarchy still applies, but the objective changes: training storage hides sequential bandwidth behind prefetching, whereas vector search spends storage budget on the index levels that keep random graph traversal inside the serving latency SLO. A disk-backed index is economical only if the extra SSD traversals do not erase the quality gain from searching a larger corpus. The retrieval workload thus reuses the same physical hierarchy while inverting the objective, which closes the access-pattern contrast that the fuel line opened.

4.9 The Synthetic Fuel Line

The storage architecture changes again when the fleet exhausts its supply of human-authored training data, because synthesized data must carry its own provenance. As high-quality human-generated text becomes harder to expand, the fleet encounters the **Data Wall**: the point where additional training samples must increasingly come from synthesis, simulation, curation, or expensive human collection (Villalobos et al. 2022). This shift from simple collection to managed data generation sends more than payload bytes through the hierarchy. A “synthetic fuel line” must also store the **provenance chain** of every sample: which model generated it, which filters accepted or rejected it, which judge or verifier models scored it, and which downstream run consumed it. Without that lineage, the system risks **model collapse**, where a model degrades by training on its own unverified errors (Shumailov et al. 2024).

Napkin Math 4.9: The synthetic tax

Problem: Calculate the storage amplification of a 1 TB synthetic dataset that requires cryptographic lineage and multi-model verification.

1. **Raw Payload:** 1 TB.
2. **Provenance Overhead:** 40 percent extra for lineage hashes, generation logs, and reward-model scores.
3. **Verification Factor:** To avoid “self-poisoning,” each sample is verified by 3 independent “judge” models.
4. **Result:** Total footprint = $1 \text{ TB} \times 1.4 \times 3 = 4.2 \text{ TB}$.

Systems insight: Synthetic data is *verified data*, and verification has a 4.2× storage tax. In the Machine Learning Fleet, storage moves from being a simple bit-bucket to a *provenance engine*. A system that cannot store the *why* and *who* behind a synthetic token risks poisoning the future of the fleet with its own past mistakes.

The synthetic fuel line closes the chapter’s storage arc by making lineage part of the payload. Large-scale training, checkpointing, retrieval, and synthetic-data generation stress different tiers, but each failure mode comes from the same mistake: treating storage as passive capacity instead of an active system that controls throughput, reproducibility, and model quality.

4.10 Fallacies and Pitfalls

Storage design errors are among the most expensive mistakes in ML infrastructure because they are discovered late, when training begins, and remediation requires either expensive hardware upgrades or time-consuming data reformatting. The following fallacies and pitfalls capture the most common errors that experienced storage engineers make when first encountering ML workloads.

Fallacy: *NVMe is fast enough to feed GPUs directly without pipelining.*

A single NVMe drive delivers 7 GB/s, while an H100 consumes 3.35 TB/s from HBM. The gap is roughly 478.6 $\times$. Even four drives in RAID-0 only close this gap to about 120 $\times$ before overhead. Without pipelining and prefetching to hide the latency of loading from NVMe to host DRAM to HBM, every batch transfer introduces a stall equal to the transfer time. NVMe speed is necessary but nowhere near sufficient; the entire pipeline architecture (multi-worker loading, prefetch buffers, async transfers) exists precisely because no single storage device can match accelerator bandwidth. The confusion arises because NVMe bandwidth is quoted in *absolute terms* (GB/s), which sounds impressive, but the relevant metric is the *ratio* of storage bandwidth to accelerator consumption rate, and this ratio is unfavorable by two to three orders of magnitude.

Pitfall: *Relying on prefetching to hide object storage latency.*

Prefetching hides *average* latency, not *tail* latency. Object storage P99 latency can spike to several hundred milliseconds during congestion or cross-region failover. A prefetch buffer of depth Q_{prefetch} absorbs variance up to $Q_{\text{prefetch}} \times T_{\text{compute}}$ milliseconds. If a tail-latency spike exceeds this window, the buffer drains and the accelerator stalls. For training jobs that run for weeks, even rare P99.9 spikes occur frequently enough (thousands of times per day at scale) to measurably reduce utilization. The mitigation is not to assume prefetching solves all problems, but to provision buffer depth based on measured tail latency and to stage data on local NVMe where possible.

Fallacy: *Millions of small training files are harmless at scale.*

Storing each training sample as an individual file (one JPEG per image, one JSON per text sample) is natural for data collection but catastrophic for training at scale. Each file requires metadata operations (`open()`, `stat()`, `close()`) that serialize on the metadata server. At 10,000 concurrent workers, metadata operations become the bottleneck long before data bandwidth saturates. The solution is to aggregate samples into large sequential shards (TFRecord, WebDataset tar, Parquet) during preprocessing. This reduces metadata operations by 10,000 to 100,000 $\times$ and transforms random access patterns into sequential streaming.

Pitfall: *Ignoring egress costs when designing the storage architecture.*

Cloud egress costs are invisible during development but can dominate at scale. Under a representative \$0.09/GB cross-boundary egress fee, a training job that reads a 100 TB dataset from object storage 10 times incurs \$90,000 in egress fees, far exceeding the annual storage cost of \$27,600 under the object-storage price assumption above. These fees apply when reads cross a region, provider, or internet boundary; same-region reads may be free or discounted, which is exactly why the cost stays hidden until a cross-region or multi-cloud topology makes it unavoidable. Teams that prototype with small datasets on object storage and then scale up discover that their storage architecture is economically unsustainable. The fix is to budget egress costs explicitly and to design the data pipeline to minimize cross-tier transfers, typically by staging data on local NVMe at job start rather than streaming from object storage each epoch.

Fallacy: *Average write bandwidth is enough for checkpoint design.*

Checkpoints are written by all nodes simultaneously, creating bursts that can exceed steady-state bandwidth by 10 $\times$ or more. A parallel file system sized for average write load will bottleneck during checkpoint storms, extending T_{write} and reducing the effective training throughput. The parallel file system must be provisioned for peak burst bandwidth, not average, even though the burst capacity sits idle most of the time.

Pitfall: *Assuming faster accelerators automatically improve training throughput.*

When an organization upgrades from A100 to H100 GPUs, they expect training time to decrease proportionally to the compute improvement. If the storage pipeline was already marginal on A100s, delivering data just fast enough to avoid stalls, the faster H100 compute simply hits the I/O wall sooner. The accelerator upgrade reduces T_{compute} without reducing $T_{\text{I/O}}$, which means the data stall ratio increases. Every accelerator upgrade must be accompanied by a storage pipeline audit to ensure that the faster compute does not simply expose a previously hidden storage bottleneck.

Fallacy: *RAID configurations optimized for databases are suitable for ML training.*

Database-oriented RAID configurations like RAID 5 or RAID 6 prioritize redundancy over raw bandwidth, incurring a 15–25 percent write performance penalty due to parity calculations. This overhead is unnecessary for ML workloads where training data is immutable and already backed up in durable object storage. For local NVMe caches feeding accelerators, the correct choice is RAID 0 (striping), which maximizes sequential read throughput by combining the bandwidth of all drives without parity overhead. The data on local NVMe is a *cache*, not a *source of truth*; losing it to a drive failure costs a re-staging operation, not data loss.

Pitfall: *Creating full copies for each dataset snapshot.*

Naive dataset versioning is financially and operationally unsustainable at scale. For a 10 TB dataset, creating a full copy for each version quickly exhausts storage budgets and slows experimentation cycles. A 5 percent change between versions stores 9.5 TB of redundant data. The correct approach uses content-addressable storage or delta encoding, where only changed samples are stored. This reduces the storage cost of a new version from 10 TB to roughly 500 GB, a 20× reduction. Tools like DVC (Data Version Control) and lakeFS implement this pattern, tracking dataset lineage without duplicating unchanged content.

Fallacy: *Compression always helps because it reduces the amount of data to read.*

This is only true if the pipeline is I/O-bound. Compression reduces I/O volume but increases CPU load due to decompression. For a CPU-bound pipeline where complex data augmentation already saturates the host processor, adding decompression work makes the bottleneck *worse*, not *better*, leading to a net decrease in throughput to the accelerator. The correct approach is to profile the pipeline first: if the host CPU is the bottleneck, use uncompressed or lightly compressed formats (LZ4); if storage or network I/O is the bottleneck, use aggressive compression (zstd, gzip). The optimal compression level is a property of the pipeline’s bottleneck, not a universal constant.

Pitfall: *Choosing a compression format before profiling the pipeline bottleneck.*

Teams often standardize on one compression format for operational simplicity, then apply it to every dataset regardless of access pattern. That shortcut hides the real question: whether the job is paying more for bytes moved or cycles spent decoding them. A storage pipeline should choose compression after measuring CPU utilization, storage bandwidth, network bandwidth, and accelerator idle time on representative batches; otherwise the format becomes another fixed assumption that moves the bottleneck rather than reducing it. These fallacies all return to the same accounting exercise: where each byte lives, how often it moves, and which tier pays the cost.

4.11 Summary

Storage in ML systems is not a passive repository; it is an active, multi-tiered pipeline whose sole purpose is to keep accelerator HBM populated with data. The hierarchy spanning HBM, host DRAM, local NVMe, parallel file systems, object storage, and cold archive exists because no single technology can simultaneously deliver the bandwidth, capacity, and cost profile that large-scale training demands. Roughly three orders of magnitude in aggregate bandwidth separate HBM from cold archive, and each intermediate tier serves as a staging buffer that absorbs the mismatch between the rate at which accelerators consume data and the rate at which persistent storage can supply it. The data pipeline throughput equation, $BW_{\text{required}} = N_{\text{GPU}} \times \eta_{\text{target}} \times D_{\text{vol, batch}} / T_{\text{iteration}}$, provides the quantitative foundation for sizing every tier: miss the required bandwidth at any level and expensive accelerators idle; over-provision and capital is wasted on storage capacity that sits underutilized.

What makes ML storage particularly challenging is that these workloads invert nearly every assumption baked into decades of storage system design. Databases optimize for random IOPS, cacheable working sets, and continuous small writes. ML training demands sequential streaming throughput over datasets that dwarf all cache levels, punctuated by massive checkpoint bursts that saturate bandwidth for seconds before returning to silence. The metadata overhead of small files,

harmless in traditional workloads, becomes the dominant bottleneck when millions of individual samples must be opened, stat'd, and closed per epoch. Aggregating samples into large shards, choosing sequential streaming formats like WebDataset or TFRecord, and designing prefetch pipelines sized for P99 tail latency rather than average latency are all direct engineering responses to these inverted access patterns. GPUDirect Storage pushes this optimization further by eliminating the CPU from the data path entirely, freeing host cores for the augmentation work that the training pipeline also requires.

The economics of the hierarchy are equally consequential. The orders-of-magnitude cost difference between HBM and archive storage mandates a tiering strategy, but the true cost of data delivery extends well beyond per-gigabyte storage prices. Egress fees for moving data out of object storage, IOPS charges for metadata-heavy access patterns, and the opportunity cost of idle accelerators waiting on slow checkpoints all factor into the total cost of ownership. Checkpoint staging, where models write first to fast local NVMe and replicate asynchronously to shared storage, exemplifies how careful pipeline design can decouple training pause time from the performance limitations of the underlying file system.

Engineers who internalize the storage hierarchy gain a systematic diagnostic framework for training performance. When a cluster reports low accelerator utilization, the instinct is often to suspect the compute configuration or the model itself. In practice, the root cause is frequently buried in the data path: a data loader reading individual files instead of shards, a prefetch buffer sized for average latency rather than tail latency, a checkpoint strategy that blocks training while writing to a slow parallel file system, or a NUMA-unaware memory allocation that halves effective DRAM bandwidth. Diagnosing these failures requires understanding which tier is the bottleneck and why, a question that the pipeline equation and the storage hierarchy framework make answerable.

This diagnostic perspective connects directly to how a training job is split across the fleet, because the splitting strategy dictates the demand patterns placed on storage. Data-parallel layouts replicate the model on every node, creating uniform read patterns but massive checkpoint redundancy as every node saves the same parameters. Pipeline-style layouts create sequential dependencies between stages, where a data loading stall in an early stage cascades down the pipeline and starves downstream work. Expert-style layouts create nonuniform access patterns where different accelerator groups require different subsets of the data at any given time. Each strategy imposes a unique storage signature, which is why storage cannot be designed independently from the computation it feeds.

Key Takeaways: Feed the accelerators or waste them

- **HBM is the destination:** Every lower tier exists to keep GPU HBM populated. The roughly $30\times$ aggregate bandwidth gap between HBM and object storage (and the much larger per-client gap once a single instance pulls from a shared object endpoint) drives every design decision in the ML storage hierarchy.
- **ML workloads invert storage assumptions:** Traditional caching, IOPS optimization, and small-write durability patterns all produce the wrong answer for ML training. Throughput (GB/s) matters more than IOPS, and small files make metadata the first bottleneck; aggregated shards reduce metadata operations by orders of magnitude.
- **The pipeline equation governs design:** Required bandwidth scales linearly with GPU count and inversely with iteration time. Use $BW_{\text{required}} = N_{\text{GPU}} \times \eta_{\text{target}} \times D_{\text{vol, batch}} / T_{\text{iteration}}$ to size every tier.
- **Pipelining hides average latency, not tail latency:** Prefetch buffers must be sized for P99 I/O latency, not average, to prevent accelerator stalls at scale. Buffer depth of $\lceil T_{\text{I/O, p99}} / T_{\text{compute}} \rceil$ is the minimum.
- **GPUDirect Storage eliminates CPU bottlenecks:** GDS bypasses the CPU in the data path, reducing per-transfer latency by $4\times$ and freeing CPU cores for augmentation.

- **Checkpoint staging minimizes T_{write} :** Write to local NVMe first, then replicate asynchronously to shared storage. This decouples checkpoint pause time from parallel file system performance.
- **Economics drive tiering:** The $5\times$ cost difference between local NVMe and object storage (and the $>3,000\times$ span from HBM to archive) mandates a tiering strategy. Egress fees often exceed storage fees; design for total cost of data delivery, not storage cost alone.

Every other chapter in this volume optimizes something the accelerators do. This one optimizes what reaches them. The whole storage hierarchy exists to keep the most expensive resource in the building from going idle, and that reframes where performance is won: not in the compute, which is rarely the bottleneck, but in the supply chain that feeds it. At fleet scale the binding constraint is the rate at which data arrives, not the rate at which it is processed, which is why a cluster can sit at half utilization with every accelerator healthy. A system is only as fast as the tier that feeds it.

What's Next: From storage to splitting

Infrastructure is complete. We have built accelerators that compute at petaFLOP/s (Chapter 2), wired them with fabrics that move gradients at TB/s (Chapter 3), and now established the storage hierarchy that feeds them data. The next challenge is not a hardware problem but an algorithmic one: partitioning a single training job across these thousands of resources. Chapter 5 explores the parallelism strategies (data, tensor, pipeline, and expert parallelism) that split computation across the fleet.

Research Questions: For further inquiry

- How should a tiered storage pipeline be designed to keep accelerator HBM fed for a specific workload?
- How do ML workloads invert database-era storage assumptions, and what data format choices follow?
- When should data be prestaged to local NVMe rather than streamed from a parallel file system or object store?
- How should checkpoint storage balance pause time, durability, restore verification, and retention cost?

II

DISTRIBUTED ML

Distributed ML Principles

Coordinating the fleet requires solving problems that a single machine does not. If Part I built the physical substrate, Part II establishes the logic of distribution: the algorithms, protocols, and coordination strategies that transform a collection of independent accelerators into a singular, unified machine. The physics of distributed learning governs this transition, supplying the first-principles reasoning that explains why adding more GPUs does not always yield linear speedups, and why communication, not computation, is often the hidden bottleneck.

At this scale, the engineering challenge is a trade-off between parallelization and coordination. We can partition a model to reduce per-device memory pressure, but we necessarily increase the communication volume required to keep the weights synchronized. We can scale to thousands of nodes to reduce training time, but we simultaneously decrease the mean time between failures (MTBF), making fault tolerance a mandatory system component rather than an operational luxury. These principles decompose the communication tax introduced in Part I and add the reliability tax of scale.

The first pressure is the economics of scale itself: frontier capability demands compute, but each improvement gets progressively more expensive.

Principle 9: The Universal Scaling Law

Invariant: For frontier foundation models, loss ($\mathcal{L}$) improves as a power-law function of compute (C), dataset size (D), and parameters (P), with γ denoting the empirical scaling exponent. The compute-only simplification used to illustrate diminishing returns is:

$$\mathcal{L}(C) \propto C^{-\gamma}$$

Implication: At the frontier of model capability, scale is the binding requirement, not an optimization choice. Because loss improves sublinearly with compute, each equal-sized improvement requires disproportionately more compute; this diminishing return drives the transition from single-server training to warehouse-scale clusters.

That demand for scale turns each training step into a negotiation between faster local work and slower global coordination.

Principle 10: The Fleet Law (Distributed Step Time Law)

Invariant: The time to complete one training step across N workers or accelerators is the sum of parallelizable computation, communication, synchronization, and the overlapped portion that can be hidden, with $0 \leq T_{\text{overlap}} \leq T_{\text{comm}}(N) + T_{\text{sync}}(N)$.

$$T_{\text{step}}(N) = \frac{T_{\text{compute}}}{N} + T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}}$$

Implication: Scaling is a race between parallelizable compute (which shrinks with N under ideal partitioning), communication overhead, and synchronization overhead. To scale efficiently, algorithms must reduce or amortize $T_{\text{comm}}(N)$ and $T_{\text{sync}}(N)$ (for example, through

Gradient Accumulation, which alters the effective batch and convergence regime, or through compression, which can introduce numerical error) and maximize T_{overlap} through **Communication Hiding** and pipelined execution.

The communication term in that negotiation is governed by the interconnect’s latency and bandwidth, so message size determines which optimization helps.

III Principle 11: The Bandwidth-Latency Trade-off (α - β Model)

Invariant: Communication time is a function of fixed latency (α), message size (n), and message-dependent bandwidth (β).

$$T(n) = \alpha + \frac{n}{\beta}$$

Implication: Small messages—for example, mixture-of-experts (MoE) routing metadata—are latency-bound; large messages (for example, gradients) are bandwidth-bound. Optimization strategies must match the regime: fuse small messages to amortize α , compress large messages to improve β .

Even when communication is tuned, a larger fleet fails often enough that progress itself must be protected.

III Principle 12: The Young-Daly Checkpoint Law

Invariant: The optimal checkpoint interval (τ_{opt}) balances the cost of writing the checkpoint (T_{write}) against the expected cost of reworking lost progress due to system-level failures ($\text{MTBF}_{\text{system}}$).

$$\tau_{\text{opt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$$

Implication: Checkpointing is not “free.” As cluster size grows, MTBF drops, forcing more frequent checkpoints. This demands high-bandwidth storage (burst buffers) to prevent I/O from dominating training time.

Fault tolerance is one example of a broader rule: distributed systems rarely remove overhead; they move it.

III Principle 13: The Displacement of Overhead

Invariant: Overhead in a distributed ML system cannot be eliminated, only relocated among Compute, Communication, and Coordination (the C^3 taxonomy). Reducing one necessarily increases at least one other.

Implication: Asynchronous training eliminates coordination barriers ($T_{\text{sync}}(N) \rightarrow 0$) but introduces gradient staleness that manifests as additional training iterations ($T_{\text{compute}} \uparrow$). Pipeline parallelism reduces communication volume but adds pipeline bubble time ($T_{\text{sync}}(N) \uparrow$). There is no free lunch in distributed systems; the C^3 taxonomy reveals where the system pays the bill.

With these invariants in place, Part II establishes how the fleet coordinates distributed training work: the parallelism strategies (data, tensor, pipeline, and expert) that partition the workload across thousands of accelerators, the collective operations (AllReduce, AllGather, AllToAll) that bind those accelerators into a coherent computer, the fault-tolerance mechanisms that absorb the inevitable failures of scale, and the orchestration layer (Slurm, Kubernetes, and their kin) that allocates the fleet to workloads. Together, these chapters develop the algorithmic and operational discipline that turns the physical fleet of Part I into a working distributed training system.

Purpose

Why does the linear logic of “more hardware = faster training” collapse at the bisection bandwidth wall?

Distributed training appears simple: split the work across machines and combine the results. As the machine learning fleet grows, however, a new physics emerges. Communication costs scale with the number of machines while computation per machine shrinks, until synchronization overhead dominates and adding hardware actively degrades performance. When a job trains on a single accelerator, the design optimizes for arithmetic intensity; when it trains on 10,000 accelerators, the design optimizes for communication intensity. The scaling ceiling is not a bug to be fixed but a fundamental property of the reliability gap and communication-computation ratio: coordinating independent machines requires moving terabytes of state across networks that are orders of magnitude slower than on-chip memory. The art of distributed training is managing this tension—partitioning work to minimize the coordination tax, overlapping communication with computation to hide latency, and choosing synchronization strategies that balance consistency against throughput. Without this understanding, organizations waste millions on hardware that sits idle waiting for gradients to arrive, or produce models that never converge because stale updates corrupted the optimization. Distributed training is the C³ taxonomy in motion: every design choice trades parallelized compute against network-bound communication and synchronizing coordination.

Learning Objectives

- Apply the fleet law to diagnose compute-, memory-, communication-, or coordination-bound distributed training regimes
- Calculate scaling efficiency, critical batch limits, and synchronization overhead for data-parallel training jobs
- Design memory-sharding plans that trade accelerator capacity for additional communication
- Map tensor, pipeline, expert, and data parallelism onto hardware bandwidth tiers and model structure
- Construct microbatch pipeline schedules that minimize bubbles while preserving throughput and convergence stability
- Select synchronization and low-precision policies using staleness, straggler tolerance, numerical stability, and cluster heterogeneity
- Synthesize hybrid parallelism configurations for frontier, recommendation, and alignment training constraints

5.1 Why Distribution Is Necessary

THE accelerator hierarchy, network fabric, and storage pipeline form the physical foundation of the fleet. The remaining challenge is algorithmic: partitioning a single training job across thousands of resources without losing the semantics of one coherent optimization process. The universal scaling law (principle 9) explains why this pressure keeps increasing: frontier quality improvements demand disproportionately more compute, data, and parameters, so the training problem eventually outgrows any single machine.

A single accelerator with 100 terabytes of memory and an exaflop of compute would make distributed training unnecessary. Real systems instead impose finite HBM capacity, finite interconnect bandwidth, and finite failure budgets, so training must be partitioned across many independent chips. In the fleet stack framework shown in figure 1.13, distributed training represents the distribution layer: the logic that partitions the *mathematical* workload across the *physical* fleet. The strategies defined here, including data, tensor, pipeline, and hybrid parallelism, create the traffic patterns that the interconnect must carry.

5.1.1 The physics of the cluster

Before optimizing algorithms, we must understand the physical constraints of the Machine Learning Fleet. The performance of any distributed training job is governed by the fleet law (principle 10), introduced in section 1.5.2, which decomposes the per-step time:

$$T_{\text{step}}(N) = \frac{T_{\text{compute}}}{N} + T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}}$$

The critical term is the **communication-computation ratio**, $\rho = T_{\text{comm}}(N)/(T_{\text{compute}}/N)$. This ratio determines whether a cluster behaves as a supercomputer or a collection of idling heaters.

Two regimes follow from this ratio. A compute-bound cluster, where $T_{\text{compute}}/N \gg T_{\text{comm}}(N)$, spends most of its time multiplying matrices; this is the ideal state, typical for large batch sizes on dense models such as ResNet. A communication-bound cluster, where $T_{\text{comm}}(N) \approx T_{\text{compute}}/N$, spends significant time waiting for gradients or activations to arrive, the common state for large language models (LLMs) and DLRM-style recommendation models, where parameter synchronization saturates the network. Section B.5.2 works this ratio into a diagnostic framework that classifies a workload as compute-bound, memory-bound, or communication-bound from its measured bandwidth and arithmetic intensity, turning the qualitative regimes above into a repeatable test.

Past a communication-to-compute threshold, scaling stops being ideal.

5.1.2 Multi-machine training requirements

Three concrete signals indicate when distributed training becomes necessary rather than merely beneficial. The first signal is **memory exhaustion**: model parameters, optimizer states, and activation storage exceed single-device capacity. For full mixed-precision training with Adam, the parameter, gradient, and optimizer-state budget alone can exceed an 80 GB accelerator at roughly 5 billion parameters before activations; larger 10–20B models require sharding, offload, or other memory-saving techniques (Rajbhandari et al. 2020). Section G.1 records the 80 GB H100 and A100 capacity figures used in these budgets throughout the chapter, so the reader can trace every memory ceiling back to a single documented source.

The second signal is unacceptable **training duration**. Even when a model fits, single-device training may require weeks or months to converge, making wall-clock time itself a systems constraint. GPT-3’s 175B-parameter training run used a cluster of V100 GPUs (Brown et al. 2020), illustrating why the calendar, not just HBM capacity, forces distribution at this scale.

The third signal is **dataset scale**. When training data reaches multiple terabytes, as occurs in large-scale vision or language modeling tasks, a single machine is no longer the natural unit of storage or input throughput. Distributed training then becomes a way to feed the model as much as a way to hold it.

5.1.3 Distributed training complexity trade-offs

Distribution changes the optimization problem by adding costs that do not exist inside one machine. Three complexity dimensions decide whether a parallelism strategy is viable, because any one of them can become the binding ceiling. Communication overhead is the cost of synchronizing gradients: for a model with P parameters distributed across N devices, all-reduce operations must transfer approximately $2P(N-1)/N$ gradient values per step, multiplied by the bytes per gradient element, and on commodity networks this can dominate computation time. Fault tolerance grows harder as the cluster grows, because the expected number of failures per unit time rises linearly with cluster size while the probability that the entire cluster survives an interval without any failure decays exponentially; if a 100-node cluster has 99.9 percent per-node hourly survival, the cluster-level failure probability is 9.5 percent per hour, corresponding to an MTBF of about 10 hours. Section E.1.2 derives this cascade from per-node survival to cluster MTBF and works the same calculation through a full example, so the reader can reproduce why MTBF collapses as the cluster grows. Algorithmic stability closes the set, because large batch sizes from data parallelism affect convergence behavior, requiring learning rate scaling and warmup strategies that single-machine training does not require (Goyal et al. 2017). Together, these costs explain why distributed training is a constraint satisfaction problem rather than a hardware multiplication exercise.

5.1.4 Single-machine to distributed transition

The systematic optimization methodology established for single-machine training extends to distributed environments with important adaptations. Profiling must capture inter-device communication patterns and synchronization overhead in addition to computation and memory metrics. The solution space expands to include data parallelism, model parallelism, pipeline parallelism, and hybrid approaches. Figure 5.1 visualizes this three-dimensional configuration space.

The key insight from figure 5.1 is that the total accelerator count is $N_{\text{total}} = d \times p \times t$: each axis is independent, and training systems select a specific coordinate in this cube based on the memory, compute, and bandwidth constraints of the target model and cluster.

5.1.5 Engineering trade-offs: Selecting a parallelism strategy

Choosing the right parallelism strategy is not a matter of preference; it is a constraint satisfaction problem governed by parameter count (P), batch size (B), and interconnect bandwidth. Table 5.1 quantifies the parallelism communication costs for each strategy, revealing which approaches are physically feasible for a given hardware topology.

Figure 5.1: The 3D Parallelism Cube: A conceptual visualization of the three orthogonal scaling axes: Data Parallelism (replicating the model), Pipeline Parallelism (splitting depth), and Tensor Parallelism (splitting layers). Large-model training occupies a specific point (d, p, t) within this cube to balance memory usage, compute efficiency, and communication overhead.

Table 5.1: Parallelism Communication Costs: Tensor parallelism has the highest communication frequency (per layer), confining it to intra-node (NVLink) usage. Pipeline parallelism has the lowest communication volume (boundary activations only), making it suitable for inter-node (Ethernet/InfiniBand) scaling. Data parallelism sits in the middle but scales poorly as communicated gradient bytes M_{grad} grow, eventually requiring memory-efficient sharding.

Strategy	Communication Pattern	Comm. Volume	Hardware Constraint
Data Parallel (DP)	AllReduce Gradients	$\propto M_{\text{grad}}$ (gradient bytes)	Requires high bisection BW
Tensor Parallel (TP)	AllReduce Activations	$\propto B \times N_L$ (Layers)	Critical: Needs NVLink
Pipeline Parallel (PP)	Point-to-Point (P2P)	$\propto B \times S \times d_{\text{model}}$ (Activations)	Low BW (Ethernet is sufficient)

The bandwidth requirements impose a hard constraint on hardware placement: each parallelism strategy must be matched to the interconnect available between the GPUs that need to communicate, or the design fails before it leaves the whiteboard. A quick back-of-envelope bandwidth feasibility check catches that mismatch before any code is written.

Systems Perspective 5.1: Bandwidth feasibility check

Tensor parallelism across server racks connected by standard Ethernet will stall. The communication volume scales with batch size B and layer count N_L . It requires the 600 GB/s–900 GB/s throughput of NVLink. For cross-rack scaling, the design must switch to pipeline or data parallelism to respect the physics of the network.

Figure 5.2 formalizes this constraint satisfaction process as a decision tree, showing how model size and hardware topology determine the viable parallelism strategies.

The decision tree reveals that parallelism strategy selection is not a preference but a consequence of physical constraints. This is a constraint-level preview: the communication-volume formulas above name what each strategy moves, but their full meaning depends on the mechanics of tensor, pipeline, and hybrid parallelism developed over the rest of the chapter. Section 5.9 completes the filter once those mechanics are in place. The next question is *how* these constraints shape the mechanics of a distributed training step on a real cluster.

5.2 The Distributed Training Step

The selection constraints of the previous section assumed the job must be split; the question now is what a distributed step must guarantee. The central challenge is ensuring that 1,024 GPUs, operating completely independently, agree on a single, mathematically rigorous set of updated weights at the end of each training iteration.

Definition 5.1: Distributed training

Distributed Training is a training methodology that partitions the optimization loop across multiple compute nodes (distributing either data, model layers, or individual tensor operations) and coordinates their outputs through synchronized communication primitives to produce a single coherent model.

1. **Significance:** Distributed training becomes necessary when a model’s memory requirement exceeds a single accelerator’s capacity. GPT-3 (175B parameters) requires approximately 350 GB in BF16—more than $4\times$ the 80 GB capacity of a single H100. Training it requires at least 5 H100s for model sharding alone, while large runs may use hundreds or thousands of accelerators to reach tractable wall-clock time.
2. **Distinction:** Unlike distributed systems for independent requests (web serving, database reads) where nodes share no mutable state, distributed training requires every node to maintain a consistent view of model parameters—making gradient synchronization a mandatory coordination step, not an optional optimization.
3. **Common pitfall:** A frequent misconception is that distributed training scales linearly with node count. In practice, communication overhead grows with cluster size and the serial fraction of each step (Amdahl’s Law): with 30 percent of a step’s time spent on synchronization, the theoretical scaling ceiling is $1/0.30 \approx 3\times$ regardless of how many accelerators are added.

A useful mental model frames these distributed strategies as loop transformations, the same conceptual toolkit that compilers use to optimize sequential code. If we view the training process as a massive loop over data and layers, distributed strategies are simply *loop transformations* applied by the cluster-level compiler. The logical training loop nests three iterators (epochs, batches, layers), and each parallelism strategy unrolls one of them across devices:

Data parallelism is the parallel for-loop, unrolling the outer loop (the batch dimension) across devices so that each device runs the same code body on different data indices. Tensor parallelism is vectorization, or single instruction, multiple data (SIMD), splitting the inner loops (matrix multiplication) across devices in a cluster-scale SIMD where NVLink acts as the vector register file. Pipeline parallelism is instruction pipelining, splitting the sequential operations (layers) across devices; just as a CPU pipeline stages fetch, decode, and execute, the cluster stages Layer 1, Layer 2, and Layer 3 to keep all ALUs busy.

Whichever loop a strategy unrolls, distributed training¹ spreads the workload across machines that must coordinate to train a single model. Coordination here means keeping every model shard or replica on a compatible training step. Basic barriers can keep a small research run ordered, but long-running training jobs also need timeout, checkpoint, and recovery mechanisms so one failed worker does not waste days of compute. Chapter 7 examines those reliability engineering challenges in depth.

Each rung of the scaling path inherits the previous one’s challenges. Single-GPU training needs only local memory management and forward/backward passes. Scaling to multiple GPUs within

¹ | **Distributed Training:** Google’s DistBelief (2012) was an early framework for training neural networks across thousands of machines, but its parameter server architecture created bandwidth bottlenecks at central nodes. This limitation drove the shift to decentralized AllReduce patterns in successors like Horovod and PyTorch DistributedDataParallel (DDP), where replicated data-parallel workers synchronize gradients at cost $2(N-1)/N$ per worker rather than concentrating traffic at a single server (Dean et al. 2012; Sergeev and Balso 2018; S. Li et al. 2020; Patarasuk and Yuan 2009).

² | **NVLink**: NVIDIA's point-to-point GPU interconnect delivers 600 GB/s–900 GB/s bidirectional bandwidth, roughly 24×–36× InfiniBand HDR per port. This bandwidth gap is why tensor parallelism, which requires AllReduce on every layer, is confined to intra-node communication, while pipeline and data parallelism tolerate the slower inter-node fabric.

³ | **NCCL (NVIDIA Collective Communications Library)**: NCCL provides topology-aware inter-GPU collective communication primitives, including AllReduce, across PCIe, NVLink, InfiniBand, and IP networks. Current NCCL deployments expose ring, tree, and related algorithm families through runtime selection and tuning controls, so training frameworks can avoid naive mappings that route all traffic through the slowest inter-node path (Jeaughey 2017; NVIDIA 2026b).

a node adds high-bandwidth communication, handled through NVLink² or PCIe with NCCL³ optimization while preserving single-machine fault tolerance and scheduling.

The leap to multi-node training adds network communication overhead, fault tolerance requirements, and cluster orchestration. Because each stage compounds the previous one's bottlenecks, single-GPU performance must be optimized before scaling out, so inefficiency does not multiply across the fleet. Although frameworks abstract away much of this through sharded data parallelism and communication libraries, implementing distributed training efficiently still demands careful network configuration (InfiniBand tuning, topology-aware routing), infrastructure management through cluster schedulers, and debugging of nonlocal issues such as synchronization hangs and communication bottlenecks.

Despite this complexity, the core workflow is mechanically straightforward; the engineering challenge is making it fast and reliable at scale. The recurring cost is the gradient synchronization that aggregates results across devices, an overhead that compounds as systems scale, as section 5.4 quantifies.

Four approaches address different constraint regimes. Data parallelism divides the training data across machines while each maintains a full model copy, making it the simplest approach for models that fit in single-device memory. Model parallelism splits the model itself across devices when parameters exceed single-device memory. Pipeline parallelism partitions models into sequential stages that process microbatches concurrently, improving utilization over naive model parallelism. Hybrid approaches integrate multiple strategies, enabling training at scales where any single approach would fail. Each strategy becomes necessary only after its predecessor reaches a physical ceiling.

5.3 Data Parallelism

The simplest approach gives each GPU a complete, identical copy of the model and assigns it a distinct slice of the data. Data parallelism is the natural starting point for distributed training because it requires minimal changes to the single-device training loop.

Definition 5.2: Data parallelism

Data Parallelism is a distributed training strategy in which each worker holds a complete replica of the model and processes an independent shard of the minibatch, then synchronizes gradient updates via AllReduce so all replicas apply identical parameter changes each step.

1. **Significance**: With N workers each processing batch size B , the effective global batch size is $N \times B$, scaling throughput linearly while keeping per-worker memory constant. For a 1B-parameter model at 2 GB in BF16, 1,024 workers achieve $1,024 \times$ the single-GPU throughput—until the gradient AllReduce (2 GB per step at ring-optimal $2(N-1)/N$ per worker) exceeds backward compute time and creates the communication bottleneck.
2. **Distinction**: Unlike model parallelism, where parameters are partitioned so no single worker holds the full model, data parallelism requires every worker to have sufficient memory capacity to store the complete model state—making it inapplicable for models larger than a single accelerator's memory without combining it with optimizer-state or parameter sharding.
3. **Common pitfall**: A frequent misconception is that data parallelism scales indefinitely with worker count. Scaling the effective batch size B beyond the workload-dependent critical batch size degrades statistical efficiency, requiring more training steps to reach target loss and eroding the throughput gains from adding more workers (Shallue et al. 2019).

Each device trains a complete copy of the model using its assigned subset of the data. When training an image classification model on 1 million images using 4 GPUs, each GPU processes 250,000 images while maintaining an identical copy of the model architecture.

Data parallelism is most effective when the dataset size is large but the model size remains manageable, since each device must store a full copy of the model in memory. This method is widely used in image classification and natural language processing, where the dataset can be processed in

parallel without dependencies between data samples. When training a ResNet model (He et al. 2016) on ImageNet, each GPU can independently process its portion of images because the classification of one image does not depend on the results of another.

The effectiveness of data parallelism stems from a property of stochastic gradient descent. Gradients computed on different minibatches can be averaged while preserving mathematical equivalence to single-device training. This property enables parallel computation across devices, with the mathematical foundation following directly from the linearity of expectation.

Consider a model with parameters θ training on a dataset D . The loss function for a single data point x_i is $\mathcal{L}(\theta, x_i)$. In standard SGD with batch size B , the gradient update for a minibatch is:

$$g = \frac{1}{B} \sum_{i=1}^B \nabla_{\theta} \mathcal{L}(\theta, x_i)$$

In data parallelism with N devices, each device k computes gradients on its own minibatch B_k :

$$g_k = \frac{1}{|B_k|} \sum_{x_i \in B_k} \nabla_{\theta} \mathcal{L}(\theta, x_i)$$

When all workers use the same local batch size, the global update averages these local gradients:

$$g_{\text{global}} = \frac{1}{N} \sum_{k=1}^N g_k$$

Under that equal-batch assumption, the averaging is mathematically equivalent to computing the gradient on the combined batch $B_{\text{total}} = \bigcup_{k=1}^N B_k$:

$$g_{\text{global}} = \frac{1}{|B_{\text{total}}|} \sum_{x_i \in B_{\text{total}}} \nabla_{\theta} \mathcal{L}(\theta, x_i)$$

For unequal local batch sizes, the combined-batch gradient is the weighted average $g_{\text{global}} = (1/|B_{\text{total}}|) \sum_k |B_k| g_k$. The equivalence shows *why* data parallelism maintains the statistical properties of SGD training: distributing distinct data subsets across devices, computing local gradients independently, and averaging them approximates the full-batch gradient. The averaging step itself is an AllReduce over the local gradient tensors; section D.2.1 derives the ring and tree AllReduce cost models that set the price of this synchronization, so the reader can predict when it overtakes the local compute saved by parallelism.

Checkpoint 5.1: Data parallelism mechanics

Verify your understanding of how data parallelism distributes work:

- ☐ **State placement:** Determine whether data parallelism shards or replicates the **model state** (weights) across GPUs.
- ☐ **Global batch size:** Calculate the **effective global batch size** for 8 GPUs with a per-GPU batch size of 32.
- ☐ **Single-device equivalence:** Explain why data parallelism is mathematically equivalent to single-device training with a larger batch size.
- ☐ **Binding constraint:** Identify the primary hardware resource that constrains data parallelism as more nodes are added: GPU TFLOP/s or network bandwidth.

The method parallels gradient accumulation, where a single device accumulates gradients over multiple forward passes before updating parameters. Both techniques use the additive properties of gradients to process large batches efficiently. However, moving the same idea into a cluster introduces operational challenges beyond this theoretical equivalence. Communication overhead, node failures, and cost constraints each impose second-order effects that the single-machine derivation does not capture.

5.3.1 Data parallelism implementation

The implementation details matter because the SGD equivalence only holds when each phase preserves disjoint data, complete local gradients, and a single synchronized update. The concrete workflow therefore traces the path from distributing data subsets to synchronizing the computed gradients. Consider figure 5.3: it traces the complete workflow from dataset splitting through gradient aggregation, showing how each GPU processes its assigned batch before synchronization brings all gradients together for parameter updates.

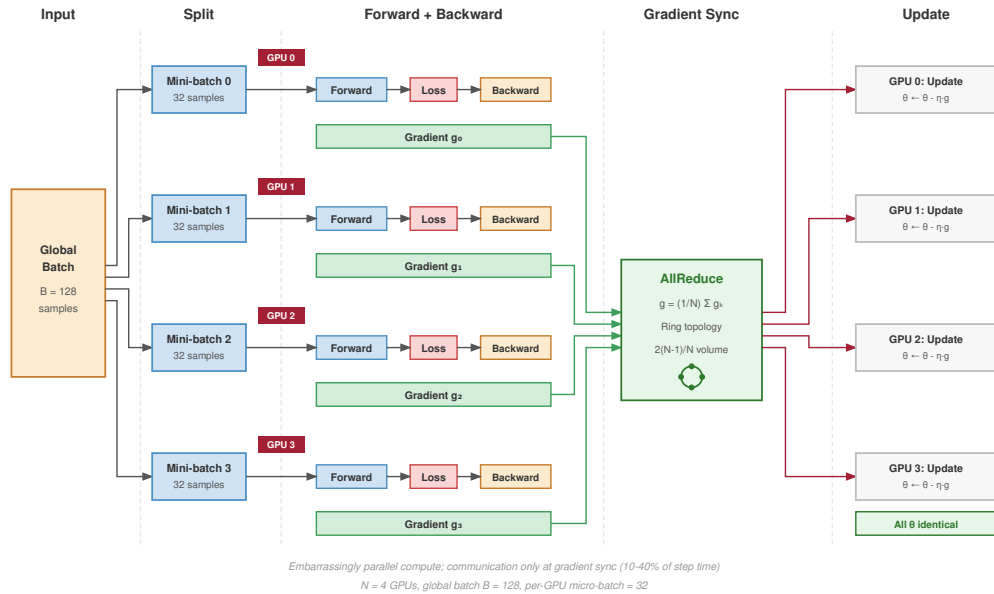

Figure 5.3: Data Parallelism Implementation Pipeline: The five-stage workflow for data parallel training: (1) split input data into nonoverlapping subsets, (2) assign batches to GPUs, (3) compute forward and backward passes independently, (4) synchronize gradients via AllReduce, and (5) update parameters uniformly across all devices. This approach contrasts with model parallelism, where the model itself is partitioned rather than replicated.

As figure 5.3 shows, the critical synchronization point is stage 4: AllReduce must complete before any GPU can update parameters, making gradient communication the dominant bottleneck as the device count grows.

5.3.1.1 Dataset splitting

Data splitting is the first place where the SGD equivalence can fail: each worker must see a unique, deterministic slice of the epoch. With a dataset of 100,000 training examples and 4 GPUs, each GPU receives 25,000 examples per epoch. The DistributedSampler must ensure no overlap between subsets to maintain gradient estimation validity: if two GPUs process the same example, the resulting gradient average would overweight that example, violating the unbiased gradient assumption that makes data parallelism mathematically equivalent to single-device training.

The sampler is therefore part of the training system, not only an input-loader convenience. Modern distributed training frameworks handle this distribution automatically through a distributed sampler that implements prefetching and caching mechanisms to keep accelerators fed without changing sample ownership. The sampler coordinates across workers using the process rank, the integer worker identifier assigned by the distributed runtime, to deterministically partition indices, ensuring reproducibility when the same random seed is used. For a 1.2 million example dataset distributed across 32 GPUs, each GPU processes approximately 37,500 examples per epoch, with the sampler padding the final batch to maintain consistent batch sizes across all workers.

5.3.1.2 Compute phase: Forward and backward passes

The defining feature of data parallelism is that the computation phase, both forward and backward, is *embarrassingly parallel*. Each GPU operates as an isolated island, executing an identical copy of the model on a unique micro-batch of data. Here, micro-batch means the per-GPU local slice used for activation accounting; pipeline microbatching uses the same word for a different mechanism, subdividing a global batch to keep pipeline stages occupied. For our 175B parameter reference model, this isolation is critical: during the forward pass, each GPU independently computes activations for its local batch (micro-batch size 4, sequence length 2048). Without optimization, storing these activations for backpropagation would consume roughly 1.1 TB of HBM, an order of magnitude beyond the capacity of even an H100 GPU. Activation checkpointing, which recomputes activations during the backward pass rather than storing them, becomes necessary in this scenario to suppress the footprint to ~19.3 GB.

The backward pass mirrors this independence but introduces the system's primary bottleneck. As the GPU traverses the computation graph in reverse, it computes gradients for the parameters held by that replica or shard. Under pure data parallelism, a full 175B FP16 replica would imply a 350 GB gradient tensor per worker, which exceeds single-accelerator memory budgets; large runs therefore combine data parallelism with sharding, tensor parallelism, or pipeline parallelism. The computation itself requires zero communication, yet the resulting gradients represent a fractured view of the true loss surface, valid only for the local micro-batch. Before the optimizer step can occur, the corresponding local gradients or gradient shards must be aggregated across data-parallel workers to form a valid global update. The transition from isolated, high-throughput compute to synchronization defines the rhythm of data parallel training: long periods of silent, intense arithmetic punctuated by bursts of heavy network traffic.

5.3.1.3 Gradient synchronization

Gradient synchronization is where independent SGD estimates become one update, so its cost determines whether data parallelism still behaves like a scaling strategy rather than a network benchmark. The immediate training requirement is simple: every data-parallel replica must apply the same averaged gradient before it moves to the next step. AllReduce is the primitive that performs this operation for replicated tensors: each worker contributes its local gradient tensor, the fleet sums the tensors, and every worker receives the same reduced result. In sharded variants, ReduceScatter and AllGather move corresponding pieces rather than the full tensor on every device, but the same synchronization cost remains. Small tensors are dominated by synchronization latency because each communication round has a startup cost; large tensors are dominated by bandwidth because the relevant gradient payload must cross links. Chapter 6 later derives the ring, tree, and hierarchical algorithms that implement this averaging operation on real fabrics.

When synchronization performance deviates from theoretical expectations, the fleet stack framework provides a structured approach to isolating the bottleneck.

Example 5.1: Debugging slow gradient synchronization

Scenario: An AllReduce of a 3 GB gradient tensor across 128 nodes (1,024 GPUs) takes 100 ms. This chapter treats AllReduce as the synchronization primitive created by data parallelism; Chapter 6 derives the ring, tree, and hierarchical algorithms in detail. For now, the useful debugging move is to compare the observation against two coarse bounds: a pessimistic flat communication path and a topology-aware path that separates fast intra-node traffic from slower inter-node traffic.

Context:

- **Topology:** 128 nodes, 8 GPUs per node
- **Fast local path:** NVLink at 300 GB/s bidirectional between GPUs
- **Slower network path:** InfiniBand HDR at 200 Gb/s (25 GB/s) per port

- **Diagnostic bounds:** A flat all-GPU path over the network would land near 239.8 ms; a topology-aware local-then-network path predicts roughly 48.5 ms because each node sends only its share across the slower link

Analysis:

- **Diagnosis:** The collective library is using a hierarchical path that treats the node boundary as the expensive communication boundary
- **Expected behavior:** The inter-node phase should scale with each node's reduced share rather than with the full tensor from every GPU
- **Diagnosis check:** A flat single ring over all 1,024 GPUs would have measured close to 239.8 ms, so the algorithm is already hierarchical

Observation:

- **Observed latency:** 100 ms (well below the 239.8 ms flat-ring upper bound, but about 51.5 ms above the hierarchical ideal)
- **Bandwidth utilization:** Switch counters during the inter-node phase show only 60 percent of theoretical InfiniBand throughput on the affected uplinks (end-to-end efficiency is lower still, since the intra-node phases add time)
- **Network counters:** Show congestion on specific switch uplinks

Diagnosis: NCCL is already using a hierarchical algorithm (100 ms vs. the 239.8 ms flat-ring prediction confirms this). The remaining gap between observed and modeled latency can come from switch congestion on a handful of inter-node uplinks, effective-bandwidth loss, or implementation overhead, not from a fully flat algorithm.

Solution: Monitor InfiniBand switch port utilization to identify hot spots. Consider the rail-optimized topology in section 3.5.3 or further tuning of the hierarchical hand-off so it explicitly partitions intra-node (NVLink) from inter-node (InfiniBand) communication. The residual gap likely represents achievable optimization through better network provisioning and bandwidth utilization rather than a wholesale algorithm change.

Systems lesson: The analysis demonstrates how the fleet stack layers interact: Physical constraints (bandwidth) bound Operational choices (algorithm), which manifest in Service metrics (latency). Debugging requires examining all three layers, not just tuning one in isolation.

Stepping back from that specific cluster to the design space, figure 5.4 contrasts three high-level synchronization topologies: the bandwidth-optimal Ring AllReduce, the centralized Parameter Server, and the fully connected All-to-All mesh. In dense synchronous data-parallel settings, ring AllReduce can avoid a single reducer bottleneck by distributing traffic evenly across participating links, as Baidu's implementation illustrates (Gibiansky 2017).

The trade-off visible in figure 5.4 is between *bandwidth* and *latency*: a ring spreads bandwidth evenly but adds a latency step per hop, while an all-to-all mesh collapses the latency path to constant rounds at the cost of a link count that grows quadratically with the node count. High-performance libraries such as NCCL select among these topologies automatically based on message size and cluster topology. Chapter 6 formalizes the latency complexity of each topology and derives when a ring beats the alternatives.

5.3.1.4 Synchronization models

Distributed training systems operate under explicit synchronization models that govern when workers observe each other's updates. The choice of model determines whether the system guarantees mathematical equivalence to single-device training or trades consistency for throughput. The baseline model, Bulk Synchronous Parallel (BSP)⁴ (Valiant 1990), requires all workers to complete their local computation in forward and backward passes, synchronize gradients through a barrier with AllReduce, and then simultaneously update parameters.

⁴ | **Bulk Synchronous Parallel (BSP):** Introduced by Valiant (1990) as a “bridging model” between hardware and software for parallel computation. BSP divides work into supersteps (compute, communicate, barrier), guaranteeing mathematical equivalence to sequential execution. The cost: iteration time equals the slowest worker's time, and at 1,000 GPUs with 1 percent straggler probability per device, roughly 10 GPUs straggle every step, making the barrier increasingly expensive.

Figure 5.4: Gradient Synchronization Topologies: Visual comparison of communication patterns. (A) Ring AllReduce distributes bandwidth evenly across all links but has linear latency scaling. (B) Parameter Server uses a central node, creating bandwidth bottlenecks at the server. (C) All-to-All mesh connects every node to every other node, achieving constant communication rounds but with a link count that grows quadratically, making it impractical beyond roughly eight nodes.

BSP provides strong guarantees where every worker sees identical parameter values at each step, ensuring mathematical equivalence to single-device training. The cost is that the slowest worker determines iteration time, creating the straggler problem.

Stale Synchronous Parallel (SSP) relaxes this constraint by allowing workers to proceed up to s iterations ahead of the slowest worker before blocking. This bounds staleness while reducing synchronization delays. SSP requires careful learning rate tuning since workers compute gradients on slightly different parameter versions. The bounded staleness guarantee provides a middle ground between BSP’s strong consistency and fully asynchronous approaches (Ho et al. 2013).

Asynchronous SGD eliminates synchronization barriers entirely as workers update parameters independently. This maximizes hardware utilization but introduces gradient staleness that can degrade convergence. The operational guarantee determines how much convergence risk the system accepts; section 5.4.4 develops the convergence rates, the staleness penalty, and the compensation techniques each model requires.

The key trade-offs across synchronization models are summarized in table 5.2, and figure 5.5 illustrates how each strategy schedules work across workers over time.

Table 5.2: Synchronization Model Trade-offs: BSP, SSP, and asynchronous SGD trade consistency for throughput along a spectrum. BSP guarantees reproducibility but pays for the slowest worker; SSP unlocks throughput under bounded staleness; async maximizes throughput at the cost of convergence guarantees.

Model	Consistency	Throughput	Convergence	Use Case
BSP	Strong	Bounded by slowest worker	Equivalent to single-GPU	Final training runs, reproducibility
SSP	Bounded staleness	Higher than BSP	Near-equivalent with tuning	Hyperparameter search
Async	Weak	Maximum	Degraded, requires compensation	Large heterogeneous clusters

The same trade-off becomes clearer when the schedules are placed on a timeline.

Figure 5.5: Distributed Synchronization Models: Timeline comparison of three synchronization strategies. (A) Bulk Synchronous Parallel (BSP) forces all workers to wait at a global barrier every step. (B) Stale Synchronous Parallel (SSP) allows workers to proceed up to s steps ahead of the slowest worker. (C) Asynchronous SGD eliminates barriers entirely, allowing maximum throughput but introducing gradient staleness.

The choice of synchronization model directly affects both system throughput and model convergence. Training teams often use BSP for final runs to preserve reproducibility, while exploring SSP or async approaches during hyperparameter search where exact reproducibility is less critical.

5.3.1.5 Barrier semantics and failure modes

AllReduce operations implement implicit barriers where no worker can proceed until all workers have contributed their gradients. This coupling creates failure modes absent from single-device training.

Worker failures during AllReduce cause all other workers to block indefinitely while waiting for the missing contribution. Without timeout mechanisms, the entire training job hangs rather than failing cleanly. Deployed systems often implement watchdog timers on the order of minutes to detect and terminate stuck jobs.

Gradient mismatches occur when workers disagree on which tensors to synchronize due to conditional computation paths or dynamic batching. AllReduce operations may block waiting for tensors that some workers never send. This commonly occurs with variable-length sequences in NLP models, dynamic computation graphs, and mixture-of-experts with different routing decisions.

Straggler-induced delays arise because iteration time equals the slowest worker's time plus synchronization overhead. A single slow worker, whether due to thermal throttling, network congestion, or OS jitter, delays all workers and reduces cluster utilization. At 1000 GPUs with 1 percent probability of straggler per GPU per step, approximately 10 GPUs straggle every iteration.

Deployed systems address these issues through timeouts, heartbeat monitoring, and elastic training mechanisms. Chapter 7 provides comprehensive coverage of failure detection, checkpointing strategies, and recovery mechanisms that enable training jobs to complete despite inevitable hardware failures.

5.3.1.6 Parameter updating

Parameter updating closes the data-parallel invariant: after aggregation, every device must apply the same optimizer update from the same gradient values. Each device independently updates model parameters using the chosen optimization algorithm such as SGD with momentum or Adaptive Moment Estimation (Adam). This decentralized update strategy avoids a central coordination server because synchronization has already made the local gradients identical.

In a system with 8 GPUs training a ResNet model, each GPU computes local gradients based on its data subset. After gradient averaging via ring all-reduce (Patarasuk and Yuan 2009), every GPU has the same global gradient values. Each device then independently applies these gradients using the optimizer’s update rule. With SGD and learning rate 0.1, the update becomes `weights = weights - 0.1 * gradients`. The example shows why the update can remain decentralized without sacrificing mathematical equivalence to single-device training.

The cycle of splitting data, computing gradients, synchronizing results, and updating parameters repeats for each batch. Frameworks automate this cycle, but they cannot remove the ordering constraint that makes the replicas coherent: every worker must update only after the synchronized gradient is complete.

5.3.2 Trade-offs: The communication wall

Data parallelism is a common starting strategy for a reason: it scales throughput linearly with device count, provided the model fits in memory and communication is not the bottleneck. However, it hits a hard ceiling defined by the communication-computation ratio: once gradient exchange dominates useful computation, more workers mainly add synchronization work (Ben-Nun and Hoefler 2019).

Data parallelism offers three principal advantages. Throughput scales linearly for compute-bound models: scaling ResNet-50 on ImageNet from 1 to 256 GPUs yields near-linear speedup because the gradient exchange is small relative to the compute time. The model architecture also remains unchanged; the framework wraps the model in a data-parallel container that intercepts backward-pass hooks to trigger gradient synchronization automatically. Utilization stays high because, unlike model parallelism, there are no pipeline bubbles: all GPUs work on the forward and backward pass simultaneously.

Three hard ceilings limit these advantages. The memory wall requires every GPU to hold a full copy of the model parameters, gradients, and optimizer states; for a 175B parameter model, this demands more than 1 TB of memory per GPU, exceeding per-device HBM budgets without ZeRO sharding. The bandwidth wall emerges as N grows: the AllReduce cost $\frac{2(N-1)}{N} \times \frac{M}{BW_{\text{net}}}$ eventually dominates, and for large language models gradient synchronization can consume more than 50 percent of the step time, collapsing efficiency. The batch size trap compounds the problem because scaling to thousands of GPUs requires increasing the global batch size ($B_{\text{global}} = N \times B_{\text{local}}$), and eventually the critical batch size is reached, where adding more data per step yields diminishing returns in convergence.

Napkin Math 5.1: GPT-2 data parallel scaling: single node

A GPT-2 scaling scenario makes the efficiency loss concrete by holding the model fixed and changing only the communication domain. The first case keeps all eight GPUs inside a single NVLink node.

Single GPU Baseline

- Batch size: 16 (with gradient checkpointing, fits in 32 GB)
- Time per step: 1.8 s
- Time to 50K steps: 25 hours

8 GPUs: Single Node with NVLink

- Per-GPU batch: 16, global batch: 128
- Gradient synchronization: 5.2 GB @ 450 GB/s (NVLink, per direction) ≈ 11.7 ms

Performance results:

- Compute: 1800 ms per step
- Communication: 11.7 ms per step
- Total: 1811.7 ms per step
- Speedup (throughput): 8×
- Parallel efficiency: 99.4 percent

Training time: 25 hours $\div$ 8 = 3.1 hours

Inside the node, NVLink keeps gradient exchange small relative to compute, so efficiency stays near 99.4 percent. The picture inverts once the same model must synchronize across nodes over a commodity network.

Napkin Math 5.2: GPT-2 data parallel scaling: commodity scale-out

The second case scales the same GPT-2 run across multiple nodes, replacing the intra-node NVLink hop with inter-node Ethernet for the bulk of the AllReduce.

Commodity network configuration: 32 GPUs across 4 nodes

- Per-GPU batch: 16, global batch: 512
- Intra-node communication: 11.7 ms (NVLink)
- Inter-node communication: 5.8 GB @ 1.25 GB/s (10GbE) $\approx$ 4650 ms

Performance results:

- Compute: 1800 ms (27.9 percent of time)
- Communication: 4661.7 ms (72.1 percent of time), so communication dominates and becomes the bottleneck.
- Total: 6461.7 ms per step
- Speedup (throughput): 8.9× faster $\rightarrow$ 2.8 hours
- Parallel efficiency: 27.9 percent

Gradient accumulation offers a direct remedy by keeping all communication within a single node's NVLink domain while still training on an equivalently large effective batch.

Napkin Math 5.3: Gradient accumulation speedup

Problem: A GPT-2 run on a commodity 10G network is communication-bound at 32 GPUs, costing \$3,021 for a fixed number of samples. Can a single 8-GPU node achieve the same effective batch size more efficiently using gradient accumulation?

Math:

1. **Effective batch size:** 8 GPUs $\times$ batch 16 $\times$ 4 accumulation steps = 512.
2. **Communication overhead:** With 4-step accumulation, we AllReduce once every 4 steps.
 - Overhead = 5.8 ms / (4 $\times$ 1800 ms) $\approx$ 0.081%.
3. **Training duration:** Total time is 3.1 hours.
4. **Total cost:** 3.1 hours $\times$ \$128/hr = \$400.

Systems insight: Gradient accumulation saves \$2,621 (86.7 percent) by concentrating computation where bandwidth is abundant (NVLink within the node) and minimizing the frequency of synchronization. When the network is slow, do not scale out—scale the batch size locally.

The calculation changes the scaling decision: when inter-node bandwidth is the binding constraint, gradient accumulation on a bandwidth-rich node can beat naive scale-out even if the wall-clock

run becomes modestly longer. Four insights emerge. NVLink enables efficient scaling within single nodes (99.4 percent efficiency), while inter-node communication kills efficiency (dropping to 27.9 percent). Gradient accumulation beats naive scale-out for communication-bound runs when the scale-out network is slow, so the sweet spot for this GPT-2 scenario is 8 GPUs per node with gradient accumulation, not naive scaling to 32+ GPUs. OpenAI's GPT-2 paper reports training on 32 V100s across 4 nodes using optimized communication (likely gradient accumulation combined with pipeline parallelism), not pure data parallelism.

5.3.3 Memory-efficient data parallelism: ZeRO and FSDP

The memory constraints of data parallelism motivate a family of techniques that shard memory state across workers while preserving the simplicity of data parallel training. ZeRO (Zero Redundancy Optimizer)⁵ (Rajbhandari et al. 2020) and its PyTorch implementation FSDP (Fully Sharded Data Parallel) (Zhao et al. 2023) enable training models that would otherwise require model parallelism.

⁵ | **ZeRO (Zero Redundancy Optimizer):** Published by Microsoft Research in 2019, ZeRO partitions optimizer states, gradients, and optionally parameters across workers instead of replicating them. At ZeRO Stage 3 with 64 GPUs, per-device memory drops from 16 bytes/parameter (full replication) to 0.25 bytes/parameter, converting a 112 GB memory footprint into 1.75 GB. The trade-off: FSDP (PyTorch's ZeRO-3 implementation) adds AllGather and ReduceScatter on every forward and backward layer, introducing 10–25 percent communication overhead that only pays off when memory pressure justifies it.

Definition 5.3: Sharded data parallelism

Sharded Data Parallelism is the data-parallelism variant (implemented as the ZeRO stages and FSDP) that partitions optimizer state, gradients, and at the deepest stage the parameters themselves across the data-parallel workers, reconstructing each shard on demand through collectives so that per-worker memory falls toward $1/N$ of the full training state while every worker still processes its own minibatch shard.

1. **Significance:** Mixed-precision Adam training carries 16 bytes of state per parameter, so a 7B-parameter model requires 112 GB of training state, out of memory on any 80 GB accelerator even though the model fits comfortably for inference. ZeRO Stage 3 across 64 workers cuts the per-device state to 1.75 GB (0.25 bytes per parameter), converting the memory wall into a communication cost: the AllGather and ReduceScatter traffic that reassembles shards on demand adds 10–25 percent overhead per step.
2. **Distinction:** Unlike vanilla data parallelism (which replicates the complete training state on every worker) and unlike model parallelism (which partitions the computation itself), sharded data parallelism partitions only the storage: every worker still executes the full forward and backward pass, gathering each layer's parameters just in time and discarding them immediately after use.
3. **Common pitfall:** A frequent misconception is that sharding is free memory. The on-demand AllGathers place parameter traffic on the critical path of every layer in every step; on slower interconnects or at small per-worker batch sizes, the exposed communication erodes throughput faster than the memory savings help. Capacity is purchased with bandwidth.

To understand the scale of memory savings ZeRO provides, consider the concrete memory budget for a large language model.

Napkin Math 5.4: ZeRO memory savings

Problem: Training a 7B parameter Llama-2 model in mixed precision requires 16 bytes per parameter for weights, gradients, and optimizer state. Does the full training state fit on a single A100-80 GB, and how does ZeRO Stage 3 with 64 GPUs change the per-device memory requirement?

Baseline: Standard DDP (Replicated State) Per-Parameter Memory Cost:

- **Weights (FP16):** 2 bytes
- **Gradients (FP16):** 2 bytes
- **Optimizer state (FP32):** 12 bytes (4 master weight + 4 momentum + 4 variance)
- **Total:** 16 bytes/parameter

Total Memory for 7B Model:

$$C_{\text{state,total}} = 7 \times 10^9 \times 16 \text{ bytes} \approx 112 \text{ GB}$$

Baseline outcome: out-of-memory (OOM) on A100-80 GB.

Optimization: ZeRO-3 (Fully Sharded) With $N = 64$ GPUs, state is partitioned:

- **Weights:** $2/N$ bytes
- **Gradients:** $2/N$ bytes
- **Optimizer:** $12/N$ bytes
- **Total:** $16/N = 0.25$ bytes/parameter effective storage!

Per-GPU Memory:

$$C_{\text{state,ZeRO3}} = \frac{112 \text{ GB}}{64} \approx 1.75 \text{ GB}$$

Result: Fits easily, leaving ~ 78 GB for activations (batch size).

ZeRO addresses this redundancy through progressive sharding, as figure 5.6 illustrates and table 5.3 summarizes.

Figure 5.6: ZeRO Memory Reduction: Standard data parallelism (DDP) replicates all model states across every GPU. ZeRO progressively partitions these states: ZeRO-1 shards optimizer states, ZeRO-2 adds gradient sharding, and ZeRO-3 shards the parameters themselves. ZeRO-3 achieves linear memory scaling, enabling models with 100B+ parameters to fit on accelerators that could not hold the replicated state.

Table 5.3: ZeRO Sharding Stages: Each stage shards a different layer of training state and trades a different communication primitive. ZeRO-1 is free relative to DDP; ZeRO-2 swaps AllReduce for ReduceScatter; ZeRO-3 (FSDP) adds an AllGather before every layer but unlocks near-linear memory scaling.

Stage	What is Sharded	Memory Reduction	Communication Overhead
ZeRO-1	Optimizer states only	$\sim 4\times$	None (same as DDP)
ZeRO-2	+ Gradients	$\sim 8\times$	ReduceScatter replaces AllReduce
ZeRO-3/FSDP	+ Parameters	$\sim N$ (linear in workers)	AllGather before each layer

ZeRO-1 shards optimizer states across GPUs. Each GPU stores only $1/N$ of the Adam optimizer-related state. After gradient AllReduce, each GPU updates only its shard of parameters, then broadcasts updates to other GPUs. Under the 12-byte convention that counts FP32 master weights, momentum, and variance, memory savings reduce optimizer state from $12N$ bytes/param to 12 bytes/param total across the cluster.

ZeRO-2 additionally shards gradients. Instead of AllReduce, which leaves full gradients on each GPU, ZeRO-2 uses ReduceScatter so each GPU receives $1/N$ of the reduced gradients. Under the FP16-gradient convention used here, memory savings reduce gradients from $2N$ bytes/param replicated across N workers to 2 bytes/param total, or $2/N$ bytes/param per GPU.

ZeRO-3 and FSDP shard parameters themselves. Each GPU stores only $1/N$ of the model. Before each layer’s forward pass, parameters are gathered via AllGather; after backward pass, gradients are reduced via ReduceScatter, then parameters are discarded. This achieves maximum memory efficiency at the cost of additional communication that FSDP introduces relative to standard DDP.

This sharding places communication on the critical path that DDP avoids. The forward pass needs an AllGather to reconstruct each layer’s parameters (M_{layer} bytes); the backward pass needs a second AllGather to reconstruct them when parameters are resharded after the forward pass (M_{layer} bytes), followed by a ReduceScatter for gradients (M_{layer} bytes). For a model with N_L layers, full-shard FSDP with resharding therefore performs about $3N_L$ collective operations per training step against the single AllReduce that DDP needs, raising total communication volume to roughly $3M_{\text{state}}$ bytes versus $2M_{\text{state}}$ for DDP. The collectives are spread across more operations with overlap opportunities, however: while layer i computes, layer $i + 1$ can prefetch its parameters.

The choice between FSDP and DDP depends on model size and memory constraints. When the model fits in GPU memory with room for activations, DDP usually wins because it avoids the repeated AllGather work. As memory pressure rises, ZeRO-2 becomes attractive because it shards gradients and optimizer state while leaving parameters replicated; once parameters themselves exceed single-GPU memory, ZeRO-3/FSDP becomes necessary even though it puts AllGather on the critical path. For training 70B+ models on 80 GB, FSDP typically has to combine with tensor parallelism rather than replace it.

Memory-efficient data parallelism requires careful tuning of sharding strategy (by layer, by transformer block, or flat) and mixed precision settings. The sharding granularity determines the trade-off: finer sharding reduces per-GPU memory but increases communication frequency as more AllGather and ReduceScatter operations must execute per training step.

Eliminating memory as the bottleneck through ZeRO and FSDP makes it tempting to scale data parallelism to hundreds of GPUs. Doing so, however, changes the optimization landscape in ways the communication analysis alone does not predict. Large global batch sizes alter gradient noise statistics, and learning-rate schedules tuned for eight-GPU runs can diverge catastrophically at 256 GPUs. A landmark large-scale demonstration of this failure mode, and an engineering response that became widely influential, came from a single experiment.

War Story 5.1: The one-hour ImageNet run (2017)

Context: Facebook AI Research set out to train ResNet-50 on ImageNet in one hour using 256 GPUs, pushing data parallelism far beyond the batch sizes that earlier practice treated as safe (Goyal et al. 2017).

Failure mode: Naively increasing the global batch size destabilized optimization. The communication system could supply more throughput, but the optimizer no longer behaved like the single-machine run.

Consequence: The team recovered accuracy by pairing the linear scaling rule with gradual learning-rate warmup, stabilizing a global batch size of 8,192 while preserving convergence.

Systems lesson: Distributed training is not just parallel hardware. Scaling changes the optimization regime, so the cluster, communication schedule, batch size, and learning-rate schedule must be tuned as one system.

5.4 Scaling Efficiency and Convergence

When doubling the number of GPUs yields only $1.5\times$ speedup, communication overhead and synchronization barriers have consumed the missing 25 percent of compute budget. Data parallelism revealed the practical mechanics of gradient synchronization and memory sharding, but understanding *why* scaling efficiency degrades and *how* convergence changes with parallelism requires a quantitative framework. The metrics and convergence theory in this section apply to all parallelism strategies—data, model, pipeline, and hybrid—governing the fundamental trade-offs between throughput, communication cost, and optimization quality.

5.4.1 The mathematics of scaling efficiency

Before examining specific parallelism strategies, we must understand the metric that determines whether scaling from one device to many is worthwhile: scaling efficiency. If a model trains in time T_1 on one device, ideal (linear) scaling would train it in time T_1/N on N devices. In practice, communication overhead, pipeline bubbles, and load imbalances reduce the speedup. Scaling efficiency is defined by equation 5.1:

$$\eta_{\text{scaling}} = \frac{T_1}{N \times T_N} \quad (5.1)$$

where T_N is the training time on N devices. An efficiency of 1.0 means perfect linear scaling; an efficiency of 0.5 means we achieve only half the expected speedup.

Definition 5.4: Scaling efficiency

Scaling Efficiency (η_{scaling}) is the ratio of actual training throughput to ideal linear throughput when increasing the number of ML compute devices (N).

1. **Significance:** It is the most important metric for cluster productivity ($\eta_{\text{scaling}} = \frac{T_1}{N \times T_N}$). A scaling efficiency of 0.50 means that a 10,000-GPU cluster is delivering only the same useful work as a 5,000-GPU cluster, wasting 50 percent of the hardware investment.
2. **Distinction:** Unlike single-node efficiency (which captures local bottlenecks like BW), scaling efficiency captures the cluster-level overhead of communication time ($T_{\text{comm}}(N)$) and synchronization.
3. **Common pitfall:** A frequent misconception is that scaling efficiency is constant. In reality, it is a function of problem size: as N increases, the communication-to-compute ratio typically worsens (Amdahl’s Law), making it harder to maintain high efficiency for small models.

For data-parallel training of our 175B model, the communication cost per step is dominated by the AllReduce of 350 GB of gradients.

Using ring-AllReduce over InfiniBand at 50 GB/s effective bandwidth, the raw communication time is approximately $2 \times (N - 1)/N \times 350/50$, which for large N approaches $2 \times 350/50$ seconds. With 75 percent overlap between gradient communication and the backward pass, the effective exposed communication time drops to $T_{\text{comm}}(N) \approx 3.5$ seconds. Under the same assumptions, the compute term is $T_{\text{compute}}/N \approx 2.1$ seconds, so the exposed step time is about 5.6 s and naive

data-parallel scaling efficiency is $2.1\text{ s}/5.6\text{ s} \approx 37.5$ percent. Well-configured systems can recover much of this loss by combining tensor parallelism, pipeline parallelism, topology-aware placement, and more effective communication overlap.

The scaling efficiency depends critically on the ratio of computation to communication. Three factors govern this ratio. Larger models have more computation per training step (more FLOPs per weight update), so the same communication overhead represents a smaller fraction of total step time; this *model-communication ratio* is why scaling efficiency improves as models grow larger. Larger batches push in the same direction, raising the computation per step without proportionally raising communication, because gradients are the same size regardless of batch size; the catch is that large batches can harm convergence and so require learning rate tuning and warmup schedules. Network bandwidth enters most directly, since doubling the InfiniBand bandwidth halves the communication time and improves scaling efficiency in proportion. The network fabric is therefore a first-order determinant of cluster productivity, not a secondary concern; its cost (10–15 percent of total system cost) is easily justified if it lifts scaling efficiency by even a few percentage points, because poor scaling efficiency wastes the other 85–90 percent of the investment.

Paradoxically, larger models are easier to scale than smaller ones.

These three factors interact in important ways. Larger models with larger batch sizes achieve better scaling efficiency, which means that the most expensive training workloads are also the ones that benefit most from scale. This creates a virtuous cycle for large-scale infrastructure: the workloads that justify building thousand-GPU clusters are also the workloads that use them most efficiently. Conversely, small models and small batch sizes scale poorly, which is why teams training 1B-parameter models on 64 GPUs often achieve only 40–60 percent scaling efficiency.

However, even for large models, scaling does not continue indefinitely. There exists a **scaling cliff** beyond which adding more GPUs actually reduces cost-efficiency. Under the assumptions of our 175B model, the cost-efficient region is approximately 1,024–4,096 GPUs, where the communication-to-compute ratio remains favorable and scaling efficiency stays above 70 percent. Beyond 8,192 GPUs, the AllReduce communication time begins to dominate the backward pass computation time, and the efficiency drops below 50 percent. While the wall-clock training time may still decrease slightly with more GPUs, the *cost per useful FLOP* increases because the organization is paying for 8,000 GPUs to do the work of 4,000. The nonlinear relationship dictates that the economic viability of training large models is bounded by the physics of interconnect latency, not merely by hardware availability. The cluster must be sized to operate in the linear regime of the scaling curve, and the model architecture (batch size, sequence length, parallelism dimensions) must be co-designed with the cluster size to maintain this balance.

Napkin Math 5.5: Scaling efficiency for a 175B model

Setup: Training a 175B model on a DGX H100 cluster with 400 Gb/s InfiniBand per GPU.

- **Compute per step** (assuming batch size 2M tokens, 6 FLOPs per parameter per token):
 $O_{\text{step}} = 6 \times 175 \times 10^9 \times 2 \times 10^6 \approx 2.1 \times 10^{18}$ FLOPs
- **Per-GPU compute time** on 1,024 GPUs, each at 1979 TFLOP/s FP8 peak (50 percent utilization): $T_{\text{compute}}/N \approx 2.1$ seconds
- **AllReduce time** for 350 GB of gradients using ring-AllReduce with overlap: $T_{\text{comm}}(N) \approx 3.5$ seconds (raw transfer is about 14 seconds; this example assumes 75 percent overlap with the backward pass)
- **Scaling efficiency:** $\eta_{\text{scaling}} \approx \frac{T_{\text{compute}}/N}{T_{\text{compute}}/N + T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}}} = 2.1/5.6 \approx 0.375$ in this simplified example, where synchronization is included in the AllReduce term and 75 percent communication overlap has already been applied.

The low efficiency (37.5 percent) shows why naive data parallelism at this scale is insufficient. Hierarchy-aware systems recover much of that lost efficiency by combining data parallelism with tensor parallelism, which communicates over NVLink, and pipeline parallelism, which overlaps computation with communication.

5.4.1.1 Parallelism-infrastructure interaction

The scaling efficiency analysis reveals a deeper insight: the effective parallelism strategy is not determined by the *model architecture alone* but by the *interaction* between the model’s communication requirements and the infrastructure’s bandwidth hierarchy. Each combination of parallelism strategy and infrastructure topology produces a different scaling efficiency curve, and selecting the wrong combination can waste a significant fraction of the cluster’s capacity. The napkin math above already showed pure data parallelism stalling near 37.5 percent efficiency at this scale; recovering that lost capacity means mapping each parallelism dimension onto the bandwidth tier that can carry its traffic. Section 5.7 works that combination through three concrete configurations and formalizes it as hierarchy-aware parallelism, once tensor and pipeline parallelism have been developed.

Selecting and combining parallelism strategies therefore leads directly to the traffic they create. Chapter 3 examined how topology is co-designed with the parallelism mapping to maximize scaling efficiency; here the next question is how the collective operations themselves shape the step time. AllReduce operations can consume 10–40 percent of total training time in data parallel systems, and this overhead grows with cluster size. BERT-Large on 128 GPUs can experience communication overhead reaching a large fraction of total runtime, while GPT-3-scale models require tensor, pipeline, and data parallelism plus communication overlap to avoid data-parallel gradient synchronization dominating the step.

AllReduce complexity depends on two components: latency (α) and bandwidth (β). Ring AllReduce achieves bandwidth-efficient communication with $(N-1)/N$ utilization, while tree-based approaches offer lower latency at $\mathcal{O}(\log N)$ steps. The choice depends on message size: tree algorithms win for latency-dominated small messages, ring algorithms win for bandwidth-dominated large gradients. High-performance implementations such as NCCL use hierarchical algorithms that combine tree latency within nodes and ring bandwidth between nodes. Chapter 6 provides detailed algorithm analysis, including complexity formulas, hierarchical variants, and topology-aware optimizations for large-scale collective operations.

Interconnect selection determines whether large-scale deployments remain compute-bound or collapse into communication-bound regimes, and the bandwidth requirements for efficient distributed training are substantial, particularly for transformer models. Efficient systems often require 100–400 GB/s aggregate bandwidth per node for transformer architectures. BERT-Base (110M parameters) requires approximately 440 MB of gradient synchronization per iteration in FP32, while BERT-Large (340M parameters) requires approximately 1.4 GB. Across 64 GPUs, these synchronization demands require 100–200 GB/s sustained bandwidth for sub-50 ms synchronization latency. For 175B-parameter language models, exact bandwidth requirements depend on the 3D-parallel configuration, gradient accumulation, overlap, and interconnect topology rather than a single universal number.

Synchronization frequency presents a trade-off between communication efficiency and convergence behavior. Accumulating gradients for 4 microsteps reduces synchronization frequency by 75 percent, but the realized step-time reduction depends on the compute/communication mix and how much communication can overlap with backpropagation. In standard implementations, gradient accumulation reuses one resident gradient buffer and accumulates in place; memory pressure comes from keeping that buffer resident and from any larger microbatch or activation choices, not from storing 4 independent gradient tensors. Asynchronous methods eliminate synchronization costs entirely but introduce staleness that degrades convergence by 15–30 percent for large learning rates.

5.4.2 The physics of scaling: Amdahl’s Law with communication

Just as the Iron Law of Processor Performance governs single-thread execution, distributed training is governed by an extended version of Amdahl’s Law that explicitly accounts for communication overhead. The time to complete one training step on N devices is not simply T_{single}/N , but is constrained by the sequential nature of synchronization. Section C.3.2 derives the speedup ceiling at fleet scale and works it through a concrete example; here we establish the idea that a fixed synchronization fraction caps speedup no matter how many accelerators are added.

Figure 5.7 visualizes this divergence from ideal linear scaling as the **Scaling Tax**—a direct consequence of the scaling efficiency bound (principle 8). It shows how communication overhead (r)

acts as a drag on performance, creating a communication wall where adding more GPUs yields diminishing returns.

Figure 5.7: The Scaling Tax: Effective speedup vs. number of GPUs. While ideal scaling (dashed black) is linear, real-world systems pay a ‘tax’ for communication. Compute-bound models like ResNet (green) scale well because they have high arithmetic intensity. Bandwidth-bound models like GPT-3 (red) hit a communication wall where adding more GPUs yields diminishing returns (efficiency < 50 percent).

The fleet law (principle 10) maps directly onto the iron law’s variables, separating compute, bandwidth, and coordination into additive terms:

$$T_{\text{step}}(N) = \underbrace{\frac{T_{\text{compute}}}{N}}_{\text{Compute-Time Term}} + \underbrace{T_{\text{comm}}(N)}_{\text{Bandwidth Term}} + \underbrace{T_{\text{sync}}(N)}_{\text{Coordination Term}} - T_{\text{overlap}}$$

The fleet-law terms separate step time into four distinct costs:

- **Compute-Time Term** (T_{compute}/N): The total computation required for the batch after ideal partitioning across N devices.
- **Bandwidth Term** ($T_{\text{comm}}(N)$): The time spent moving data. This is governed by the iron law’s data-movement term, D_{vol}/BW . For Ring AllReduce, this term is $\frac{2(N-1)}{N} \times \frac{M}{\text{BW}_{\text{net}}}$, where M is the communicated gradient or model-state bytes and BW_{net} is network bandwidth.
- **Coordination Term** ($T_{\text{sync}}(N)$): The nonoverlapped cost of barriers, ordering, and straggler waiting.
- **Overlap** (T_{overlap}): The portion of communication hidden behind computation.

The fleet law leads to the scaling efficiency metric for fixed global work, where T_{compute} is the single-device compute time for that work:

$$\eta_{\text{scaling}} = \frac{T_{\text{compute}}}{N \times T_{\text{step}}(N)} = \frac{1}{1 + \frac{N(T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}})}{T_{\text{compute}}}}$$

This is the scaling efficiency bound (principle 8): perfect linear scaling ($\eta_{\text{scaling}} = 1.0$) is a *theoretical limit*, not a *practical target*. Well-configured systems can achieve $\eta_{\text{scaling}} = 0.85\text{--}0.95$ at moderate scale

and degrade further as N grows. The gap between $\eta_{\text{scaling}} = 1.0$ and the achieved efficiency is the communication tax and coordination tax: the price of distributed execution.

The equation reveals the **scaling wall**: as N increases, the compute term (T_{compute}/N) shrinks, but the communication and synchronization terms can remain constant or grow. Eventually, the denominator is dominated by overhead, driving efficiency toward zero. Beyond wall-clock time, this communication overhead imposes an energy tax that scales with physical distance between devices.

Systems Perspective 5.2: The energy tax of scale

Distributed training is a race against energy as much as against time. In a single GPU, moving a byte from HBM to the cores costs roughly 1–2 pJ/bit. Moving that same byte across an NVLink interconnect costs 5–10 pJ/bit. Moving it across an InfiniBand network through switches costs 20–50 pJ/bit.

At the scale of 10,000 GPUs, the multiplication by aggregate bandwidth is what changes the engineering problem. A full H100 NVLink envelope is roughly 9 PB/s across the cluster; at 7.5 pJ/bit, that movement represents about 540 kW before cooling and switch overhead. The aggregate NDR InfiniBand envelope is smaller (500 TB/s), but at 35 pJ/bit it still represents about 140 kW. Communication-computation overlap is therefore necessary for wall-clock efficiency, but avoiding unnecessary movement is the direct way to reduce the power term itself.

IB 35 pJ/bit

NVLink 7.5

HBM 1.5

Communication energy climbs from HBM out to the network.

Wall-clock efficiency and the energy tax degrade together as N grows, following predictable patterns across GPU counts. As a representative rule of thumb, systems in the linear scaling regime of 2–32 GPUs often achieve 85–95 percent parallel efficiency because communication overhead remains small. The communication-bound regime emerges at 64–256 GPUs, where efficiency can drop to 60–80 percent even with well-matched interconnects. Beyond 512 GPUs, coordination overhead can become dominant and limit efficiency to 40–60 percent due to collective operation latency.

Hardware selection critically impacts these scaling characteristics. NVIDIA DGX A100 systems provide 600 GB/s of bidirectional NVLink bandwidth per GPU, with aggregate NVSwitch bandwidth at the system level, enabling high parallel efficiency inside an 8-GPU node. Multi-node scaling requires a network fabric with enough bisection bandwidth; EDR-class 100 Gbps links can support smaller multi-node jobs, while HDR-class 200 Gbps links can support larger clusters when topology, placement, and overlap are well matched.

The efficiency metrics directly influence the choice of parallelism strategy. Data parallelism works well in the linear scaling regime but becomes communication bound at scale. Model parallelism addresses memory constraints but introduces sequential dependencies that limit efficiency. Pipeline parallelism reduces device idle time but introduces complexity in managing microbatches. The effective strategy depends on which constraint—memory, bandwidth, or synchronization—dominates the target workload.

Hardware efficiency metrics govern throughput, but convergence theory determines whether distributed training reaches the same solution quality as single-device training. Parallelism affects optimization convergence in three ways: convergence rate changes with batch size, adding workers yields diminishing returns beyond the critical batch size, and learning rates must scale with batch size.

5.4.3 Convergence rate for synchronous data parallel SGD

The fundamental convergence result for distributed SGD explains why adding workers can reduce iteration count without changing the optimizer’s meaning. The theorem uses two standard regularity assumptions: the loss is smooth enough that gradients cannot change arbitrarily fast, and each stochastic gradient has bounded variance around the true gradient. Written formally, for a loss function $\mathcal{L}(\theta)$ with L_s -Lipschitz gradients and variance-bounded stochastic gradients $\mathbb{E}[\|g_i - \nabla \mathcal{L}(\theta)\|^2] \leq \sigma^2$, synchronous data parallel SGD with N workers achieves the following convergence rate.

Theorem 5.1: Convergence rate for distributed SGD

For synchronous data parallel SGD with N workers, each computing gradients on a local batch of size b , after K total iterations the expected optimization error satisfies:

$$\mathbb{E}[\mathcal{L}(\theta_K)] - \mathcal{L}^* \leq \underbrace{\frac{L_s \|\theta_0 - \theta^*\|^2}{2K}}_{\text{optimization error}} + \underbrace{\frac{\eta L_s \sigma^2}{2Nb}}_{\text{variance floor}}$$

where η is the learning rate, L_s is the smoothness constant, $\mathcal{L}^*$ is the optimal loss value, θ^* is an optimal parameter vector, and σ^2 is the gradient variance. The effective convergence rate is $\mathcal{O}(1/\sqrt{NbK})$ when the learning rate is tuned optimally as $\eta = \mathcal{O}(\sqrt{Nb/K})$.

The theorem reveals several important insights. First, the variance floor decreases linearly with the number of workers N , explaining why distributed training can achieve the same final loss with fewer iterations in the linear scaling regime. With equal local batch size b , synchronous data-parallel SGD computes the same minibatch gradient as a single worker using batch size Nb for that step; convergence speed still depends on learning-rate scaling and critical-batch-size effects. Second, the convergence rate $\mathcal{O}(1/\sqrt{NbK})$ shows that workers, local batch size, and iteration count jointly determine statistical progress, assuming infinite bandwidth. This is the **statistical efficiency** of distributed training, distinct from hardware efficiency.

However, the theorem assumes perfect synchronization (BSP). When workers proceed at different rates or use stale gradients, convergence guarantees degrade, as we examine next.

5.4.4 Staleness impact: BSP vs. SSP vs. ASP

The operational guarantees of BSP, SSP, and ASP established in section 5.3.1.4 have a convergence cost, which this section sketches with stylized smooth-objective bounds. The staleness parameter τ_{stale} quantifies how many iterations behind a gradient may be when applied to parameters, and it is the variable that ties throughput to solution quality (Ho et al. 2013; Dutta et al. 2018).

Definition 5.5: Gradient staleness

Gradient Staleness (τ_{stale}) is the number of parameter updates that occur between the time a gradient is computed and the time it is applied to the global model state.

1. **Significance:** It represents the synchronization error in distributed optimization. Increasing τ_{stale} can improve throughput by reducing barrier waits ($T_{\text{sync}}(N)$), but it typically degrades the rate of convergence, requiring more operations ($\mathcal{O}$) to reach the same accuracy.
2. **Distinction:** Unlike network latency, which is a physical delay, staleness is an algorithmic offset that arises from the choice of synchronization protocol (e.g., ASP, SSP).
3. **Common pitfall:** A frequent misconception is that staleness is “always bad.” In reality, it is a throughput-convergence trade-off: for some large-scale workloads, allowing bounded staleness is one practical way to keep thousands of GPUs in use.

The convergence behavior differs across these models in ways that directly affect training cost and solution quality. In Bulk Synchronous Parallel (BSP, $\tau_{\text{stale}} = 0$), all workers compute gradients on the same parameter version, then synchronize via barrier before updating. This guarantees mathematical equivalence to single-device training with larger batch size, an optimal convergence rate of $\mathcal{O}(1/\sqrt{NbK})$, and no hyperparameter adjustment beyond batch size scaling.

Stale Synchronous Parallel (SSP, $\tau_{\text{stale}} \leq s$) relaxes the barrier by allowing workers to proceed up to s iterations ahead of the slowest worker. In a stylized bound, the convergence rate gains an additive delay term:

$$\mathbb{E}[\mathcal{L}(\theta_K)] - \mathcal{L}^* \leq \mathcal{O}\left(\frac{1}{\sqrt{NbK}}\right) + \mathcal{O}\left(\frac{s^2 \eta^2 L_s^2}{Nb}\right)$$

The second term represents the **staleness penalty**. For bounded staleness s , this penalty is controlled by keeping delay small and retuning the learning rate. Deployments that choose bounded staleness accept convergence degradation for throughput improvement on heterogeneous clusters.

Asynchronous SGD (ASP, $\tau_{\text{stale}} = \infty$) eliminates waiting entirely: workers update parameters immediately. While this maximizes throughput, the same teaching model shows a larger delay-dependent term:

$$\mathbb{E}[\mathcal{L}(\theta_K)] - \mathcal{L}^* \leq \mathcal{O}\left(\frac{1}{\sqrt{K}}\right) + \mathcal{O}(\bar{\tau}_{\text{stale}}^2 \eta^2 L_s^2)$$

where $\bar{\tau}_{\text{stale}}$ is the average staleness. The staleness penalty now scales with the square of average delay, and critically, the variance reduction from N workers disappears in the dominant term. Several techniques compensate for this. Learning rate decay ($\eta' = \eta / \sqrt{1 + \bar{\tau}_{\text{stale}}}$) reduces the staleness penalty but slows convergence. Momentum correction adjusts the momentum term to account for delayed updates. Gradient clipping prevents stale gradients with large magnitudes from destabilizing training.

Table 5.4 summarizes the convergence properties of each synchronization model.

Table 5.4: Convergence Properties by Synchronization Model: BSP provides optimal convergence guarantees at the cost of synchronization overhead. SSP offers a tunable trade-off between throughput and convergence. ASP maximizes throughput but loses the variance reduction benefit of parallelism.

Model	Staleness	Convergence Rate	Variance Reduction	Best For
BSP	$\tau_{\text{stale}} = 0$	$\mathcal{O}(1/\sqrt{NbK})$	Full ($1/N$)	Final training, reproducibility
SSP	$\tau_{\text{stale}} \leq s$	$\mathcal{O}(1/\sqrt{NbK}) + \mathcal{O}(s^2 \eta^2 L_s^2 / Nb)$	Partial	Heterogeneous clusters
ASP	$\tau_{\text{stale}} = \infty$	$\mathcal{O}(1/\sqrt{K}) + \mathcal{O}(\bar{\tau}_{\text{stale}}^2 \eta^2 L_s^2)$	None	Maximum throughput, early exploration

5.4.5 Learning rate scaling rules

When increasing the effective batch size through data parallelism, the learning rate must be adjusted to maintain convergence quality. Two primary scaling rules have emerged from both theory and practice.

The linear scaling rule (Goyal et al. 2017) states that when the batch size is multiplied by k , the learning rate should also be multiplied by k :

$$\eta_{\text{large}} = k \cdot \eta_{\text{base}}$$

This rule is justified by approximating one large-batch step at learning rate $k\eta$ as k consecutive small-batch steps each at learning rate η . With batch size kB , the gradient variance decreases by factor k , so the larger step is well-conditioned; the approximation holds when parameters do not move much during those k small-batch steps. The rule is empirical rather than universal: Goyal et al. validated it for ResNet-50/ImageNet at global batch size 8,192 with gradual warmup, while LARS and LAMB extend large-batch recipes through layer-wise adaptation for ImageNet and BERT-style pretraining (Goyal et al. 2017; You et al. 2017; You et al. 2020). A **warmup period** that increases the learning rate linearly from η_{base} to $k \cdot \eta_{\text{base}}$ over the first W iterations lets the model reach a region of the loss landscape where large learning rates are stable:

$$\eta_t = \eta_{\text{base}} + \frac{t}{W}(k \cdot \eta_{\text{base}} - \eta_{\text{base}}) \quad \text{for } t < W$$

The square root scaling rule applies when batch sizes grow so large that linear scaling fails:

$$\eta_{\text{large}} = \sqrt{k} \cdot \eta_{\text{base}}$$

The more conservative square root rule is motivated by the observation that gradient noise (not just magnitude) affects optimization dynamics. The square root rule better preserves the signal-to-noise ratio of gradient updates. Empirically, square root scaling becomes necessary when batch sizes exceed the critical batch-size regime.

For extreme batch sizes (32K–1M), layer-wise adaptive learning rate scaling (LARS) (You et al. 2017) and its Adam variant LAMB (You et al. 2020) automatically adjust learning rates per layer based on the ratio of weight norm to gradient norm:

$$\eta_\ell = \eta_{\text{global}} \cdot \frac{\|w_\ell\|}{\|g_\ell\| + \lambda_{\text{wd}}\|w_\ell\|}$$

Here λ_{wd} is the optimizer’s weight-decay coefficient in the LARS/LAMB update, avoiding collision with the failure-rate parameter used in reliability analysis. Layer-wise scaling prevents layers with small weights from receiving disproportionately large updates. LAMB enabled BERT training with batch sizes up to 64K while maintaining convergence quality.

5.4.6 Critical batch size and diminishing returns

A fundamental property of distributed training is that adding more workers stops helping past a threshold. The critical batch size B^* marks the transition point beyond which increasing batch size yields diminishing returns in convergence per sample seen.

Definition 5.6: Critical batch size

Critical Batch Size (B^*) is the distributed-training batch size at which the gradient noise scale is large enough that further batch growth yields diminishing returns in sample efficiency (McCandlish et al. 2018; Shallue et al. 2019).

1. **Significance:** It marks the transition point for parallel scaling efficiency. Below B^* , increasing the batch size linearly improves the convergence per step. Above B^* , larger batches yield diminishing returns, requiring proportionally more samples (D) to reach the same loss.
2. **Distinction:** Unlike the memory-limited batch size (determined by memory capacity and activation footprint), the critical batch size is an algorithmic property of the model and dataset.
3. **Common pitfall:** A frequent misconception is that training can be sped up indefinitely by adding GPUs. In reality, B^* defines the physical ceiling for data parallelism: adding workers beyond this point wastes energy and compute (O) without reducing total training time (T).

The gradient-noise-scale proxy for the critical batch size can be estimated as:

$$B^* \approx \frac{\text{tr}(\Sigma)}{\|\nabla \mathcal{L}(\theta)\|^2}$$

where $\text{tr}(\Sigma)$ is the trace of the gradient covariance matrix (total gradient variance) and $\|\nabla \mathcal{L}(\theta)\|^2$ is the squared gradient norm (signal strength). Intuitively, B^* is the batch size at which averaging reduces gradient variance to the level of the true gradient magnitude.

Published large-batch regimes illustrate the scale rather than providing fixed thresholds. On ImageNet, Goyal et al. stabilized ResNet-50 at global batch 8,192 with warmup, and LARS extends ImageNet large-batch training further in some settings (Goyal et al. 2017; You et al. 2017). For BERT-Large pretraining, LAMB reports training at 32K–64K batch sizes with layer-wise adaptive updates (You et al. 2020). Across other domains, McCandlish et al. show useful batch-size limits ranging from tens of thousands in ImageNet-like settings to millions in reinforcement-learning workloads, so new frontier-language-model thresholds should be measured rather than copied (McCandlish et al. 2018).

The scaling law regime exhibits three distinct behaviors. Below the critical batch size ($B < B^*$), linear scaling holds: doubling the batch size halves the iterations needed to reach the target loss,

and hardware efficiency determines throughput. At the critical point ($B \approx B^*$), samples-per-second efficiency is maximized, the optimal trade-off. Above it ($B > B^*$), returns diminish, because doubling the batch size requires more than double the total samples, so additional workers add throughput but not sample efficiency.

Figure 5.8 illustrates this relationship between batch size and training efficiency.

Above B^* , adding replicas yields sub-linear throughput gains; statistical noise degrades convergence.

Figure 5.8: Critical Batch Size and Scaling Regimes: Below the critical batch size B^* , larger batches reduce noise and improve sample efficiency (linear scaling regime). Above B^* , larger batches provide diminishing returns: while throughput increases, total samples required also increases, reducing sample efficiency. The optimal operating point balances hardware utilization against convergence efficiency.

The critical batch size has important implications for distributed training system design. Adding workers beyond B^*/b (where b is the per-worker batch size) improves throughput but not sample efficiency, though it may still be worthwhile for cost if the marginal cost of additional workers is low. The learning rate schedule matters too, because above B^* aggressive warmup becomes essential, since the loss landscape near initialization may not support the large updates that linear scaling would produce. Communication trade-offs shift as well, because above B^* the reduced benefit of larger batches makes communication overhead relatively more costly, strengthening the case for gradient compression or asynchronous methods.

Checkpoint 5.2: Scaling decisions

Given a 7B parameter model distributed across a cluster of 64 A100 GPUs (80 GB HBM2e each), determine the maximum useful batch size. Use a pilot trace with $\text{tr}(\Sigma) = 1.6 \times 10^6$, $\|\mu\|^2 = 100$, per-GPU batch $b = 4$, and a proposed gradient-accumulation depth of 32 steps, giving $B_{\text{global}} = 64 \times 4 \times 32 = 8192$ samples.

- ☐ **Critical batch size:** Calculate the critical batch size (B_{crit}), where the gradient noise scale equals the batch size.
- ☐ **Proposed batch:** Use the Gradient Noise Scale metric $\mathcal{B} \approx \frac{\text{tr}(\Sigma)}{\|\mu\|^2}$ to evaluate the proposed batch size.

- **Scaling efficiency:** Classify scaling efficiency as meeting the 80 percent threshold or as marginal convergence gain from additional compute.

5.4.7 Worked example: Convergence comparison for 8 vs. 64 workers

To illustrate these concepts concretely, consider scaling from 8 to 64 workers when training a transformer language model with baseline batch size $B = 32$ per worker.

Napkin Math 5.6: Scaling from 8 to 64 workers

Setup: Transformer model with 1.3B parameters, target perplexity 15, baseline training: 100K iterations on single GPU with $b = 32$.

8 Workers (BSP)

- Effective batch size: $B = 8 \times 32 = 256$
- Learning rate: $\eta = 8 \times \eta_{\text{base}}$ (linear scaling with warmup)
- Expected iterations: $100\text{K} / 8 = 12.5\text{K}$ iterations
- Convergence: Reaches target perplexity in 12.8K iterations (98 percent efficiency)
- Communication overhead: 15 percent (NVLink intra-node)
- Wall-clock speedup: $100\text{K} \times 1 / (12.8\text{K} \times 1.15\times) = 6.8\times$

64 Workers (BSP)

- Effective batch size: $B = 64 \times 32 = 2,048$
- Learning rate ($N = 64$ workers): $\eta = N \times \eta_{\text{base}}$ (if $B < B^*$) or $\eta = \sqrt{N} \times \eta_{\text{base}}$ (if $B > B^*$)
- Assuming $B^* \approx 4,000$ (below critical): Linear scaling applies
- Expected iterations: $100\text{K} / 64 = 1.56\text{K}$ iterations
- Convergence: Reaches target perplexity in 1.72K iterations (91 percent efficiency)
- Communication overhead: 45 percent (InfiniBand inter-node, 8 nodes)
- Wall-clock speedup: $100\text{K} \times 1 / (1.72\text{K} \times 1.45\times) = 40.1\times$

SSP workers: 64 workers ($s = 4$)

- Same effective batch size: $B = 2,048$
- Learning rate: $\eta' = \eta_{\text{BSP}} / \sqrt{1 + s}$ with $s = 4$, giving $\eta' \approx 0.45 \times \eta_{\text{BSP}}$
- Expected iterations: Higher due to staleness penalty
- Convergence: Reaches target perplexity in 2.1K iterations (74 percent efficiency)
- Communication overhead: 25 percent (reduced synchronization)
- Wall-clock speedup: $100\text{K} \times 1 / (2.1\text{K} \times 1.25\times) = 38.1\times$

Analysis (table 5.5)

Table 5.5: Scaling SGD across cluster sizes: Iteration count, communication overhead, wall-clock speedup, and sample efficiency for the same training job at 1, 8, and 64 GPUs.

Configuration	Iterations	Comm. Overhead	Wall-clock Speedup	Sample Efficiency
1 GPU (baseline)	100,000	0%	1×	100%
8 GPU BSP	12,800	15%	6.8×	98%
64 GPU BSP	1,720	45%	40.1×	91%
64 GPU SSP	2,100	25%	38.1×	74%

The 64-GPU BSP configuration achieves 40× speedup despite only 91 percent sample efficiency because the communication overhead (45 percent) is offset by the massive parallelism. SSP provides comparable wall-clock time with lower communication overhead but requires more total samples.

Cost Analysis (assuming \$3/GPU-hour):

- 8: 12.8K iters $\times$ 0.4 s/iter $\times$ 8/3600 $\times$ \$3/GPU-hour = \$34
- 64 BSP: 1.72K iters $\times$ 0.58 s/iter $\times$ 64/3600 $\times$ \$3/GPU-hour = \$53
- 64 SSP: 2.1K iters $\times$ 0.50 s/iter $\times$ 64/3600 $\times$ \$3/GPU-hour = \$56

Despite higher parallelism, 64-GPU training costs more per run due to communication overhead and reduced sample efficiency. The 8-GPU configuration is more cost-efficient but takes 6× longer wall-clock time. The choice depends on whether minimizing cost or minimizing time-to-result is the priority.

5.4.8 Trade-off: Communication cost vs. convergence speed

The fundamental trade-off in distributed training is between communication efficiency and convergence quality. Figure 5.9 visualizes this trade-off space.

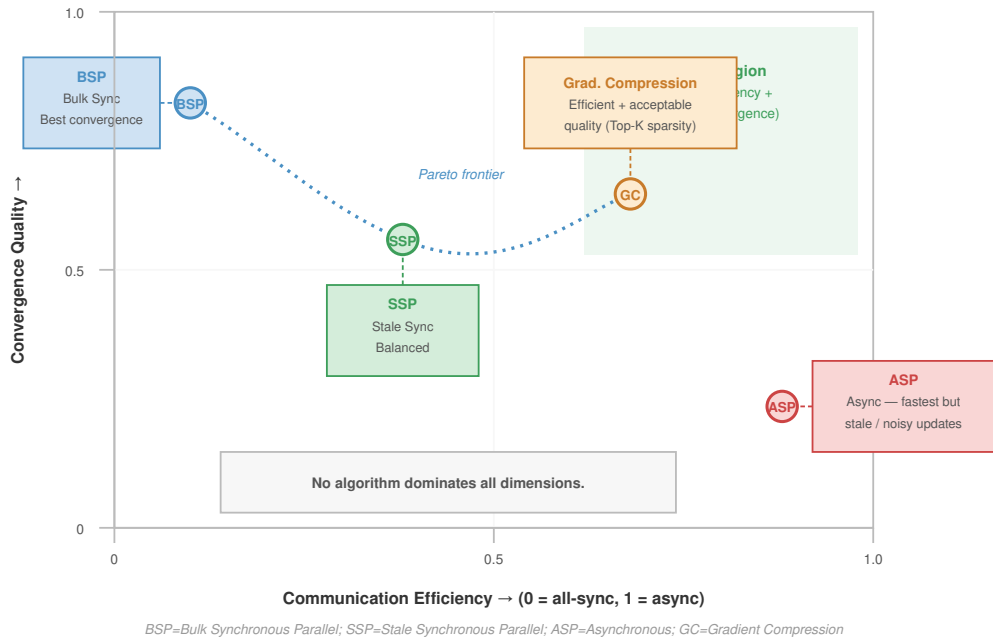

Figure 5.9: Communication-Convergence Trade-Off Space: Each point represents a different distributed training configuration. The Pareto frontier (dashed line) shows optimal configurations where improving one metric requires sacrificing the other. BSP sits at high convergence quality but lower throughput; ASP provides maximum throughput at convergence cost. Gradient compression and SSP occupy intermediate positions.

Several techniques occupy different positions on this trade-off curve. Gradient compression reduces communication volume by transmitting compressed gradient information through quantization, sparsification, or low-rank approximation. Examples include sign-based updates (Bernstein et al. 2018), Deep Gradient Compression (Lin et al. 2018), PowerSGD (Vogels et al. 2019), QSGD quantization with convergence analysis (Alistarh et al. 2017), and empirical sparse gradient dropping for neural machine translation (Aji and Heafield 2017).

Local SGD takes a different approach: workers perform H_{local} local updates before synchronizing, reducing communication frequency by factor H_{local} . Convergence analysis shows that for smooth, strongly convex objectives, Local SGD achieves the same asymptotic rate as synchronous SGD with appropriately tuned learning rates (Stich 2019).

Decentralized SGD restricts workers to communicating only with neighbors in a communication graph rather than performing global AllReduce. This reduces bandwidth requirements at the cost of slower mixing, making it suitable for geo-distributed training where global synchronization is expensive.

The choice among these methods depends on the specific bottleneck. When network bandwidth limits throughput, gradient compression provides the best trade-off. When synchronization latency dominates, Local SGD or SSP are preferred. When network topology constraints exist, decentralized approaches may be necessary.

5.5 Model Parallelism

When model state, activations, optimizer state, or an individual tensor operation exceeds the memory or communication budget of one accelerator group, data parallelism entirely collapses. This is the memory capacity gap (principle 3) in operational form: model parameter growth outpaces device memory growth, forcing the model’s computation and state to be partitioned. Data-parallel memory optimizations extend replication’s reach, but eventually the model itself must be partitioned.

Definition 5.7: Model parallelism

Model Parallelism is a distributed training strategy that partitions a single neural network’s parameters or operations across multiple devices so each device computes a distinct portion of the model.

1. **Significance:** If a model with parameter state S_{model} is split across N_{mp} devices, the ideal per-device parameter footprint falls toward $S_{\text{model}}/N_{\text{mp}}$, enabling training of models that exceed single-device memory. The cost is extra communication for activations and gradients plus idle time from sequential dependencies, so the memory gain must exceed the transfer and pipeline-bubble overhead introduced by the partition.
2. **Distinction:** Unlike data parallelism, which replicates the full model on every worker and shards the minibatch, model parallelism shards the model itself. Pipeline parallelism and tensor parallelism are implementation forms of model parallelism: one partitions layers into stages, while the other partitions individual tensor operations.
3. **Common pitfall:** A frequent misconception is that model parallelism automatically speeds up training. Its primary benefit is capacity, not throughput; without careful scheduling and overlap, downstream devices wait for upstream activations and utilization can fall below a single-device baseline.

Even with ZeRO-3 fully deployed, sharding optimizer states, gradients, and parameters across workers, some architectures remain intractable. Tensor parallelism, illustrated in figure 5.10, addresses this by partitioning individual weight matrices across devices; pipeline parallelism partitions layers across stages and is introduced later in section 5.5.2.2. For a 175B parameter model, weights alone occupy 350 GB, or about 5.5 GB per GPU across 64 GPUs. Full mixed-precision Adam training state is much larger: 2,800 GB globally, or roughly 43.8 GB per GPU before activations. This distinction matters because optimizer sharding reduces static state, but it does not eliminate the activation and per-layer capacity constraints that force model parallelism.

For long-context transformers where activation memory dominates, a 2048-token sequence through 175B parameters generates on the order of a terabyte of intermediate activations at even a small micro-batch (roughly 1.1 TB at micro-batch 4, as computed earlier), and no amount of optimizer sharding addresses this constraint. Model parallelism addresses these limitations by splitting the model architecture itself across devices, rather than replicating it with sharded state.

Optimizer state, not weights, dominates the per-replica training budget.

Figure 5.10: Tensor Parallelism Data Flow: Tensor parallelism column-splits a single weight matrix ($W_0 \dots W_3$) across four GPUs, with each GPU computing a partial output that is recombined through an AllGather. The companion strategy, pipeline parallelism, partitions layers vertically across stages and is shown separately in the layer-block figure. The two strategies are often combined in hybrid 3D parallelism for large models.

Napkin Math 5.7: The memory wall of scale

Problem: Training a 175B parameter model (like GPT-3) on NVIDIA A100s (80 GB). Can data parallelism with ZeRO-3 handle this?

Math:

1. **Parameter storage:** 175B params $\times$ 2 bytes (FP16) = 350 GB.
2. **Gradients and optimizer state:** gradients add 175B params $\times$ 2 bytes = 350 GB, while Adam FP32 master weights, momentum, and variance add 175B params $\times$ 12 bytes = 2,100 GB.
3. **Total static memory:** 2,800 GB.
4. **ZeRO-3 sharding:** With 64 GPUs, per-GPU static memory = 2,800 GB / 64 GPUs $\approx$ 43.8 GB.
5. **Activation memory:** For sequence length 2048 and batch size 1, a 96-layer transformer generates $\approx$ 50 GB of activations per GPU.

Systems insight: 43.8 GB (static) + 50 GB (dynamic) = 93.8 GB. This exceeds the 80 GB capacity of the A100. Even with full ZeRO-3 sharding, pure data parallelism fails. The only recourse is tensor parallelism to split the layers themselves.

Model parallelism addresses this limitation by distributing the model architecture itself across devices, but the placement decision is where to cut the model. Layer-based splitting assigns devices to sequential layer groups, such as layers 1–4 on one device and layers 5–8 on the next. Channel-based splitting divides the channels within a layer, such as 512 channels on one device and the remaining channels on another. Transformer architectures add attention-head splitting, where separate devices own different heads. Each cut changes a different cost: layer cuts save memory

but serialize the pipeline, while channel and head cuts expose more parallel work but require faster intra-layer communication.

These cuts enable the large-scale cases that exceed a single device for different reasons. GPT-3, with 175B parameters, relies on model parallelism for training. Vision transformers processing high-resolution $16k \times 16k$ pixel images use model parallelism to manage activation and memory constraints. Mixture-of-Experts architectures use this approach to distribute their conditional computation paths across hardware (Shazeer et al. 2017; Lepikhin et al. 2021; Fedus et al. 2022).

Device coordination proceeds in three phases. In the forward pass, data flows sequentially through model segments on different devices. The backward pass propagates gradients in reverse order through these segments. During parameter updates, each device modifies only its assigned portion of the model. The coordination ensures mathematical equivalence to training on a single device while enabling models that exceed individual device memory capacities. The cost is sequential dependency between stages: while one device computes its forward pass, downstream devices sit idle, creating the pipeline bubble that dominates utilization analysis for model-parallel systems.

Checkpoint 5.3: Model parallelism foundations

Verify your understanding of model sharding:

- ☐ **Memory relief:** Determine whether model parallelism reduces the **memory footprint** per GPU for a given model.
- ☐ **Sequential dependency:** Identify whether sequential dependencies between model shards arise in the forward pass, the backward pass, or both.
- ☐ **Pipeline bubble:** Explain why pure model parallelism often leads to lower GPU utilization than data parallelism through the “pipeline bubble.”
- ☐ **Layer vs. tensor split:** Distinguish layer-based and tensor-based ways to split a Transformer layer.

5.5.1 Model parallelism implementation

Once the model itself is the object being partitioned, the implementation problem is placement: every cut must save enough memory to justify the activation transfer and idle time it introduces. Figure 5.11 captures this bidirectional data flow: input data propagates forward through sequentially assigned model partitions while gradients flow backward to update parameters, with intermediate results transferring across device boundaries at each stage.

Figure 5.11: Model Parallelism Data Flow: Sequential distribution of model partitions across three devices: input data flows forward through each partition in order (top path), while gradients propagate backward during the update phase (bottom path). Each device handles a distinct portion of the model, with intermediate activations and gradients transferring at partition boundaries. This approach enables training of models exceeding single-device memory at the cost of sequential dependencies that reduce hardware utilization.

Consider our running example: the 175B parameter model requires 350 GB of memory in FP16, exceeding the 80 GB capacity of a single A100 by a factor of four. Model parallelism addresses this **capacity wall** by partitioning model weights across multiple devices, effectively stitching them into a single super-accelerator. Unlike data parallelism, where every GPU holds a full replica of the model and processes a unique fraction of the global batch, model parallelism requires each GPU to hold a *unique* fraction of the model and process the *same* data stream sequentially. With 8-way partitioning on A100s, BF16 weights alone occupy approximately 44 GB per GPU. That is only the weights budget: full training still needs activations, gradients, and optimizer state, so pure 8-way model parallelism is not sufficient by itself. Training requires additional sharding or offload for

optimizer and gradient state, plus pipeline or hybrid parallelism to keep activation memory within capacity.

In a typical pipeline parallel implementation, the training loop operates as a relay race. The forward pass initiates on GPU 1, which computes the initial transformer blocks and transmits the resulting intermediate activation tensor across the interconnect to GPU 2. For our 175B model with a hidden dimension of 12,288 and a micro-batch size of 4 sequences at 2,048 tokens each, this handoff involves moving approximately 200 MB of data per stage boundary per step. GPU 2 must wait for this payload before it can begin its computation, creating a strict dependency chain that propagates through all stages. The backward pass mirrors this path in reverse, propagating error gradients from the final layer back to the input, with each device computing gradients only for its local parameters.

The architecture fundamentally changes the optimization dynamics compared to data parallelism. Instead of a global AllReduce to average gradients across replicas, each GPU performs a local optimizer step (Adam (Kingma and Ba 2014), AdaFactor, or similar) on its specific slice of parameters. A device holding transformer layers 1–12 updates only those layers’ weights and biases, with no cross-device synchronization required during the optimization step. While this eliminates the bandwidth-heavy gradient synchronization of data parallelism, it trades one bottleneck for another: pipeline bubbles. If the layers assigned to GPU 1 are computationally heavier than those on GPU 2 (common when attention layers have different head counts or when embedding layers are unevenly sized), valuable compute cycles are lost to waiting. The primary engineering challenge thus shifts from maximizing arithmetic intensity to minimizing serialization latency and ensuring balanced load across the partitioned fleet (Rasley et al. 2020).

5.5.2 Parallelism variations

Partitioning strategy determines which cost the model pays after memory no longer fits on one device. Layer-wise partitioning spends idle time to reduce per-device memory; pipeline parallelism spends scheduling complexity to hide that idle time; tensor parallelism spends NVLink bandwidth to split a single layer. The approaches below separate these choices by the architecture and interconnect that make each viable.

5.5.2.1 Layer-wise partitioning

Layer-wise partitioning is the least invasive model cut: it saves memory by assigning consecutive layers to separate devices, but it preserves the model’s sequential dependence. In transformer architectures, this translates to specific devices managing defined sets of attention and feed-forward blocks. Figure 5.12 demonstrates this partitioning for a 16-layer transformer: four consecutive blocks reside on each of four devices, with forward activations flowing left-to-right and backward gradients propagating right-to-left across the device boundaries.

Sequential processing introduces device idle time, as each device must wait for the previous device to complete its computation before beginning work. While device 1 processes the initial blocks, devices 2, 3, and 4 remain inactive. Similarly, when device 2 begins its computation, device 1 sits idle. This pattern of waiting and idle time reduces hardware utilization efficiency compared to other parallelization strategies.

5.5.2.2 Pipeline parallelism

Pipeline parallelism extends layer-wise partitioning by introducing microbatching to minimize device idle time. Instead of waiting for an entire batch to sequentially pass through all devices, the computation is divided into smaller segments called microbatches, with overlapping execution across pipeline stages. Figure 5.13 shows how this overlapping works: while device 1 processes microbatch $i + 1$, device 2 computes microbatch i , device 3 handles $i - 1$, and device 4 executes $i - 2$, creating a continuous flow that keeps all devices active simultaneously.

As figure 5.13 shows, each device, as represented by the rows in the drawing, processes its assigned model layers for different microbatches simultaneously. The forward pass involves devices passing activations to the next stage, such as $F_{0,0}$ to $F_{1,0}$. The backward pass transfers gradients back through the pipeline, such as $B_{3,3}$ to $B_{2,3}$. This overlapping computation reduces idle time and increases throughput while maintaining the logical sequence of operations across devices, giving the strategy its formal shape.

Figure 5.12: Layer-Wise Model Parallelism: A 16-layer transformer distributed across four GPUs, with four consecutive transformer blocks assigned to each device (L1–L4, L5–L8, L9–L12, L13–L16). Forward activations (black arrows) flow left-to-right through device boundaries, while backward gradients (red arrows) propagate right-to-left during parameter updates. This partitioning reduces per-GPU memory from the full model size to 1/4, but introduces sequential dependencies where downstream devices wait for upstream computation to complete.

Definition 5.8: Pipeline parallelism

Pipeline Parallelism is a model parallelism technique that partitions a neural network’s layers into sequential stages assigned to different devices, passing activations forward and gradients backward between stages while overlapping computation across stages using micro-batches to maintain throughput.

1. **Significance:** Inter-stage communication transmits only the activation tensor at each stage boundary, sized as $B_\mu \times S \times d_{\text{model}} \times 2$ bytes at BF16, where B_μ is the micro-batch size. For a hidden dimension of 8,192 with micro-batch size 1 and a 2,048-token sequence, this is approximately $8,192 \times 2,048 \times 2 \approx 32$ MB per boundary, compared to the gigabytes required for gradient AllReduce in data parallelism. This low communication volume makes pipeline parallelism the primary technique for scaling model depth across nodes connected by 50 GB/s InfiniBand. The pipeline bubble wastes approximately $(p-1)/(m+p-1)$ of total compute, where p is the number of stages and m is the number of micro-batches—with $p = 8$ stages and $m = 32$ micro-batches, bubble overhead is about 18 percent.
2. **Distinction:** Unlike tensor parallelism, which shards individual matrix multiplications within a single layer and requires AllReduce on every layer’s output (demanding NVLink-class bandwidth within each stage), pipeline parallelism shards at layer boundaries and requires only point-to-point activation transfers between stages—tolerating InfiniBand bandwidth between nodes.
3. **Common pitfall:** A frequent misconception is that adding more pipeline stages always improves throughput. The pipeline bubble fraction grows as $(p-1)/(m+p-1)$: with $p = 16$ stages and $m = 16$ micro-batches, 48 percent of compute is wasted idle—requiring large micro-batch counts ($m \gg p$) to keep the bubble below 10 percent, which in turn increases peak activation memory and the memory pressure on each stage.

bubble tax

Configuration	Work	Idle
p8 m32	82%	18%
p16 m16	52%	48%

The same bubble term becomes concrete in the worked example below, where an 8-stage pipeline and 32 microbatches still leave a measurable idle-time tax.

More stages require enough microbatches or the bubble dominates utilization.

Figure 5.13: Pipeline Parallelism Schedule: A 4-stage pipeline processing 4 microbatches, showing forward passes ($F_{i,j}$) and backward passes ($B_{i,j}$) across time. Rows represent pipeline stages (GPUs), columns represent time steps. The staggered execution keeps all devices active: while stage 0 computes $F_{0,1}$, stage 1 processes $F_{1,0}$ from the previous microbatch. After all forward passes complete, backward passes propagate in reverse order. The “Update” column shows synchronized parameter updates after gradient accumulation across all microbatches.

Napkin Math 5.8: The cost of the pipeline bubble

Problem: A large-model training run uses pipeline parallelism across 8 stages. To hide the sequential delay, the batch is split into 32 microbatches. What is the “bubble tax”—the fraction of GPU cycles lost to idle waiting?

Math: In a synchronous pipeline (1F1B), the bubble fraction is determined by the ratio of stages to microbatches.

1. **Wait time:** At the start and end of each batch, GPUs sit idle for $p - 1$ steps.
2. **Productive time:** GPUs compute for m steps.
3. **Bubble fraction:** $(p - 1) / (p - 1 + m) = 7 / (7 + 32) \approx 17.9$ percent.

Systems insight: Pipeline parallelism is a *utilization-memory trade-off*. Reducing the bubble from 18 percent to 5 percent requires more microbatches (m), which consume additional activation memory on each GPU. In the machine learning fleet, depth does not scale for free; the cluster pays a 17.9 percent capacity tax just to keep the stages coordinated. This is why techniques like interleaved pipelining are essential: they chop the bubble into smaller pieces to recover that lost 18 percent of fleet capacity.

GPipe⁶ (Huang et al. 2019) introduced synchronous pipeline parallelism with micro-batch accumulation, while PipeDream (Narayanan et al. 2019) developed asynchronous approaches with weight stashing. Modern systems employ **1F1B (One-Forward-One-Backward)**⁷ scheduling to reclaim activation memory earlier; that lower memory pressure makes larger microbatch counts practical, and the larger m is what shrinks the bubble term.

⁶ | **GPipe:** Published by Google in 2019, GPipe introduced synchronous microbatch pipelining that trained a 557M-parameter AmoebaNet across 8 Tensor Processing Units (TPUs) with near-linear scaling. The key trade-off GPipe exposed: the pipeline bubble fraction $(p - 1) / (m + p - 1)$ means that with $p = 4$ stages and $m = 4$ microbatches, 43 percent of compute is wasted in idle time — driving the field toward schedules that reduce activation residency and make larger microbatch counts feasible.

At the schedule level, 1F1B is a warmup, steady-state, and drain loop. Algorithm 5.1 makes the contract explicit: each stage alternates forward work for newer microbatches with backward work for older microbatches once gradients arrive, so activations can be released before the whole batch has completed.

Algorithm 5.1 One-forward-one-backward pipeline schedule

Require: p ordered pipeline stages; m microbatches; activation links $j \rightarrow j+1$ and gradient links $j+1 \rightarrow j$

Ensure: one optimizer update after gradients accumulate across all m microbatches

- 1: split the global batch into m microbatches; assign consecutive layers to the p stages
 - 2: warm-up: launch forwards from stage 0, forwarding each activation downstream as produced
 - 3: **for** each stage in steady state **do**
 - 4: alternate one backward (oldest ready microbatch) with one forward (next microbatch)
 - 5: release a microbatch’s activation as soon as that stage’s backward consumes it
 - 6: **end for**
 - 7: drain: finish the remaining backward passes in reverse stage order
 - 8: apply the optimizer update once every stage has accumulated gradients for all m microbatches
-

The warm-up and drain phases still leave a bubble of roughly $(p-1)/(m+p-1)$, but interleaving backward work in the steady state frees each activation as soon as its backward consumes it, so peak activation memory grows with the stage count rather than the microbatch count. That is the gain over GPipe-style all-forward-then-all-backward scheduling, and it lets the system raise m until activation memory, recomputation, or the global-batch constraint becomes the next limit. In a transformer model distributed across four devices, device 1 would process blocks 1-6 for microbatch $i+1$ while device 2 computes blocks 7-12 for microbatch i . Simultaneously, device 3 executes blocks 13-18 for microbatch $i-1$, and device 4 processes blocks 19-24 for microbatch $i-2$. Each device maintains its assigned transformer blocks but operates on a different microbatch, creating a continuous flow of computation.

The transfer of hidden states between devices occurs continuously rather than in distinct phases. When device 1 completes processing a microbatch, it immediately transfers the output tensor of shape $B_\mu \times S \times d_{\text{model}}$ to device 2 and begins processing the next microbatch. This overlapping computation pattern maintains full hardware utilization while preserving the model’s mathematical properties.

One important variant targets the remaining bubble directly. GPUs at the beginning of the pipeline are idle while waiting for gradients to flow back from the end, and vice versa. These bubbles represent wasted compute. The 1F1B schedule in algorithm 5.1 keeps SMs busy during the steady state and reduces activation residency, but the fill and drain bubble remains unless the system increases m or schedules useful work into those otherwise idle slots.

Zero-bubble pipeline schedules further reduce idle time by overlapping weight gradient computation with activation gradient communication. In a standard backward pass, the GPU computes $\partial\mathcal{L}/\partial W$ (weight gradient) and $\partial\mathcal{L}/\partial X$ (activation gradient, sent to the previous stage) together. Zero-bubble scheduling splits these into separate kernels: a B kernel that computes only the activation gradient $\partial\mathcal{L}/\partial X$ and sends it to the previous stage, and a W kernel that computes the weight gradient $\partial\mathcal{L}/\partial W$ locally. The B kernel must execute promptly (it is on the critical path), but the W kernel can be scheduled opportunistically to fill bubbles.

The scheduling freedom provided by this B/W split is substantial. In a 4-stage pipeline with 8 microbatches, the standard 1F1B schedule has a bubble fraction of approximately $(p-1)/(m+p-1)$ where p is the number of stages and m is the number of microbatches. For $p=4, m=8$, this is $3/11 \approx 27\%$ idle time. Zero-bubble scheduling can reduce this to near zero by filling the startup and teardown bubbles with W computations.

The trade-off is memory: zero-bubble scheduling requires storing intermediate activations for longer (because the W computation is deferred), increasing peak memory usage. Some implementations address this by combining zero-bubble scheduling with activation checkpointing, selectively recomputing certain activations rather than storing them. The interaction between these techniques

⁷ | **1F1B Scheduling:** “One-Forward-One-Backward.” Unlike GPipe (which processes all forward passes before any backward passes), 1F1B interleaves them. This reduces the peak activation memory footprint from $\mathcal{O}(m \times p)$ to $\mathcal{O}(p)$, where m is the number of microbatches and p is the number of pipeline stages. This memory reclamation is what enables the massive micro-batch counts ($m \gg p$) required to keep the pipeline bubble small.

creates a three-way trade-off among pipeline bubble size, memory consumption, and recomputation overhead, an example of the displacement of overhead (principle 13).

5.5.2.3 Tensor parallelism

Pipeline parallelism, examined above, addresses device idle time by overlapping microbatch processing across stages. Each device holds complete layers and processes them sequentially, with communication only at stage boundaries when activations transfer between devices. This approach tolerates moderate interconnect bandwidth because communication occurs infrequently, once per layer boundary per microbatch. However, pipeline parallelism cannot help when individual layers themselves exceed device memory, or when the communication pattern within layers benefits from a different granularity than layer boundaries.

Tensor parallelism takes a fundamentally different approach: instead of assigning complete layers to devices, it splits the weight matrices within each layer. This operator-level parallelism (also called intra-layer parallelism) enables finer-grained distribution but requires high-bandwidth interconnects for the frequent intra-layer communication it introduces.

Definition 5.9: Tensor parallelism

Tensor Parallelism is a model parallelism technique that partitions individual tensor operations—primarily matrix multiplications—across multiple devices using column-parallel or row-parallel weight splits, typically requiring two AllReduce operations per transformer layer in Megatron-style transformer blocks to sum partial results from all participating devices.

1. **Significance:** Megatron-LM style tensor parallelism places two AllReduce operations per transformer block—one after attention and one after the MLP—with each collective reducing an activation tensor of size $B_{\text{batch}} \times S \times d_{\text{model}} \times 2$ bytes in BF16. A ring AllReduce moves roughly $2(t-1)/t$ times that payload per GPU. At degree $t=8$ on NVLink with 900 GB/s bandwidth, each AllReduce takes approximately 0.1–0.5 ms. The same operation over InfiniBand (50 GB/s) takes 2–10 ms per layer—with 96 transformer blocks, this adds 200–960 ms of pure synchronization overhead per step, collapsing MFU to single digits.
2. **Distinction:** Unlike pipeline parallelism, which communicates only at layer boundaries and transfers small activation slices, tensor parallelism synchronizes within every layer via AllReduce, making it sensitive to the per-operation latency of the interconnect and restricting it to within-node NVLink fabrics in practice.
3. **Common pitfall:** A frequent misconception is that tensor parallelism can simply be scaled across nodes over InfiniBand. NVLink delivers approximately 900 GB/s bidirectional, or 450 GB/s per direction; InfiniBand NDR delivers 50 GB/s per port—a 9× per-direction gap. Running tensor parallelism across InfiniBand typically collapses MFU to single-digit percentages, making the communication overhead larger than the compute benefit of distributing the matrix multiplication.

Tensor parallelism needs NVLink bandwidth; pipeline parallelism tolerates slower fabric.

⁸ | **Megatron-LM:** NVIDIA's 2019 framework that trained an 8.3B-parameter transformer – 24× BERT and 5.6× GPT-2 at the time – by strategically placing only two AllReduce operations per transformer block (one after attention, one after the multilayer perceptron (MLP)). This column-then-row partitioning eliminates inter-GPU communication between the two linear layers within each block, achieving 76 percent scaling efficiency across 512 GPUs and establishing tensor parallelism patterns that remain influential in large-scale transformer training.

The interconnect topology dictates which form of model parallelism is viable at each level of the cluster hierarchy. Tensor parallelism's per-layer synchronization demands NVLink-class bandwidth; pipeline parallelism's boundary-only communication tolerates InfiniBand. This bandwidth pattern creates the design pressure for a hybrid: use tensor parallelism for bandwidth-intensive intra-layer splits and pipeline parallelism for coarser inter-layer splits.

Megatron-style tensor parallelism⁸ (Shoeybi et al. 2019) partitions matrix multiplications in two ways. Examine figure 5.14: column-parallel splitting divides weight matrices along columns for QKV projections, allowing independent computation across GPUs, while row-parallel splitting divides along rows for output layers, requiring AllReduce to combine partial sums at the end of each block.

Column-parallel linear layers split weights along columns. For input X and weight matrix $W = [W_1|W_2]$ split across 2 GPUs:

$$Y = XW = X[W_1|W_2] = [XW_1|XW_2]$$

Each GPU computes its partition independently, and the outputs are concatenated without communication when the next operation is row-parallel. The row-parallel half of the pattern splits weights

$$\text{along rows, } W = \begin{bmatrix} W_1 \\ W_2 \end{bmatrix}:$$

$$Y = XW = X_1W_1 + X_2W_2$$

Each GPU computes a partial sum, and the system pays one AllReduce to combine the partial outputs.

Figure 5.14: Tensor Parallelism - Matrix Partitioning: Illustration of Megatron-LM style tensor parallelism. The first linear layer (e.g., QKV) is split column-wise $[W_1 \mid W_2]$. The second layer (e.g., Output) is split row-wise $[W_1; W_2]$. This arrangement allows the output of the first layer to flow directly into the second without synchronization, requiring only one AllReduce after the second layer to sum the partial results.

The column-then-row arrangement shown in figure 5.14 is the key design insight. By pairing a column-parallel layer with a row-parallel layer, the intermediate activations flow directly between them without communication, confining synchronization to the end of the pair. Megatron applies this pattern twice in each transformer block: the QKV projection is column-parallel and its attention output projection is row-parallel, then the first feed-forward layer is column-parallel and the second feed-forward layer is row-parallel. The design places AllReduce operations strategically, one after attention and one after the feed-forward network, for two AllReduce operations per transformer layer. Communication volume per transformer layer depends on sequence length S , hidden dimension d_{model} , tensor-parallel degree t , and batch size B . The activation payload is:

$$M_{\text{act}} = B \times S \times d_{\text{model}} \times \text{sizeof}(\text{dtype})$$

A ring AllReduce transfers approximately $2(t-1)/t \times M_{\text{act}}$ bytes per GPU, which is close to $2M_{\text{act}}$ for large t . With $S = 2048$, $d_{\text{model}} = 4096$, $B = 4$, and FP16, the activation payload is $4 \times 2048 \times 4096 \times 2 \approx 67$ MB. Applying the ring factor gives roughly 134 MB per AllReduce. For a 96-layer model with two AllReduce operations per layer, this totals approximately 25.7 GB per forward pass; including the symmetric backward AllReduces brings per-training-step communication to roughly 51 GB, requiring NVLink bandwidth to avoid becoming the bottleneck.

Tensor parallelism scaling degrades rapidly beyond 8-way parallelism because the same split that reduces memory also reduces the computation available to hide communication. As the tensor-parallel degree grows, per-GPU work falls while collective latency and aggregate traffic rise; per-GPU ring AllReduce bytes approach $2\times$ the activation tensor size rather than growing linearly without bound, but the smaller local matrix multiply leaves less useful work to cover that exchange. Once NVLink bandwidth saturates, adding another tensor-parallel shard mainly exposes more synchronization rather than more throughput. Published systems such as Llama 3 405B use TP=8 within NVLink-connected H100 nodes (Dubey et al. 2024), and similar node-local tensor parallelism is a common design pattern for large LLM training (Z. Jiang et al. 2024).

The same partitioning idea can apply to sequence length as well as matrix dimensions. While standard tensor parallelism tiles computation across the HBM-NVLink boundary within a node, **Ring Attention** partitions the attention state across GPUs rather than forcing every device to hold the full prefix (Liu et al. 2023). This becomes relevant for sequences that exceed a single GPU’s memory, such as million-token context windows. Each GPU owns a block of queries Q and circulates the key/value (K/V) blocks around a ring, computing attention against the block currently resident in memory and then forwarding that block to its neighbor.

The algorithm proceeds in $N - 1$ communication rounds (where N is the number of GPUs). In each round, each GPU computes attention between its local Q block and the currently resident K/V block, sends that K/V block to its ring neighbor, and receives the next block from its other neighbor. The implementation overlaps this exchange with computation: while GPU i computes attention using K_j/V_j , it simultaneously receives K_{j+1}/V_{j+1} from the ring.

If the compute time for one tile exceeds the communication time for transferring one tile over NVLink, the communication is fully hidden. On an H100 with 3.35 TB/s HBM bandwidth and 900 GB/s NVLink bandwidth, this overlap is achievable for typical tile sizes.

The practical impact of Ring Attention is measured in context length. Without it, a single GPU’s attention computation is limited by HBM capacity: the key/value state for a sequence of length S must fit entirely in one GPU’s memory. With Ring Attention across N GPUs, each GPU holds S/N tokens of that state, enabling context lengths of $N \times S_{\text{single}}$. Chapter 9 later connects this sequence-level distribution to FlashAttention’s tile-level HBM reuse; here, the distributed-training lesson is that sequence length can become a partitioning dimension just like layers, tensors, or data.

5.5.3 Parameter servers and embedding sharding

While AllReduce dominates dense model training, the **Parameter Server (PS)** architecture, formalized by Li et al. (2014), remains common for recommendation systems and other sparse workloads. A Parameter Server architecture separates workers (who compute gradients) from servers (who store parameters and apply updates).

For dense models (like ResNet or BERT), the PS architecture creates a bottleneck: with N workers, the server’s inbound bandwidth must absorb N gradient streams simultaneously, saturating the server’s network bandwidth and making it the communication chokepoint. This “incast” problem drove the adoption of Ring AllReduce, where each worker sends and receives at its own link rate, achieving N -fold higher aggregate bandwidth by distributing the load across all nodes. For dense models beyond 4–8 GPUs, decentralized AllReduce wins decisively.

However, for **Recommendation Systems**—specifically DLRM—the model parameters are dominated by massive Embedding Tables (often 10 TB+) that cannot fit on any single GPU. Furthermore, the updates are sparse: a batch of users interacts with only a tiny fraction (e.g., 0.001 percent) of the items.

In this sparse regime, the parameter server avoids dense synchronization by moving only the rows that a batch touches:

1. **Embedding Sharding:** The massive tables are partitioned across the PS fleet (often CPU nodes with massive DRAM).
2. **Sparse Lookups:** Workers send a list of IDs to the PS.
3. **Sparse Pull:** The PS returns only the requested embedding vectors, not the full table.
4. **Sparse Push:** Workers send gradients only for the touched embedding rows.

The **Sparse Pull/Sparse Push** pattern avoids the bandwidth bottleneck of dense AllReduce. Implementations such as TorchRec or Meta’s hierarchical sharding place “hot” embeddings on GPUs and “cold” embeddings on CPU PS nodes, creating a tiered memory hierarchy for model parameters.

5.5.4 Expert parallelism (mixture of experts)

While tensor parallelism splits dense layers across devices, expert parallelism enables scaling model capacity (parameters) without increasing compute cost (FLOPs) by using conditional computation. In a Mixture-of-Experts (MoE) architecture (Shazeer et al. 2017), the feed-forward network (FFN) of each transformer block is replaced by a set of E “experts” (independent FFNs). For each token, a gating network selects a small subset (typically top-1 or top-2) of experts to process it.

In a distributed setting, experts are partitioned across workers. If we have 8 GPUs and 8 experts, each GPU hosts one expert. The training process introduces a distinct communication pattern, as figure 5.15 illustrates:

1. **Gating:** Each token determines its destination expert.
2. **All-to-All Dispatch:** Tokens are routed across the network to the device hosting their selected expert.
3. **Computation:** Experts process their assigned tokens.
4. **All-to-All Combine:** Processed tokens are routed back to their original device to resume the sequence.

Figure 5.15: Mixture of Experts (MoE) All-to-All Routing: Expert parallelism requires a unique ‘All-to-All’ communication pattern. Tokens from a local batch are routed by a gating network to experts sharded across the cluster. This involves a global shuffle where every GPU sends tokens to and receives tokens from potentially every other GPU, stressing the cluster’s bisection bandwidth.

The primary advantage is decoupling model size from compute budget. A trillion-parameter MoE model might use only 10B parameters per token, enabling training on feasible hardware budgets. The constraint is the **All-to-All** communication, which is bandwidth-intensive and sensitive to load imbalance.

Definition 5.10: Expert parallelism

Expert Parallelism is the distribution strategy for mixture-of-experts models that places different experts on different devices and routes each token's activations to the devices hosting its selected experts through All-to-All collectives, scaling total parameter count across the cluster without scaling the compute each token consumes.

1. **Significance:** It decouples model capacity from compute budget: a trillion-parameter MoE model may activate on the order of 10B parameters per token, so per-token FLOPs remain near those of a 10B dense model while capacity grows roughly $100\times$. The price is communication structure: every MoE layer requires two All-to-All shuffles per pass (dispatch and combine) whose volume scales with tokens moved times hidden dimension, stressing the cluster's bisection bandwidth rather than any single link.
2. **Distinction:** Unlike tensor parallelism, which splits dense operations so that every device computes a fraction of every token, expert parallelism is conditional computation: each device computes only the tokens routed to its experts, making both the communication pattern and the load distribution data-dependent rather than fixed by the architecture.
3. **Common pitfall:** A frequent misconception is that experts share work evenly. Natural token distributions are skewed: a hot expert can receive $3\text{--}5\times$ its fair share of traffic, overflowing its device's activation buffer while sibling devices idle, which is why production MoE systems cap per-expert token budgets and penalize routing skew during training rather than trusting the router alone.

At the heart of expert parallelism lies the All-to-All communication primitive, which shuffles tokens across the cluster based on dynamic routing decisions. Consider a configuration with $E = 64$ experts distributed across 64 GPUs, processing a batch of $B = 4$ sequences at length $S = 2048$ with hidden dimension $d_{\text{model}} = 4096$. For every MoE layer, the system must dispatch $B \times S$ tokens to their assigned experts. In FP16, this moves $B \cdot S \cdot d_{\text{model}} \cdot 2$ bytes—approximately 67 MB—in a single direction. Since the processed embeddings must return to their original device for the residual connection, the total network overhead is roughly 134 MB per transformer block. While manageable in isolation, this latency accumulates rapidly in deep, sparse architectures like the Switch Transformer (Fedus et al. 2022) (up to 2,048 experts) or GShard (Lepikhin et al. 2021).

Network efficiency relies on the assumption of uniform token distribution, but natural language is inherently skewed: specific experts handling common syntax or connector words may receive $3\text{--}5\times$ their fair share of traffic. A hot expert is both a memory problem and a scheduling problem. If one expert receives too many tokens, its GPU runs out of activation buffer while other experts sit underused.

MoE systems therefore enforce a hard limit defined by the **capacity factor** C , typically set between 1.25 and 1.5. This parameter caps the maximum number of tokens an expert processes at roughly $C \cdot (B \times S)/E$ for the routing group. If the routing gate assigns more tokens than this buffer allows, the excess tokens are dropped, passing through the layer unprocessed via the residual connection. To reduce that data loss, training objectives include an **auxiliary load balancing loss**, weighted at 0.01–0.1 relative to the main cross-entropy loss, that penalizes the router for favoring specific experts. Models such as Mixtral 8x7B use top-2 routing across 8 experts, achieving a favorable balance between capacity scaling and routing stability.

The sparse communication pattern distinguishes recommendation and MoE workloads (Archetype B (DLRM at Scale)) from dense LLM training (Archetype A (GPT-4/Llama-3)) (section 1.6.1).

Lighthouse 5.1: Archetype B (DLRM at Scale): DLRM vs. LLM scaling

Each scales through a different mechanism, bound by a different resource:

- **LLMs (Dense):** Scale via Tensor/Pipeline Parallelism. Constraint: compute and interconnect bandwidth (NVLink).

- **DLRM-style models (Sparse):** Scale via Embedding Sharding (Parameter Servers). Constraint: memory capacity and interconnect latency (Random Access).

The distinction dictates fundamentally different cluster designs: dense GPU pods for LLMs vs. memory-rich CPU/GPU hybrids for RecSys.

5.5.5 Trade-offs: The bubble vs. bandwidth dilemma

Model parallelism breaks the memory wall but introduces sequential dependencies that reduce hardware utilization. The engineering challenge is balancing pipeline bubbles (idle time) against all-to-all bandwidth (communication time).

Model parallelism offers three principal advantages. Memory scaling enables training of models that exceed single-device capacity: with 8-way tensor parallelism, the FP16 weight slice of a 175B model fits within A100 HBM before optimizer state and activation budgets are counted. Splitting the model also allows larger global batch sizes without out-of-memory errors, since each GPU processes a smaller parameter slice. The approach maps naturally to the physical structure of transformers, where attention heads split via tensor parallelism and layers split via pipeline parallelism.

The advantages come at the cost of three fundamental limitations. Pipeline bubbles cause GPUs to sit idle while filling and draining the pipeline; the bubble fraction is approximately $(p-1)/(m+p-1)$, where p is pipeline stages and m is microbatches, and achieving more than 90 percent efficiency requires $m \gg p$, which increases activation memory. Communication intensity in tensor parallelism is equally constraining: two AllReduce operations execute per layer on the critical path, demanding extremely high-bandwidth, low-latency interconnects (NVLink) and typically preventing scaling beyond a single node (8 GPUs) before hitting the bandwidth wall. Implementation complexity rounds out the trade-off, requiring invasive changes to the model definition—replacing standard linear layers with column-parallel and row-parallel variants—unlike data parallelism, which wraps the model externally without modifying internals.

5.6 FP8 for distributed training

Numerical precision is itself a distribution lever: halving the bytes per value halves the gradient and activation payloads that the AllReduce and tensor-parallel collectives move, shrinking the $T_{\text{comm}}(N)$ term that dominates step time at scale. The 8-bit floating point (FP8) format exploits this lever by reducing the numerical precision of computation while trying to preserve enough range for stable optimization.

FP8 matters to distributed training when its narrower formats reduce communication without destabilizing optimization. Traditional mixed-precision training uses FP32 master weights with FP16 forward and backward passes. FP8-capable accelerators such as the NVIDIA H100 add support for FP8, offering two formats optimized for different phases of training (Micikevicius et al. 2022).

The choice between the two FP8 formats is therefore not an instruction-set detail; it decides which tensors can be narrowed without breaking the optimizer. E4M3 (4-bit exponent, 3-bit mantissa) provides a range of approximately ± 448 with moderate precision, making it suitable for *weights and activations* in the forward pass where values cluster in predictable distributions. E5M2 (5-bit exponent, 2-bit mantissa) provides a much larger range of approximately ± 57344 but coarser precision, which is why it is used for *gradients* that can span many orders of magnitude during backpropagation. Using E4M3 for gradients would cause frequent overflow and underflow, while E5M2 captures the full gradient distribution at the cost of slightly noisier updates. Read table 5.6 as a distribution constraint map: each row changes the balance among range, precision, memory traffic, and trainability.

Table 5.6: Training Precision Formats: Each row represents a floating-point format used in training. FP8 formats (E4M3, E5M2) occupy the communication-efficient middle ground between FP16/BF16 training stability and the byte reduction needed to shrink distributed payloads.

Format	Exponent	Mantissa	Range	Precision	Use Case
FP32	8 bits	23 bits	$\pm 3.4 \times 10^{38}$	Very high	Master weights
FP16	5 bits	10 bits	± 65504	High	Mixed-precision
BF16	8 bits	7 bits	$\pm 3.4 \times 10^{38}$	Moderate	Training
E4M3	4 bits	3 bits	± 448	Low	FP8 forward pass
E5M2	5 bits	2 bits	± 57344	Very low	FP8 gradients

As table 5.6 summarizes, the critical engineering challenge in FP8 training is *dynamic scaling*. FP8’s narrow dynamic range means that a fixed scale factor will cause either overflow or underflow. Per-tensor scaling multiplies each tensor by a scale factor before casting to FP8, then divides by that factor after the FP8 computation. The scale factor is adjusted dynamically, typically by tracking the running maximum absolute value of each tensor and choosing a scale that maps this maximum to near the FP8 maximum representable value.

The three-precision approach (FP32 master weights, FP8 general matrix multiply (GEMM) operations, FP16 accumulation) can achieve near-FP16 training quality while improving effective throughput on FP8-capable hardware for suitable workloads. The systems implication is concrete but hardware-dependent: FP8 halves the bytes moved relative to FP16/BF16 tensors, while operation throughput and energy gains depend on the accelerator implementation. The throughput gain is therefore a performance expression of narrower movement and hardware support, not an additional multiplicative factor.

For distributed training, FP8 earns its place only when smaller payloads reduce communication while dynamic scaling protects convergence. It changes the payload size, not the parallelization axis. If precision reduction is still insufficient, the system must decide how data, tensor, and pipeline parallelism map onto the hardware hierarchy.

5.7 Hybrid Parallelism

Training a large model when data parallelism runs out of memory and model parallelism runs out of network bandwidth requires orchestrating both strategies simultaneously across three dimensions. The preceding sections revealed a fundamental tension: data parallelism scales throughput but demands massive memory, while model parallelism enables large models but starves the compute.

Hybrid parallelism resolves this tension by applying both strategies orthogonally: model parallelism splits the architecture to fit available memory, while data parallelism scales throughput across multiple model replicas. Training a 175B parameter language model on a dataset of 300 billion tokens demonstrates this approach in practice. The neural network layers distribute across multiple GPUs through model parallelism, while data parallelism enables different GPU groups to process separate batches. This dual strategy addresses both memory constraints from model size and computational demands from dataset scale simultaneously, and it is precisely this combination that defines Archetype A training at large-model scale.

Lighthouse 5.2: Archetype A (GPT-4/Llama-3): physics of 3D parallelism

Archetype A (GPT-4/Llama-3) is the primary driver for hybrid parallelism. Because the model parameters (P) exceed the memory of any single accelerator ($C_{\text{mem,device}}$), and the training dataset (D) requires massive throughput, we must split the problem along three orthogonal axes:

1. **Tensor parallelism:** Splits individual layers to fit P within a node’s memory.
2. **Pipeline parallelism:** Splits layers across nodes when the parameter footprint exceeds a single node.
3. **Data parallelism:** Replicates the entire split-model pipeline to scale throughput on D .

Only by combining all three can we train Archetype A systems efficiently.

To see why the combination matters, consider three parallelism configurations for training the 175B model on a 1,024-GPU cluster organized as 128 nodes of 8 GPUs each. The progression from pure data parallelism through tensor and pipeline parallelism makes the efficiency gain concrete.

Configuration A: Pure Data Parallelism (DP-1024). All 1,024 GPUs replicate the full model (using ZeRO to shard optimizer states), and each GPU processes a different data shard. The gradient AllReduce exchanges 350 GB across the full InfiniBand fabric. As the scaling-efficiency analysis showed, this achieves approximately 37.5 percent efficiency because the inter-node communication dominates.

Configuration B: TP-8, DP-128. Within each node, 8 GPUs use tensor parallelism over NVLink. Across nodes, 128 data-parallel groups synchronize gradients over InfiniBand. Each data-parallel group now needs to AllReduce only the gradients for its 1/8 shard of the model (43.75 GB instead of 350 GB), and the TP communication is contained within the fast NVLink domain. The inter-node AllReduce time drops from 14 seconds to approximately 1.75 seconds. If the compute time is still 2.1 seconds, the efficiency improves to $2.1/(2.1 + 1.75) \approx 54.5$ percent, and with communication-computation overlap, practical efficiency reaches 75–85 percent.

Configuration C: TP-8, PP-4, DP-32. Within each node, 8 GPUs use tensor parallelism. Across 4 nodes, pipeline parallelism divides the model into 4 stages. Across the remaining 32 data-parallel groups, gradient synchronization occurs over InfiniBand. Pipeline parallelism reduces the gradient AllReduce volume further (each stage has roughly 1/4 of the parameters), and the pipeline communication (forwarding activations between stages) has lower volume than a full AllReduce. The trade-off is the pipeline bubble: at the beginning and end of each microbatch, some pipeline stages are idle while waiting for activations from earlier stages or gradients from later stages. The bubble fraction is approximately $(p - 1)/m$, so with 4 pipeline stages and 32 microbatches per training step, the bubble wastes roughly 9 percent of compute.

The three-way comparison reveals a clear pattern: configurations that keep high-bandwidth communication (tensor parallelism) within the fast NVLink domain and push only low-bandwidth communication (data-parallel AllReduce of smaller gradient shards) onto the slower InfiniBand fabric achieve the highest efficiency. *The infrastructure hierarchy dictates the parallelism hierarchy.* The resulting principle is called hierarchy-aware parallelism, and it is a common approach for large-scale training systems.

Definition 5.11: Hierarchy-aware parallelism

Hierarchy-Aware Parallelism is the strategy of mapping different parallel execution modes to the physical bandwidth tiers of the cluster.

1. **Significance:** It ensures that high-frequency synchronization (for example, tensor parallelism) stays on the fastest links (NVLink), while lower-frequency tasks (for example, data parallelism) use slower tiers (InfiniBand). This alignment maximizes scaling efficiency (η_{scaling}) by reducing exposed communication time ($T_{\text{comm}}(N)$) and latency (L_{lat}).
2. **Distinction:** Unlike Uniform Parallelism, which treats all node-to-node links as equal, Hierarchy-Aware strategies respect the Bandwidth Cliffs between die, node, and rack boundaries.
3. **Common pitfall:** A frequent misconception is that any model can be sharded across any number of nodes. In reality, if the Hierarchy Mapping is wrong (for example, sharding a large tensor across a slow inter-rack link), the communication time will dwarf the compute time, making the scale-out useless.

The interaction also flows in the reverse direction: the choice of parallelism strategy influences infrastructure design. A training system that uses TP-8, PP-4, DP-32 generates a communication pattern where the most bandwidth-intensive traffic (tensor-parallel AllReduce) is confined to within each node, the moderate-bandwidth traffic (pipeline stage communication) flows between groups of

4 neighboring nodes, and the lowest-bandwidth traffic (data-parallel AllReduce of reduced gradient shards) flows across the full cluster.

The layered communication pattern favors a hierarchical network topology where nearby nodes have higher bandwidth between them (a “locality-aware” topology) over a flat topology where all node pairs have equal bandwidth (a uniform fat-tree). Rail-optimized and hierarchical fat-tree designs exploit this locality, placing the nodes that communicate most frequently on the same switch or in the same rack, minimizing the number of switch hops for the most bandwidth-intensive traffic.

The practical implication for infrastructure procurement is that the network topology must be co-designed with the parallelism strategy, not selected independently. An organization that purchases a flat fat-tree fabric (optimized for any-to-any communication) but trains exclusively with hierarchy-aware parallelism (where most traffic is local) has over-provisioned the network’s global bandwidth while potentially under-provisioning local bandwidth. Conversely, an organization that purchases a rail-optimized fabric (optimized for local communication) but later needs to run Mixture-of-Experts models with AllToAll communication (which requires global bandwidth) will find the fabric inadequate. The network fabric, which represents 10–15 percent of total system cost, must be matched to the anticipated workload mix, and changing the fabric after deployment is prohibitively expensive and disruptive.

5.7.1 The 3D training loop

Training a 175B parameter model requires **3D parallelism**: the coordinated composition of data, pipeline, and tensor parallelism across thousands of devices.⁹ This approach does not merely sum the benefits of individual parallelism strategies; it composes them geometrically to match the physical topology of the hardware.

Consider a training fleet configured with Tensor Parallelism (TP) of 8 GPUs, Pipeline Parallelism (PP) of 16, and Data Parallelism (DP) of 128. This configuration uses 16,384 GPUs (8 GPUs $\times$ 16 $\times$ 128) organized into a hierarchy of bandwidth domains.

The training step begins at the data-parallel level. Each of the 128 model replicas receives a distinct slice of the global batch. Within each replica, the model is split across 16 pipeline stages (nodes), with micro-batches flowing sequentially from the embedding layer on Node 0 to the loss calculation on Node 15. At the finest granularity, within each node, the 8 GPUs fuse into a single “super-accelerator” via TP. Every matrix multiplication in the forward pass is fractured across these devices, which must exchange partial results via high-bandwidth NVLink after every operation. For a 175B-scale hidden dimension, the activation payload is roughly 201.3 MB; the resulting tensor-parallel traffic is about 4.2 GB per pipeline stage per microbatch in the forward pass, or 8.5 GB including the backward pass. Across the full 96-layer replica, the forward tensor-parallel traffic is about 67.6 GB. This traffic is the highest-intensity in the system, but its exposed latency can remain small relative to compute because the chips communicate over 600 GB/s–900 GB/s local bandwidth.

The backward pass inverts this flow and exposes the critical dependencies between parallelism dimensions. As gradients flow backward through the pipeline, nodes exchange activation gradients point-to-point. This traffic is relatively light—roughly 201.3 MB per stage boundary—allowing it to traverse slower inter-node InfiniBand links without stalling the pipeline. The true bottleneck emerges at the end of the step: data-parallel synchronization. The full model’s gradient state is still about 350 GB, but in a 3D-parallel layout each data-parallel group synchronizes the corresponding parameter shards for its tensor- and pipeline-parallel replica rather than every GPU moving the full tensor. Gradient bucketing groups ready layer-gradient tensors into larger messages as backward computation proceeds; when the bucket schedule and cross-sectional bandwidth line up, synchronization runs under useful computation instead of extending the critical path.

The architectural imperative is *bandwidth matching*: the communication volume of each algorithm must map inversely to the latency of the hardware interconnects. Chatty, blocking TP communication stays within the NVLink domain (600 GB/s or higher). Serialized, point-to-point PP transfers traverse the cluster spine at InfiniBand speeds. The massive but infrequent DP synchronization amortizes across the full training step. Attempting to run TP across racks, or DP without gradient accumulation, can violate this hierarchy and leave the 16,000-GPU fleet waiting for data to traverse the wire. This bandwidth-matching principle completes the feasibility check introduced in section 5.1.5.

⁹ | **3D Parallelism**: Named after the three orthogonal axes of decomposition: (1) Data Parallelism (batch), (2) Pipeline Parallelism (depth), and (3) Tensor Parallelism (layer width). Organizations visualize their training fleets as a 3D grid (d, p, t) , where the product $N_{\text{total}} = d \times p \times t$ equals the total GPU count. This geometric perspective is essential for balancing the tiered bandwidth constraints of high-bandwidth clusters.

5.7.2 Hybrid-parallelism worked example

Applying this bandwidth-matching principle to physical infrastructure transforms cluster design into a placement problem: each parallelism dimension must sit on the network tier that can tolerate its traffic. Tensor parallelism is the most latency-sensitive because it launches frequent AllReduce operations inside transformer blocks, so it belongs on the intra-node NVLink domain (600 GB/s–900 GB/s). Pipeline parallelism moves activation tensors only at stage boundaries, so it can span nearby nodes over InfiniBand (50 GB/s–100 GB/s). Data parallelism produces the largest payload, the gradient synchronization, but it occurs once per step and can be overlapped with backward computation. Memory capacity per device (80 GB–80 GB) sets the hard limit for every placement.

For a DGX A100-style deployment, this reasoning leads to a concrete layout. Fix tensor parallelism at $t = 8$ so the bandwidth-heavy matrix-multiplication collectives stay within one 8-GPU node. Map pipeline parallelism across nodes in the same high-bandwidth rack or island, often $p = 8$ or $p = 16$ depending on the memory footprint. Use data parallelism for the remaining scale-out dimension across pods. The result is not a generic rule but a consequence of matching each traffic pattern to the cheapest fabric tier that can carry it.

With the placement fixed, the next question is whether the static model state fits inside each accelerator’s HBM budget.

The memory budget for training a 175B-parameter model is dominated by model states and requires aggressive sharding to fit within the 80 GB HBM capacity of H100-class accelerators. The FP16 weights alone consume approximately 350 GB ($175 \times 10^9 \times 2$ bytes). If we relied solely on Tensor Parallelism with 8-way sharding, each GPU would hold a 43.75 GB slice of the weights. However, the optimizer state presents a larger hurdle. In the simplified optimizer-state convention used for this 3D-parallelism budget, Adam’s FP32 momentum and variance consume 8 bytes per parameter, adding about 1.4 TB globally; the fuller 12-byte accounting that also includes FP32 master weights would be about 2.1 TB. Even with 8-way tensor parallelism, the simplified combined weight and optimizer state would exceed 218.8 GB per GPU, causing an Out-Of-Memory (OOM) error. Consequently, we must employ Pipeline Parallelism (p) to further partition the model layers. With a hybrid configuration of tensor parallelism 8 and pipeline parallelism 16, the simplified static memory footprint drops to 13.7 GB per GPU (often budgeted as roughly 15 GB after framework buffers), leaving the remaining HBM available for the dynamic activation memory (A) generated during the forward pass, which scales linearly with micro-batch size and sequence length. Under the fuller 12-byte Adam convention, the same 8-way tensor, 16-stage pipeline split would be 19.1 GB per GPU.

Once the configuration fits in memory, the same layout has to satisfy the communication hierarchy that motivated it. Each parallelism dimension imposes a distinct traffic profile on the network. Tensor parallelism is the most chatty, requiring two AllReduce operations for every transformer block (one for the Attention projection, one for the MLP) in both the forward and backward passes. These messages are relatively small but occur thousands of times per step, making them strictly latency-bound and necessitating NVLink. Pipeline parallelism, in contrast, involves point-to-point transfers of activation tensors (size $B_\mu \times S \times d_{\text{model}}$) only at the boundaries of the pipeline stages. While these messages are moderate in size, they occur less frequently, making them manageable over standard InfiniBand links. Data parallelism generates the largest burst of traffic, requiring a global AllReduce of the entire 350 GB gradient buffer. However, this communication occurs only once per global batch update. By using gradient bucketing to overlap this transmission with the compute-intensive backward pass, the effective cost of DP communication can often be hidden, provided the cluster maintains sufficient cross-sectional bandwidth.

The last cost is not bandwidth but scheduling: a pipelined model is only efficient when enough micro-batches are in flight to keep all stages busy. This remaining cost is the pipeline bubble developed in section 5.5.2.2. Applying its bubble fraction $\frac{p-1}{m+p-1}$ to this hybrid layout, a GPT-175B configuration with $p = 16$ stages and $m = 32$ micro-batches wastes $\frac{15}{47} \approx 31.9\%$ of theoretical compute capacity, nearly one-third. The 1F1B scheduling that reclaims activation memory, and the larger micro-batch counts it makes practical, drive that fraction down asymptotically.

5.7.3 Blackwell-class scaling example

The Blackwell architecture provides a concrete example of how accelerator packaging changes the 3D parallelism trade-offs. First, NVLink 5 provides 1.8 TB/s of bidirectional bandwidth per

GPU, doubling the intra-node capacity of the Hopper generation. This allows for larger tensor parallelism (t) groups (for example, $t = 16$ or $t = 32$ across multiple nodes) with lower latency overhead. Second, Blackwell adds FP4 Tensor Core support, improving low-precision throughput and memory efficiency for supported workloads; whether FP4 is used for training depends on the numerical recipe and software stack.

For a 1 trillion parameter model, a Blackwell-class configuration can use $t = 16$ (spanning two 8-GPU nodes via NVLink Switch) and $p = 32$, reducing the total number of pipeline stages and associated bubble overhead relative to a 16,384-GPU Hopper-scale fleet reference configuration. The 10 TB/s die-to-die interconnect within the Blackwell GPU further collapses the distinction between intra-chip and intra-package communication, allowing the two reticle-limited dies to function as a single high-bandwidth tensor parallel unit. The general systems lesson is that improving local bandwidth shifts pressure outward: once intra-node communication is less binding, rail-optimized topologies (section 3.5.3) and All-to-All optimization become more important for larger Machine Learning Fleet configurations.

The same placement constraints can be made operational through design-space search.

Example 5.2: Automated design space search (Tier 3 optimizer)

Scenario: An engineering team needs to schedule Archetype A (a 175B parameter model) on a cluster of 8,192 H100 GPUs. Manually searching the 3D-parallelism space ($TP \times PP \times DP$) is error-prone: a split that maximizes DP might exceed the 80 GB HBM capacity, while a split that maximizes TP might saturate the NVLink interconnect.

Approach: Instead of trial and error, we invoke a constrained design-space search over TP, PP, and DP factorizations, implemented here as the Tier 3 Optimizer (`ParallelismOptimizer`) in our physics engine, configured to maximize Model FLOPs Utilization (MFU). The optimizer performs a constrained grid search over all valid algebraic factorizations and, in under a second, selects the best strategy under the stated objective:

- **Tensor parallelism (TP):** 8 GPUs
- **Pipeline parallelism (PP):** 8
- **Data parallelism (DP):** 128

Systems insight: The optimizer formalizes what engineers discover empirically: TP should match the intra-node GPU count (8 GPUs) to avoid traversing the slower inter-node fabric, while the best pipeline depth under this objective is only $PP=8$ once tensor parallelism and sharded state make the memory budget fit. Deeper pipelines would reduce per-stage memory further, but they also increase the pipeline bubble and reduce MFU. This automated synthesis achieves a projected 25.9 MFU, demonstrating that empirical engineering heuristics often reflect structural mathematical laws.

Adjusting any one dimension shifts the pressure onto the other two, making the factorization $TP \times PP \times DP$ a tightly coupled system rather than three independent knobs.

Checkpoint 5.4: Hybrid 3D parallelism

Verify your understanding of how parallelism strategies combine:

- ☐ **Dimension roles:** Identify which dimension in a $TP=8, PP=16, DP=128$ configuration shards layers within a single node.
- ☐ **Bubble vs. depth:** Determine how moving from $PP=16$ to $PP=8$ changes the “Pipeline Bubble” fraction.
- ☐ **DP vs. PP:** Explain the trade-off, under a 1,024-GPU budget, between increasing DP (Data Parallelism) and increasing PP (Pipeline Parallelism).
- ☐ **Latency sensitivity:** Identify which dimension, TP, PP, or DP, is most sensitive to **inter-node latency**.

The MFU values need a historical utilization baseline to show how published systems approached 50 percent utilization. Figure 5.16 traces the evolution of Model FLOPs Utilization across published training systems from 2020 to 2024. The progression from GPT-3’s 21 percent MFU to PaLM’s 46 percent MFU reflects not improvements in raw hardware speed but advances in the parallelism strategies, communication overlap techniques, and scheduling optimizations discussed throughout this chapter. The plateau near 40–46 percent reveals that the theoretical ceiling imposed by communication overhead, pipeline bubbles, and memory management remains formidable even in highly optimized hybrid-parallel systems. Notably, Meta’s Llama 3 training at 16,384 H100 GPUs achieved slightly lower MFU (41 percent) than the same model at 8,192 GPUs (43 percent), confirming that the scaling tax described in section 5.4.2 is not merely theoretical but measurable in large published runs.

Figure 5.16: The MFU Progression: Model FLOPs Utilization across published training systems, ordered chronologically. MFU doubled from 21 percent (GPT-3, 2020) to 46 percent (PaLM, 2022) through advances in hybrid parallelism and communication overlap, then plateaued near 40–45 percent for large-scale runs. The Llama 3 data points illustrate the scaling tax: MFU drops from 43 percent at 8,192 GPUs to 41 percent at 16,384 GPUs as communication overhead grows with cluster size. Data sources: Chowdhery et al. (2022), Dubey et al. (2024).

5.8 Multi-Model Training: RLHF and Alignment

The parallelism strategies examined so far assume a single model being trained on a single objective. Reinforcement Learning from Human Feedback (RLHF) and its variants break this assumption by requiring multiple models to coordinate within a single training loop, each with different memory footprints, compute profiles, and gradient requirements. At a high level, RLHF generates model outputs, scores them with preference-derived reward signals, regularizes updates against a reference model, and then updates the policy; Proximal Policy Optimization (PPO) implements this online loop with separate policy, reference, reward, and value models, while Direct Preference Optimization (DPO)-style methods remove much of that rollout and value-model machinery. This creates a heterogeneous fleet management problem that cannot be solved by any single parallelism strategy and represents a qualitatively different distributed systems challenge from standard pretraining.

5.8.1 The multi-model coordination problem

Standard pretraining involves one model, one loss function, and one gradient stream. RLHF alignment, by contrast, orchestrates a system of models that interact during every training step. In

Proximal Policy Optimization (PPO) (Schulman et al. 2017), as used in InstructGPT-style RLHF systems (Ouyang et al. 2022), four distinct models must operate in concert. Table 5.7 separates those models by role, execution mode, and memory burden.

Table 5.7: RLHF Model Coordination Roles: PPO-style RLHF coordinates models with different execution modes and memory footprints, so placement decisions must separate trainable policy and value state from inference-only reference and reward state.

Model	Role in PPO-style RLHF	Execution mode	Memory burden
Policy model	The model being aligned and optimized.	Training mode with gradients, optimizer moments, and activations.	For a 70B parameter model in mixed precision with Adam, memory is approximately $70B \times (2 + 2 + 12) = 1,120$ GB, the same budget as standard pretraining.
Reference model	A frozen copy of the pretrained policy that supplies the KL-divergence penalty.	Inference mode only.	FP16/BF16 parameters without gradients or optimizer state; a 70B model needs about $70B \times 2 = 140$ GB, roughly $8\times$ less than the training configuration.
Reward model	A preference-trained scorer that produces scalar rewards for generated sequences.	Inference mode only.	Often smaller than the policy; a 13B reward model requires approximately 26 GB in FP16, but it must process every generated sequence.
Value model	The PPO critic that estimates expected future reward.	Training mode, either separate or sharing a policy backbone.	A full-size separate critic can add another 1,120 GB; smaller models or shared-backbone designs reduce this to 200–400 GB.

The aggregate memory demand of the four-model PPO system dwarfs standard pretraining. A naive co-location of a 70B policy, 70B reference, 13B reward, and 13B value model requires approximately 1,494 GB of accelerator memory, before accounting for the KV caches and intermediate activations generated during sequence generation. On H100 GPUs with 80 GB of HBM each, this system requires a minimum of 19 GPUs for parameter storage alone. Once generation-phase KV caches (which grow linearly with output sequence length) and training-phase activations are included, the practical minimum rises to 64–128 GPUs for a single RLHF training instance.

5.8.2 Infrastructure asymmetry: Training vs. inference models

The defining infrastructure challenge of RLHF is not the *total memory footprint* but the *asymmetry* between the models’ compute profiles. The policy and value models require full backward passes with gradient computation, activation checkpointing, and optimizer updates—compute-intensive operations that benefit from tensor parallelism and high arithmetic intensity. The reference and reward models, by contrast, perform only forward passes: they are inference workloads embedded within a training loop, with memory access patterns dominated by KV cache management rather than gradient accumulation.

The asymmetry creates a placement dilemma. Co-locating training and inference models on the same GPUs wastes compute during the generation phase (when the training models sit idle) and wastes memory during the gradient phase (when the inference models’ parameter storage could be reclaimed for activations). Separating them onto dedicated GPU pools eliminates waste but introduces network latency for reward queries—each generated token batch must traverse the interconnect to reach the reward model and return a scalar signal before the policy gradient can be computed.

The generation phase itself introduces a sequential bottleneck absent from standard pretraining. RLHF requires the policy model to generate complete sequences (typically 256–2,048 tokens) autoregressively before computing rewards and policy gradients. Autoregressive generation is memory bandwidth bound, not compute bound: each token requires a full forward pass through the model to produce a single output token. For a Llama-2-70B-style grouped-query attention policy, the KV cache grows by approximately $2 \times N_L \times H_{KV} \times d_{\text{head}} \times 2$ bytes per generated token per sequence. With 80 layers, 8 KV heads, 128-dimensional heads, 1,024 generated tokens, and a batch of 256 prompts, the cache consumes 85.9 GB: $2 \times 80 \times 8 \times 128 \times 1024 \times 256 \times 2$ bytes. A dense multi-head attention model using the full 8,192-wide hidden state for K and V would yield 687.2 GB. Even with

GQA, the cache uses about one H100 GPU's worth of HBM for intermediate attention state that is discarded after reward computation.

RLHF systems address this asymmetry through temporal multiplexing. During the generation phase, the cluster behaves like an inference system: the policy model generates sequences while the reference model computes log-probabilities, and the dominant resource is HBM reserved for token-by-token attention state. During the training phase, the same fleet switches back to training mode: gradients are computed through the policy and value models using the 3D parallelism configuration developed earlier in the chapter. Serving systems handle that phase with request batching and KV-cache placement; here, the important point is the mode switch. RLHF is not one steady training loop, but an alternation between inference-shaped work and training-shaped work, and standard training frameworks rarely manage that transition by themselves.

5.8.3 DPO: Simplifying the fleet

Direct Preference Optimization (DPO) (Rafailov et al. 2023) eliminates the reward model and value model entirely by reformulating the alignment objective as a classification loss over preference pairs. Instead of generating sequences, computing rewards, and estimating advantages, DPO directly optimizes the policy to assign higher log-probability to preferred responses over dispreferred ones, using the reference model only to compute a KL-divergence regularization term.

The infrastructure implications are substantial. DPO reduces the multi-model system from four models to two: the policy model (training mode) and the reference model (inference mode). For the 70B policy with 13B reward and value models quantified below, static parameter memory drops from about 1,494 GB to 1,260 GB, a 16 percent reduction. If the PPO value model is policy-sized, the reduction is much larger: about 2,406 GB to 1,260 GB, or roughly 48 percent. DPO also eliminates the autoregressive generation phase entirely. Training operates on a fixed dataset of (prompt, preferred response, dispreferred response) triples, restoring the standard pretraining data pipeline: fixed-length sequences, deterministic batching, and no sequential token-by-token generation. The training loop becomes a standard supervised learning step with a modified loss function, amenable to the same 3D parallelism, gradient accumulation, and communication overlap techniques used for pretraining.

The trade-off is capability. DPO operates on a static preference dataset, meaning the policy cannot explore new responses and receive feedback during training. PPO's online generation allows the policy to improve iteratively on its own outputs, potentially discovering better strategies that the static dataset does not contain. For deployment scenarios where the preference data comprehensively covers the target distribution, DPO's infrastructure simplification dominates. For scenarios requiring adaptive exploration (training models to solve novel reasoning tasks, for example), PPO's online feedback loop may justify the $2\times$ infrastructure overhead.

5.8.4 Quantitative analysis: PPO vs. DPO resource requirements

To make the infrastructure trade-off concrete, consider aligning a 70B policy model on a cluster of 256 H100 GPUs (80 GB HBM each).

Napkin Math 5.9: RLHF infrastructure budget: PPO vs. DPO

Problem: Aligning a 70B policy model requires co-locating it with a 70B reference model and, for PPO, a 13B reward model and a 13B value model. Under 3D parallelism (TP=8 GPUs, PP=4, DP=8), how much per-GPU memory does each approach consume, and how much headroom does DPO free by eliminating the reward model, value model, and generation-phase KV cache?

PPO memory budget (per-GPU, with TP=8 GPUs, PP=4, DP=8 for policy)

The policy model under 3D parallelism with TP=8 GPUs and PP=4 distributes its 1,120 GB training state across 32 GPUs, yielding 35 GB per GPU. The reference model, requiring only 140 GB for inference, can be sharded across a separate pool of 8 GPUs at 17.5 GB each, or co-located with the policy GPUs at an additional 4.4 GB per GPU (140 GB / 32 GPUs). The 13B reward model adds 26 GB shared across its pool. The 13B value model in training mode adds approximately 208 GB ($13\text{B} \times 16 \text{ bytes/param}$) across its pool.

Total static memory (co-located policy + reference on 32 GPUs): 35 GB + 4.4 GB $\approx$ 39.4 GB per GPU, leaving $\sim$ 40.6 GB for activations and KV cache. With generation-phase KV caches for a rollout batch containing 256 sequences and 1,024 tokens inside one $TP \times PP$ policy replica, each policy GPU must reserve an additional 85.9 GB/32 GPUs $\approx$ 2.7 GB for its KV cache shard. The remaining $\sim$ 37.9 GB constrains the micro-batch size during the training phase.

DPO Memory Budget (same parallelism configuration)

The policy model uses the same 35 GB per GPU. The reference model adds 4.4 GB per GPU (co-located). No reward model, no value model, no KV cache for generation.

On the policy GPUs, total static memory is 35 GB + 4.4 GB = 39.4 GB per GPU, identical to PPO's co-located policy/reference footprint. Cluster-wide, however, DPO avoids the PPO reward and value model memory, and it also removes the generation-phase KV cache burden. The full $\sim$ 40.6 GB remaining on each policy GPU is available for training activations, permitting modestly larger micro-batches (about 1.07 $\times$ under this co-located policy/reference memory budget) or reducing the need for activation checkpointing that PPO requires.

Throughput Comparison

PPO's two-phase design (generate then train) introduces a fundamental throughput penalty. If generation consumes 60 percent of the step time (typical for autoregressive decoding of long sequences), the training hardware achieves only 40 percent utilization during an RLHF step. DPO, operating as a standard training loop, achieves the same 40 percent–55 percent MFU as pretraining. Table 5.8 compares the two regimes side by side.

Table 5.8: PPO vs. DPO Memory and MFU: Per-GPU memory and effective training MFU for PPO and DPO on the same accelerator budget.

Metric	PPO (70B policy)	DPO (70B policy)
Models required	4 (policy, ref, reward, value)	2 (policy, reference)
Total parameter memory	$\sim$ 1,494 GB	$\sim$ 1,260 GB
Minimum GPUs (memory)	64–128 GPUs	32–64 GPUs
Generation phase	Yes (sequential, BW-bound)	None
Effective training MFU	15–25%	40–55%
Data pipeline	Online generation	Static preference pairs

Systems insight: In this 13B reward/value-model scenario, DPO reduces static parameter memory by 15.7 percent and doubles the effective compute utilization by eliminating the reward model, value model, and autoregressive generation phase. The choice between PPO and DPO is not only a modeling preference but an infrastructure constraint: organizations with limited GPU budgets may prefer DPO because it restores the workload to a fixed-data training loop. If the PPO value model is policy-sized rather than 13B, the memory reduction approaches the larger 2,406 GB to 1,260 GB comparison discussed earlier.

5.8.5 Sequence length variance and batching challenges

Both PPO and DPO face a data engineering challenge absent from standard pretraining: extreme variance in sequence length. Pretraining typically uses fixed-length sequences (2,048 or 4,096 tokens, padded or packed to fill each position), enabling uniform batch shapes and predictable memory consumption. RLHF training data consists of variable-length prompts (10–500 tokens) concatenated with variable-length completions (50–2,048 tokens), producing sequence lengths with 10–50 $\times$ variance within a single batch.

Length variance creates two interacting problems. Fixed-size batching pads all sequences to the maximum length in the batch, wasting compute on padding tokens. A batch containing one 2,048-token sequence and fifteen 128-token sequences wastes 88 percent of the compute on padding.

Dynamic batching groups sequences by similar length to minimize padding, but introduces load imbalance across data-parallel workers: one worker may receive a batch of long sequences consuming 60 GB of activation memory while another processes short sequences using only 8 GB, causing the short-sequence worker to stall at the synchronization barrier while the long-sequence worker completes.

RLHF systems mitigate this through a combination of sequence packing (concatenating multiple short sequences into a single fixed-length input with attention masking to prevent cross-contamination) and adaptive micro-batching (dynamically adjusting the number of sequences per micro-batch based on the aggregate token count rather than the sequence count). These techniques can recover much of the compute lost to padding variance but add complexity to the data pipeline that standard pretraining frameworks do not provide. The interaction between variable-length data and distributed synchronization remains an active area of systems engineering research, because every worker must process the same number of tokens per step to maintain gradient consistency.

RLHF is therefore not a detour from parallelism strategy; it is the case that shows why no strategy is sufficient by itself. The policy model may need tensor and pipeline parallelism, the reference and reward models behave like inference services, the value model may require training state, and the rollout data pipeline changes shape from step to step. With that stress test in view, the final comparison can return to the general engineering question: identify the binding constraint first, then choose the parallelism pattern that moves the least data while fitting the required state.

5.9 Parallelism Strategy Comparison

A parallelism strategy is useful only if it moves the binding constraint without creating a larger one. The feasibility filter previewed by the decision tree in section 5.1.5 named those constraints; now that tensor, pipeline, and hybrid parallelism have been developed, the same filter can be stated as engineering signals rather than a generic ranking. For a new 50-billion parameter model, the decisive questions are which memory state fits, how often communication occurs, where the pipeline bubble appears, and which abstraction cost the engineering team can tolerate. Table 5.9 turns those questions into engineering signals.

Table 5.9: Parallel Training Strategies: Parallelism strategy selection is an engineering feasibility test: identify the binding constraint, the communication primitive it creates, the placement decision it forces, and the measurement that proves the strategy is helping.

Strategy	Binding constraint	Primary movement	Placement decision	Validation signal
DDP	Model state fits on one accelerator	AllReduce gradients every step	Replicate full model across data-parallel workers	Step time dominated by compute, not synchronization
FSDP/ZeRO	Model state exceeds one accelerator	Shard and gather parameters or optimizer state	Place shards to minimize gather and reduce-scatter cost	Peak memory remains below device budget
Tensor parallelism	One layer or tensor operation exceeds local capacity	AllReduce or AllGather within layer blocks	Keep tightly coupled partitions on fast intra-node links	Layer latency stays below activation handoff cost
Pipeline parallelism	Layer stack fits only when split by stage	Activations and gradients between stages	Balance stages so bubbles are smaller than useful work	Bubble fraction falls as microbatch count increases
Hybrid parallelism	More than one constraint binds at once	Multiple collectives on different axes	Align data, tensor, pipeline, and shard groups to topology	MFU improves without exceeding memory or network budget

Figure 5.17 converts the same filter into a decision tree. It begins with memory fit because capacity failure is nonnegotiable, then asks whether data scale alone justifies replication. The tree is intentionally simplified; hardware heterogeneity, communication bandwidth, and workload imbalance enter as second-order checks after the binding constraint has been identified.

The table and flowchart are intentionally coarse, but their purpose is precise: identify the binding constraint before choosing the implementation stack.

Figure 5.17: Parallelism Strategy Decision Tree: A systematic selection guide based on two key questions: Does the model state fit in single-device memory, and does the required data throughput justify multiple replicas? Models exceeding device memory require model parallelism or sharding; workloads whose model fits but whose throughput target exceeds one device benefit from data parallelism; significant constraints in both dimensions demand hybrid approaches. While simplified, this framework captures the primary decision points before practitioners must consider secondary factors like hardware heterogeneity and workload imbalance.

5.10 From Principles to Systems

Choosing DDP, FSDP/ZERO-style sharding, tensor parallelism, or pipeline parallelism is a decision about which constraints the runtime owns and which constraints the engineer must manage directly. The parallelism strategies examined throughout this chapter (gradient averaging, AllReduce synchronization, tensor splitting, pipeline scheduling) translate into deployed training systems through this layered abstraction hierarchy.

At the data-parallel layer, the simplest distributed training abstraction wraps a model so that the framework automatically replicates it across available accelerators, splits each batch, and averages gradients after the backward pass. Historically, parameter-server systems organized this work with server nodes that store shared parameters while workers push and pull updates (Li et al. 2014). As section 5.5.3 established, that design concentrates gradient bandwidth at the server tier, so dense synchronous training favors the decentralized collectives below.

Large-scale data parallelism eliminates this bottleneck by replacing the central server with decentralized AllReduce. Each worker participates symmetrically in the reduction: every device both sends and receives gradient chunks at its own link rate, distributing the bandwidth load across all nodes rather than concentrating it. The framework initializes a process group that maps workers to the physical topology, selects an appropriate collective algorithm (ring, tree, or hierarchical) based on the detected interconnect, and inserts gradient synchronization hooks into the backward pass automatically. Gradient bucketing further improves efficiency by grouping small tensors into larger messages before transmission, and computation-communication overlap allows the AllReduce for early layers to proceed while later layers are still computing gradients. These optimizations can reach high parallel efficiency at moderate scale—not because the API is simple, but because the underlying runtime makes topology-aware decisions that a manual implementation would otherwise need to reproduce.

Model and pipeline parallelism require a fundamentally different abstraction because the framework must manage cross-device tensor placement and the sequential data flow between partitions. The core principle is explicit device assignment: the engineer specifies which layers reside on which devices, and the framework handles the activation transfers between devices during the forward pass and the gradient flow in reverse during backpropagation. Explicit device assignment makes the sequential dependencies of model parallelism visible, since each downstream device must wait for its upstream neighbor to complete. The engineer must reason about pipeline bubbles and load balance at the architecture level rather than hiding them behind an opaque wrapper.

For large-scale model parallelism, the key architectural insight is that tensor splitting and pipeline scheduling require different levels of framework support. Tensor parallelism replaces standard linear layers with column-parallel and row-parallel variants that automatically insert AllReduce operations at the correct points in the transformer computation graph, as described in section 5.5.2.3. Pipeline parallelism adds microbatch scheduling logic that interleaves forward and backward passes across stages to minimize bubble overhead. Memory-efficient sharding integrates ZeRO-3 style parameter partitioning by wrapping model layers with automatic AllGather operations before each forward pass and ReduceScatter after each backward pass. The critical design decision is which abstraction levels to compose: pure data parallelism suffices when the model fits in memory, memory-efficient sharding extends data parallelism to memory-constrained regimes, and full tensor or pipeline parallelism becomes necessary when individual layers or the full model depth exceed single-device capacity.

Across these abstraction layers, distributed training ultimately reduces to a small set of collective communication primitives. Rather than exploring the network mechanics of how these primitives physically route data across the cluster, which is extensively covered in Chapter 6, framework abstractions focus on *when* and *why* these primitives are invoked.

The primitives compose into the communication patterns that define each parallelism strategy. Data parallelism uses one AllReduce per training step. Full-shard FSDP with resharding uses about $3N_L$ collectives per step (two AllGathers and one ReduceScatter for each of N_L layers). Tensor parallelism uses 2 AllReduce operations per transformer block on the critical path. The choice of primitive, its message size, and its frequency relative to computation determine whether the system operates in the compute-bound or communication-bound regime. *No framework abstraction changes the underlying physics*: the efficiency of distributed training ultimately depends on physical interconnect bandwidth, memory capacity, and synchronization latency.

5.11 Fallacies and Pitfalls

Many engineering teams who scale cluster capacity by $4\times$ find that their training iterations take longer to complete, reflecting a fundamental misunderstanding of distributed training physics. The following misconceptions capture errors that waste compute resources and delay research.

Fallacy: *Linear speedup is achievable with sufficient engineering effort.*

Amdahl's Law establishes hard limits: any sequential component bounds maximum speedup regardless of parallelism. In distributed training, gradient synchronization is inherently sequential since all gradients must be collected before any update proceeds. As section 5.4 demonstrates, the scaling efficiency equation $\eta_{\text{scaling}} = 1/(1 + N(T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}})/T_{\text{compute}})$ reveals how communication and synchronization overhead dominate as N increases. Even with perfect overlap and ideal algorithms, communication overhead grows with cluster size. For data parallelism, AllReduce time increases logarithmically with tree algorithms or linearly in the latency term with ring algorithms as GPU count grows. A 1000-GPU cluster will never train $1000\times$ faster than a single GPU; achieving $500\times$ speedup would be exceptional, and $100\text{--}200\times$ is more typical for communication-heavy workloads. Organizations that budget projects assuming linear scaling inevitably miss deadlines and overspend on compute.

Pitfall: *Optimizing MFU without considering scaling efficiency.*

A team achieves 50 percent MFU on a single node, scales to 1,024 GPUs, and expects 512 GPU-equivalents of useful work. Scaling efficiency at 1,024 GPUs can be near 50 percent for communication-heavy workloads, so actual useful throughput is roughly $0.50 \times 0.50 = 0.25$ of peak, or 256 GPU-equivalents: half the expected value. MFU and scaling efficiency are independent multiplicative factors. Optimizing one without measuring the other produces capacity estimates

that are off by $2\times$ or more. Capacity planning at fleet scale requires reporting both metrics together and tracking their product as “useful goodput.”

Fallacy: *Hyperparameters tuned on small clusters transfer directly to large-scale training.*

Engineers tune hyperparameters on 8-GPU workstations then deploy to 256-GPU clusters expecting identical behavior. At scale, convergence patterns change fundamentally. The most critical hyperparameter is learning rate: as section 5.3 explains, batch size increases proportionally with GPU count in data parallelism, requiring learning rate adjustments. The “linear scaling rule”¹⁰ (Goyal et al. 2017) suggests $\eta_{\text{large}} = \eta_{\text{base}} \times (B_{\text{large}}/B_{\text{base}})$, but this relationship holds only within bounds. As models scale, they eventually encounter the critical batch size¹¹, where adding more data per step yields diminishing returns in convergence.

Beyond the critical batch size, this relationship breaks down in a model-, data-, and optimizer-dependent way. A team that takes a small-cluster learning rate, multiplies it mechanically with GPU count, and jumps directly to a much larger global batch may see lower final quality or slower sample efficiency even though hardware throughput improved. Warmup schedules, weight decay adjustment, layer-wise optimizers such as LARS/LAMB, and careful momentum tuning can recover accuracy in some regimes, but require systematic experimentation at target scale. Organizations that skip these scaling studies waste thousands of GPU-hours on suboptimal runs.

Pitfall: *Adding GPUs to data-parallel jobs without modeling communication.*

Engineers assume more GPUs always accelerate training. At scale, statistical efficiency limits overwhelm hardware gains. As section 5.3 establishes, data parallelism increases effective batch size proportionally with GPU count ($B_{\text{total}} = N \times B_{\text{local}}$), but gradient quality grows sublinearly beyond model-specific thresholds. A 100K-sample batch may provide only $2\times$ the gradient information of a 10K-sample batch, not $10\times$, because samples become redundant within the loss landscape. The critical batch size defines where marginal returns collapse: the chapter’s earlier examples put ResNet-50 around 8K–16K and BERT-Large around 32K–65K, with exact thresholds depending on optimizer, schedule, and target quality. Beyond this threshold, doubling GPU count doubles cost but provides minimal convergence acceleration. In a representative cost model, a 1024-GPU run that converges in 18 hours at \$45,000 compute cost may be worse than a 512-GPU run that converges in 19 hours at \$22,000, demonstrating how exceeding critical batch size wastes resources without meaningful time savings.

Fallacy: *Memory capacity alone determines the parallelism strategy.*

Engineers see that a 70B model exceeds 80 GB memory and immediately choose tensor parallelism or pipeline parallelism to split weights. In a deployed run, the effective strategy depends on the interaction between memory pressure, computation patterns, and communication topology. As section 5.9 explains, tensor parallelism splits each layer across devices with AllReduce synchronization per layer, achieving even memory distribution but placing communication on the critical path. Pipeline parallelism assigns complete layers to stages with point-to-point transfers between stages, reducing per-step communication but introducing pipeline bubble overhead that wastes 10–30 percent of cycles. For a 175B model on 64 A100 GPUs where tensor parallelism degree-8 enables training, pipeline parallelism with 8 stages achieves 23 percent higher throughput due to reduced all-to-all communication despite similar memory footprints. The decision requires profiling communication patterns and bubble overhead, not just checking if weights fit in memory.

Pitfall: *Applying FSDP or ZeRO without measuring efficiency trade-offs.*

Engineers adopt FSDP universally after reading that it “reduces memory and enables larger models”. In a deployed run, sharding introduces 10–25 percent communication overhead that only pays off when memory pressure justifies it. FSDP reduces memory footprint by sharding optimizer state, gradients, and optionally parameters across GPUs, but requires AllGather operations before each forward pass and ReduceScatter after backward pass. For a 7B model on A100-80 GB with batch size 4, standard DDP achieves 145 samples/second while FSDP achieves only 118 samples/second (19 percent slower) because the model fits comfortably without sharding and the added communication overhead provides no benefit. FSDP provides value when model plus optimizer state exceeds single-GPU memory, when enabling larger per-GPU batch sizes justifies the overhead, or when ZeRO-Offload to CPU memory extends capacity. A 65B model that cannot fit on 80 GB becomes trainable with FSDP ZeRO-3, accepting 15 percent throughput loss to enable training at all. Applying FSDP universally without measuring memory pressure wastes performance.

¹⁰ | **Linear Scaling Rule:** Established by Goyal et al. (2017) at Facebook AI Research, who trained ResNet-50 on ImageNet in one hour across 256 GPUs with a batch size of 8,192 while matching small-batch accuracy. The rule – multiply learning rate by k when batch size increases by k – works only while the large-batch approximation remains valid. Above the workload’s measured critical-batch-size regime, gradient noise drops below the useful signal scale and additional parallelism yields diminishing convergence returns (McCandlish et al. 2018; Shallue et al. 2019).

¹¹ | **Critical Batch Size:** The gradient-noise-scale view introduced by McCandlish et al. treats the largest useful batch size as a measurable statistic that varies by domain, model, optimizer, and training phase (McCandlish et al. 2018). Scaling beyond that measured point improves hardware throughput but does not proportionally reduce the number of optimization steps needed to reach target quality, collapsing the scaling efficiency (η_{scaling}).

Fallacy: *Parallelism overhead is roughly constant regardless of model size.*

Engineers benchmark parallelism strategies on convenient small models then apply conclusions to large-scale training. At scale, the ratio between computation and communication time changes dramatically with model size, inverting strategic decisions. AllReduce communication time depends primarily on gradient tensor size and network bandwidth, growing roughly linearly with parameter count, while forward and backward pass computation time grows superlinearly due to larger matrix operations. For a 1B parameter model where forward/backward pass takes 50 ms and AllReduce takes 25 ms, communication overhead consumes 33 percent of step time. For a 70B parameter model where forward/backward takes 2400 ms and AllReduce takes 180 ms, communication overhead drops to 7 percent despite the gradient size being $70\times$ larger. Decisions made on small models (“pipeline parallelism’s 15 percent bubble overhead makes it always slower than data parallelism”) can invert at scale where data parallelism’s communication overhead reaches 25–40 percent. Reliable strategy selection requires either profiling at target scale or analytical models that account for how computation scales as $\mathcal{O}(n^2)$ to $\mathcal{O}(n^3)$ while communication scales as $\mathcal{O}(n)$.

Pitfall: *Treating scaling efficiency as a property of the hardware alone.*

Vendor benchmarks publish “85 percent scaling efficiency at 1,024 GPUs” and procurement teams plan capacity as if that number is a cluster constant. Scaling efficiency is a joint property of four things: the workload’s communication-to-computation ratio, the parallelism strategy (data, pipeline, tensor, hybrid), the network topology (fat-tree vs. torus vs. dragonfly), and the software stack (NCCL version, kernel fusion, overlap quality). Reference numbers from large-language-model training benchmarks may overstate scaling for graph neural networks with irregular communication, and they may understate scaling for embedding-heavy recommendation models with mostly local computation. Capacity planning should use measured scaling on the target workload, not a vendor hero benchmark.

Fallacy: *Gradient accumulation is free.*

Engineers use gradient accumulation to simulate larger batch sizes, reducing synchronization frequency from every step to every K steps. The technique appears cost-free since it eliminates $(K-1)/K$ of synchronization events. In a real training loop, accumulation introduces update latency, memory-residency, and numerical precision risks. Standard implementations accumulate into one resident gradient buffer rather than allocating a separate full gradient tensor per microstep; for a 7B model, that FP16 gradient buffer is still 14 GB and must remain live throughout the accumulation window. If the implementation retains computation graphs, overlaps multiple outstanding microbatches, or increases local microbatch size, activation memory can grow further and exhaust HBM. Effective optimizer-step latency increases proportionally with accumulation steps, so accumulating 8 steps means optimizer updates occur $8\times$ less frequently, potentially slowing convergence despite higher throughput. Most critically, accumulated FP16 gradients risk overflow when summing hundreds of gradient tensors, particularly in early training when loss values are large. A team training a transformer model with 16-step gradient accumulation in FP16 experienced loss spikes and divergence at step 1200; switching to 4-step accumulation with more frequent synchronization resolved the instability despite higher communication costs. Gradient accumulation trades communication frequency for update latency, memory residency, and numerical stability.

Pitfall: *Using fixed checkpoint intervals regardless of system characteristics.*

Engineers checkpoint distributed training “every hour” or “every 1000 steps” based on intuition rather than analysis. Chapter 7 derives the Young-Daly checkpoint law (principle 12); the training lesson here is that checkpoint cadence is not a constant. It depends on the mathematical relationship between checkpoint write cost and failure rate.

The formula sets the optimal checkpoint interval to $\tau_{\text{opt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$, where T_{write} is checkpoint write time and $\text{MTBF}_{\text{system}}$ is mean time between system failures. For a 1024-GPU cluster at the canonical 50,000-hour per-GPU MTBF, the cluster-level $\text{MTBF}_{\text{system}}$ is 48.8 hours ($\text{MTBF}_{\text{GPU}}/N$). With a 5-minute checkpoint time, the optimal interval is approximately 171.2 minutes (~ 2.9 hours), with an unavoidable checkpoint-plus-rework tax of 5.8 percent. Checkpointing every 15 minutes “to be safe” raises the total tax to 33.6 percent, while checkpointing every 8 hours risks losing significant work on failure. For larger models where checkpoint time increases to 15 minutes due to model size and storage bandwidth, the optimal interval shifts again. The cost of guessing scales with the

cluster: a 1024-GPU run loses approximately \$13,638 per day to excessive checkpointing when it uses a 15-minute interval instead of the Young-Daly optimum.

5.12 Summary

This chapter introduced the “scaling wall”: the point where adding more GPUs eventually makes training slower rather than faster. Distributed training is not a simple hardware problem; it is a constraint satisfaction problem governed by the interaction between model size, batch size, and interconnect bandwidth.

The 3D Parallelism Cube (figure 5.18) is a useful framework for scaling large models. Data parallelism unrolls the outer loop of training to scale throughput; tensor parallelism vectorizes the inner loops of matrix multiplication to fit memory; and pipeline parallelism stages sequential layers to reduce communication frequency. Together, these strategies map models larger than any single memory bank onto a fleet of accelerators with finite bandwidth.

Figure 5.18: 3D Parallelism Strategy Space: Concrete 8-GPU configuration filling out a 3D-parallel coordinate grid. Each GPU is placed at a (d, p, t) coordinate combining Data Parallelism (d — replicate models across workers), Pipeline Parallelism (p — partition layers vertically across stages), and Tensor Parallelism (t — split individual operations horizontally within a layer). A single training step coordinates $d \times p \times t$ GPUs, with tensor-parallel communication within layers, pipeline communication at microbatch stage boundaries, and data-parallel synchronization once per optimizer step.

Ultimately, the choice of parallelism is a loop transformation applied by the cluster-level compiler. By matching logical communication patterns to physical hardware hierarchies, the system moves from the “linear scaling regime” of small clusters to the “communication-bound” reality of very large accelerator fleets.

Throughout this chapter, the partitioning strategies were developed directly for dense large-model training and recommendation-style workloads. Table 5.10 also shows how the same constraint logic reaches the federated edge case, where the bottleneck shifts from accelerator memory and fabric bandwidth to unreliable devices, privacy, and intermittent connectivity.

Lighthouse 5.3: Distributed archetype spectrum

The operating point in the 3D Parallelism Cube shifts depending on the system’s primary bottleneck:

Table 5.10: Partitioning strategy by archetype: The operating point in the 3D-parallelism cube shifts with the dominant bottleneck.

Archetype	Primary Partitioning Strategy	The Logic
Archetype A (GPT-4/Llama-3)	Hybrid 3D Parallelism	Combine Tensor (width), Pipeline (depth), and Data (throughput) to fit 3.5 TB of weights.
Archetype B (DLRM at Scale)	Embedding Sharding	Partition massive 10 TB+ tables across a Parameter Server fleet; use sparse AllToAll updates.
Archetype C (Federated MobileNet)	Federated Learning	The same logic extends to coordinating on-device MobileNet updates across unreliable, privacy-constrained edge devices; Chapter 11 develops this regime.

The parallelism strategies explored throughout this chapter (data, tensor, pipeline, and expert) provide the conceptual toolkit for partitioning any training workload across a cluster. The key insight is that these strategies are not mutually exclusive alternatives but complementary dimensions of a unified optimization space. Systems such as Megatron-LM achieve efficient scaling precisely because they combine multiple strategies, using tensor parallelism within nodes, pipeline parallelism across node groups, data parallelism for throughput, and expert parallelism for capacity scaling.

Key Takeaways: Parallelism relocates the tax

- **Splitting work moves the bottleneck:** Distributed training does not make the underlying computation smaller; it converts memory pressure into communication volume, synchronization delay, or idle pipeline time. The winning strategy is the split that sends overhead to the least binding part of the fleet.
- **Data parallelism ends at convergence:** Replicas scale throughput cleanly only while larger global batches still improve optimization. Past the critical batch size, AllReduce cost and reduced gradient noise turn “more workers” into slower or less stable learning unless schedules, warmup, and accumulation change.
- **Sharding buys memory with messages:** ZeRO and FSDP make 100B+ parameter models feasible by partitioning optimizer state, gradients, and parameters. The price is a stricter communication schedule of ReduceScatter and AllGather operations that must be overlapped or hidden.
- **Tensor parallelism belongs near NVLink:** Tensor parallelism splits matrix operations inside layers, so it needs the high-bandwidth intra-node fabric that A100 and H100 NVLink provide. Stretching that traffic across racks turns a memory-capacity solution into a communication bottleneck.
- **Pipeline parallelism trades bytes for bubbles:** Layer staging reduces communication frequency, but fill and drain slots leave accelerators idle. Microbatching with $m \gg p$ is the mechanism that turns model depth into throughput rather than pipeline slack.
- **The 3D cube is a hardware map:** Real frontier training combines data, tensor, pipeline, expert, and sharded parallelism because no single axis fits the model and the fleet. Logical groups must map to HBM, NVLink, InfiniBand, and failure domains together.

Beneath the cube and its three axes lies a single trade. No way of splitting a model makes the underlying work smaller; each only moves it, turning a memory limit into a communication cost or a communication cost into idle time. Data, tensor, and pipeline parallelism spend communication to win the memory headroom no single accelerator has, and coordination is the tax paid to keep the split consistent. This is displacement of overhead, the law the rest of the volume turns on: the execution tax of scale cannot be removed, only relocated among compute, communication, and

coordination. The cube is the map of where the tax can be sent; the engineering is choosing the destination that binds least.

What's Next: From logic to traffic

We have defined the *logical* traffic patterns of the Machine Learning Fleet, the *how* of splitting the math. These logical patterns, however, eventually hit the *physical* wires of the data center. In Chapter 6, we open the black box of the collective operations (AllReduce, AllToAll) that make this consistency possible. We move from the logic of *what* to send to the mechanics of *how* to route it through rings, trees, and rails.

Research Questions: For further inquiry

- How should an engineer choose among data, tensor, pipeline, expert, and sharded parallelism when adding accelerators begins to reduce scaling efficiency?
- When does increasing global batch size stop improving time-to-quality, even if more hardware is available?
- How should logical parallel groups map onto HBM, NVLink, InfiniBand, storage, and failure domains?
- How much extra communication should a memory-sharding design accept before it stops improving time-to-train?

Purpose

Why does communication between machines become the fundamental constraint that governs large-scale machine learning systems?

Computation scales by adding processors; communication scales by moving data between them. These scale differently: adding a processor increases aggregate compute linearly, but coordinating that processor with all others moves more total data and, for the most general synchronization patterns, multiplies the logical connections among workers quadratically. At sufficient scale, the time spent exchanging gradients, activations, and parameters exceeds the time spent computing them. This crossover point is not a bug to be fixed but a fundamental property of distributed systems that determines which parallelization strategies work, which model sizes are trainable, and which organizations can operate at the largest scales. The physics of light-speed delays, bandwidth limits, and energy costs of data movement constrains communication as firmly as transistor physics constrains computation, yet communication is far less intuitive to reason about, making it the hidden bottleneck that undermines systems designed by those who understand only the compute side. In C³ terms, collective communication forms the instruction set of the fleet: the physical operations that govern how compute is penalized by communication.

Learning Objectives

- Apply communication cost models to bound collective latency, bandwidth, and message-size crossover points
- Match collective communication primitives to parallelism strategies and model archetypes
- Compare ring, tree, butterfly, double-tree, and hierarchical reduction algorithms using scale-dependent cost models
- Analyze communication-library reality gaps by comparing theoretical costs with measured latency, bandwidth, and topology mapping
- Design topology-aware collective schedules for NVLink, InfiniBand, rail-optimized, torus, and in-network reduction fabrics
- Evaluate compression, sparsification, and error feedback by balancing communication savings against convergence risk
- Implement overlap strategies with bucket fusion, asynchronous operations, and layer-by-layer gradient scheduling

6.1 From Parallelism to Communication Patterns

WHEN 10,000 GPUs need to apply one weight update, the splits created by data, tensor, pipeline, and expert parallelism have to be made consistent again. The workers are not sending arbitrary messages; they are executing choreographed collective operations. In the fleet stack shown in figure 1.13, those operations sit in the Distribution Layer, where logical parallelism becomes physical traffic.

The 3D Parallelism Cube assumes that replicas, shards, stages, and experts can exchange gradients, activations, parameters, and tokens quickly enough for the optimizer to see one coherent training run. That assumption is the handoff from parallelism to communication: every way of splitting the model relocates work onto the network.

The gap between that assumption and the wire reveals a fundamental asymmetry in *how* computation and communication scale. Computation is local: each GPU works on its own data, so aggregate compute grows with the number of GPUs. Communication is global: keeping the fleet synchronized requires information to cross physical links with finite latency, bandwidth, topology, and energy. The central case is gradient synchronization; from there the mechanics become concrete through alpha-beta cost models, collective primitives, AllReduce schedules, topology-aware routing, compression, and overlap.

Definition 6.1: Gradient synchronization

Gradient Synchronization is the collective communication step in synchronous data-parallel training in which every worker contributes its locally computed gradient tensor to an aggregate reduction, then receives the same reduced result so all model replicas apply an identical update.

1. **Significance:** A 70B-parameter model in BF16 generates 140 GB of gradient data per worker per step. Synchronizing across 1,000 GPUs via ring AllReduce at 50 GB/s per link requires approximately $2 \times 140/50 \approx 5.6$ s of communication per step, making the bandwidth (data-movement) term large enough to dominate the iron law unless overlap, hierarchy, or compression reduces the exposed transfer.
2. **Distinction:** Unlike parameter-server approaches (where all workers send gradients to a centralized aggregator whose bandwidth scales as $\mathcal{O}(N)$), ring AllReduce distributes the communication across all workers so that each worker's per-step communication cost stays constant at $2 \times (N - 1)/N \times M$ regardless of cluster size.
3. **Common pitfall:** A frequent misconception is that ring AllReduce behaves like an all-to-all exchange. In ring AllReduce, each worker communicates with neighbors according to a schedule, and the per-node communication volume is approximately constant as the

cluster grows. The scaling pressure comes from latency steps, topology, and the gradient volume per step, not from every worker opening a distinct stream to every other worker.

For standard synchronous data-parallel SGD, gradient synchronization is not a design convenience; it is the mechanism that preserves one shared optimization trajectory. If different GPUs apply different gradient updates to their local copies of the model, the copies diverge. After enough steps, the models on different GPUs represent entirely different functions, and the training process no longer approximates stochastic gradient descent on the global loss. Synchronization ensures that all copies remain identical (within floating-point precision) at every step, preserving the theoretical convergence guarantees of the optimization algorithm via the AllReduce¹ primitive.²

The volume of data that must be synchronized is proportional to the model size. A model with P parameters stored in BF16 (2 bytes per parameter) generates $2P$ bytes of gradient data per training step per GPU. For a 70 billion parameter model, this is 140 GB of gradients that every GPU must send and receive.³

At large scale (hundreds of billions of parameters across thousands of GPUs), gradient synchronization can dominate training step time unless aggressive optimization techniques are applied. The next step is to model that data movement as physics rather than as an API call.

6.1.1 The physics of data movement

Before designing algorithms, we must understand the physical constraints governing data movement. Section 3.3 establishes the wire-level physics behind these algorithms: the speed of light sets a latency floor⁴ (roughly 5 μ s per kilometer in fiber), the bandwidth-distance product limits how far a fast link can reach before it needs optics (PAM4 signaling and copper-vs-optics reach are developed in section 3.3.1), and kernel-bypass transports such as RDMA and GPUDirect RDMA strip the per-message software tax down to a few microseconds (section 3.4.1). Collective communication adds the energy cost of moving a bit, which the algorithms must respect as firmly as latency and bandwidth.

Moving data costs energy that scales with distance, as figure 6.1 illustrates. Concrete reference values are: local SRAM at roughly 0.5 pJ/bit, NVLink (on-package PCB) at the tens of pJ/bit, and inter-node InfiniBand at the hundreds-to-thousand-plus pJ/bit. The figure uses the higher published estimates that include link-, switch-, and transceiver-side power; chapter prose elsewhere uses the lower bound of each range. Both views agree on the central point: the energy cost climbs by two-to-three orders of magnitude between SRAM and inter-node fabric.

At the exascale (tens of thousands of GPUs), the power budget for communication rivals the power budget for computation itself. A 10,000-GPU cluster exchanging 1 GB of gradients per step at 30 pJ/bit consumes approximately 4.8 kJ per AllReduce (accounting for the factor of 2 in data movement), a nontrivial fraction of the total per-step energy budget.

These three constraints interact multiplicatively. Latency sets the floor for every message regardless of size. Bandwidth caps the throughput for large transfers. Protocol overhead adds a per-message tax that penalizes fine-grained communication, which is why the kernel-bypass transports recalled above⁵ matter for collective performance. A quick AllReduce estimate makes their combined cost concrete for a realistic training scenario.

Napkin Math 6.1: AllReduce cost for a 70B model

Problem: A 70B parameter model trains with data parallelism across 64 GPUs connected by InfiniBand NDR (50 GB/s per port). Each GPU computes gradients in BF16 (2 bytes per parameter, common for Llama-class training). How long does one AllReduce take?

Step 1: Size the gradient payload. Each GPU produces a full gradient tensor: $7 \times 10^{10} \times 2$ bytes = 140 GB.

¹ | **AllReduce:** A compound term from MPI (Message Passing Interface) indicating a Reduce operation (summing data from all nodes to one) followed by a Broadcast (sending the sum to all nodes). Ring-based AllReduce optimizes this by performing both phases simultaneously in $2(N-1)$ steps, ensuring that every GPU ends with the global sum without any single node becoming a bottleneck.

² | **Parameter Server (PS):** Google's DistBelief used a parameter-server architecture for large-scale neural-network training, and later parameter-server systems made the server-side bandwidth and consistency trade-offs explicit as worker counts grew (Dean et al. 2012; Li et al. 2014). The collective-communication lesson is that star-like aggregation concentrates traffic in the server tier, whereas peer-to-peer collectives such as Ring AllReduce distribute that traffic so each worker's bandwidth cost can remain bounded.

³ | **Ring AllReduce:** The algorithm dates to the HPC collective-communication literature; Patarasuk and Yuan analyzed bandwidth-optimal AllReduce algorithms for workstation clusters, Baidu's Andrew Gibiansky popularized ring AllReduce for deep learning in February 2017, and Horovod plus NVIDIA NCCL helped make it a common distributed-training primitive (Patarasuk and Yuan 2009; Gibiansky 2017; Sergeev and Balso 2018; Jeaugey 2017).

⁴ | **The Speed of Light Constraint:** Light travels through optical fiber at approximately 200,000 km/s, or 200 meters per microsecond. In a massive data center where cables between racks span 100 meters, the "wire delay" alone contributes 500 ns to every message—a physical limit that no amount of better networking hardware can reduce.

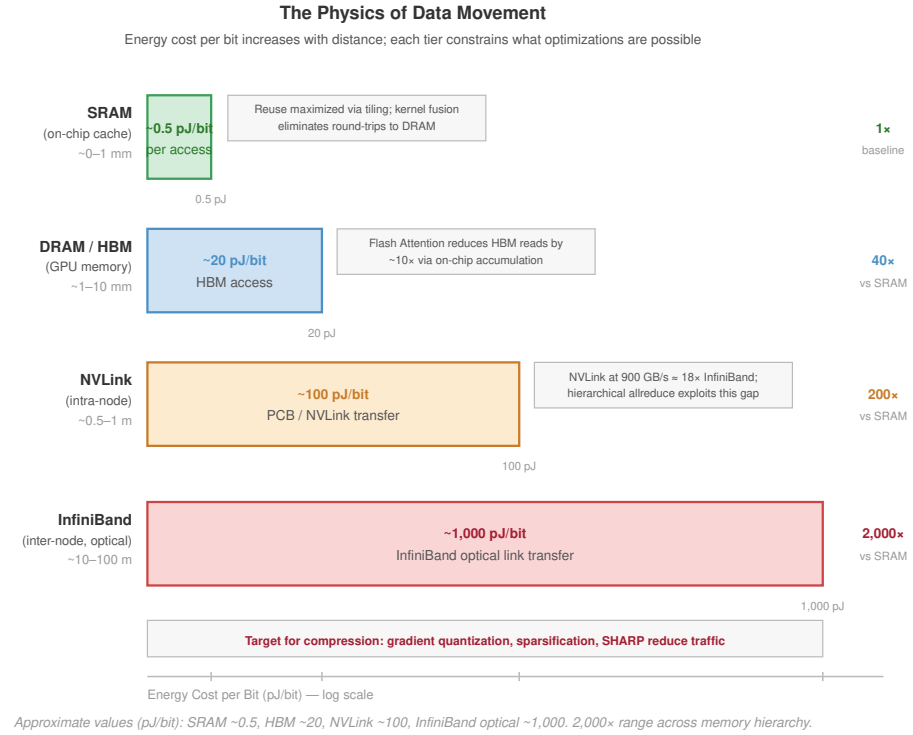

Figure 6.1: The Data Movement Energy Hierarchy: The energy cost of moving a single bit climbs by orders of magnitude across the system hierarchy — from SRAM through HBM to intra-node NVLink to inter-node InfiniBand. The figure plots higher-bound published estimates (NVLink in the tens of pJ/bit, InfiniBand near 1,000 pJ/bit) that include switch and transceiver overheads. The chapter prose elsewhere uses the lower-bound estimates for back-of-the-envelope calculations. Either way, the gradient makes data locality the primary driver of sustainable and efficient distributed ML system design.

5 | Zero-Copy Communication: RDMA (Remote Direct Memory Access) allows the NIC to transfer data directly from the application’s memory on one node to the application’s memory on another, bypassing the operating system’s kernel buffers. For a 140 GB gradient exchange, zero-copy avoids moving 280 GB of data between the CPU and main memory, reclaiming significant memory bandwidth (BW).

Step 2: Apply the Ring AllReduce bandwidth formula.

$$T_{\text{bandwidth}} = 2 \cdot \frac{N-1}{N} \cdot \frac{n}{\beta}$$

Substituting: $T_{\text{bandwidth}} = 1.96875 \times 140 \text{ GB} / 50 \text{ GB/s} \approx 5,512.5 \text{ ms}$.

Step 3: Add the latency term.

$$T_{\text{latency}} = 2(N-1) \cdot \alpha$$

Substituting: $T_{\text{latency}} = 126 \times 1.5 \mu\text{s} = 0.2 \text{ ms}$.

Step 4: Total communication time. Total: $T_{\text{AllReduce}} \approx 5,512.5 \text{ ms} + 0.2 \text{ ms} \approx 5,512.7 \text{ ms}$.

Systems insight: The gradient AllReduce alone takes over five seconds. This is pure communication overhead added to every training step. At this scale, communication dominates the step time unless overlapped with backward pass computation. This is why large-scale training systems pipeline AllReduce with the backward pass, launching communication for early layers while later layers are still computing.

The calculation reveals why data movement, not computation, becomes the governing constraint at scale. A single AllReduce on a 70B model’s gradients consumes seconds of wall-clock time, during which all GPUs would otherwise sit idle. This asymmetry between local computation (which parallelizes perfectly) and global coordination (which requires physical data movement) motivates every collective algorithm that follows. Halving that multi-second AllReduce would save thousands

compute

comm

Gradient synchronization devours 30 to 70 percent of each step at scale.

of GPU-hours over a typical training campaign, translating directly to reduced cost and faster time to deployment.

The cost analysis also explains why the choice of collective algorithm matters far more than most practitioners realize. Using a suboptimal algorithm that achieves only 60 percent of theoretical bandwidth (a common outcome with poor topology mapping) would inflate the five-second AllReduce to over nine seconds, adding several seconds of pure waste to every training step. Because this waste propagates through the entire fleet, communication algorithms occupy the Distribution Layer of the fleet stack: the Infrastructure Layer below provides raw bandwidth through NVLink, InfiniBand, and network topologies (covered in Chapter 3), while the Serving Layer above depends on efficient gradient synchronization to complete training runs that produce deployable models. When communication algorithms fail to saturate the available bandwidth, training takes longer, serving models are delivered later, and the entire fleet operates below its economic potential.

Figure 6.2 quantifies how this communication overhead compounds as the fleet grows. At 8 GPUs within a single NVLink-connected node, communication consumes roughly 25 percent of each training step because the 900 GB/s interconnect bandwidth keeps pace with gradient volume. As the cluster expands to 64 GPUs across 8 nodes, the transition to InfiniBand (50 GB/s per port) shifts the balance: communication dominates at approximately 50 percent of step time, with an additional 5 percent lost to synchronization barriers. At a 4,096-GPU scale, communication and synchronization overhead together consume 80 percent of the training step, leaving only 20 percent for useful computation. This progression explains why collective algorithms matter: without hierarchical collectives, gradient compression, and communication-computation overlap, large-scale training would spend the vast majority of its multi-million-dollar compute budget waiting for data to arrive.

Figure 6.2: The Compute-Communication Timeline: As training scales from 8 GPUs (one node) to 4,096 GPUs, communication grows from approximately 25 percent to over 65 percent of each training step. This shift from NVLink-dominated to InfiniBand-limited communication drives the design of all collective optimization strategies. Proportions derived from H100 cluster measurements with a 70B parameter model using data parallelism with Ring AllReduce.

6.1.2 The gradient’s travel manifest

The journey begins at the moment the backward pass completes. On a single machine, that was the end of the story: the weights were updated, and the neuron learned. At production scale, however, the gradient is born into isolation. It exists on one GPU, while the “truth” of the model is distributed across thousands. To achieve global convergence, the gradient must find its peers.

The specific “travel manifest” for this journey is dictated by the parallelism strategy chosen in Chapter 5. The choice of *how the math is split* determines *how the data moves*. For our Lighthouse

⁶ | **DLRM:** Meta’s 2019 architecture for click-through rate prediction, where embedding tables can exceed 100 GB and must be sharded across workers. Each forward pass triggers AllToAll to exchange sparse embedding lookups, creating a communication pattern where message sizes are small (hundreds of KB) but fan-out is $\mathcal{O}(N)$, making DLRM one of the most latency-sensitive distributed workloads in production.

Archetypes (section 1.6.1), these manifests differ fundamentally. For Archetype A (GPT-4/Llama-3), our gradient is part of a massive, dense tensor that must meet every other gradient in the fleet to compute a global average, so its primary vehicle is the AllReduce. For Archetype B (DLRM at Scale), the DLRM workload⁶, our gradient or activation is sparse and targeted: it does not need to meet everyone, only the specific GPU that holds its embedding shard. Mixture-of-experts (MoE) routing creates the same targeted pattern, sending each token to the GPU that hosts its assigned expert, so both rely on the AllToAll.

Understanding this mapping is essential: the *what* of parallelism directly determines the *how* of communication. At large scale, these strategies are not mutually exclusive. A single training run for a large language model typically employs 3D parallelism (combining data parallelism, tensor parallelism, and pipeline parallelism simultaneously), which means multiple collective primitives execute concurrently on overlapping subsets of GPUs. Tensor parallelism drives AllReduce operations within each node (over NVLink), pipeline parallelism drives point-to-point sends between pipeline stages (often between nodes), and data parallelism drives AllReduce operations across groups of nodes (over InfiniBand).

Each primitive operates on a different **process group**, a subset of the total GPU population that participates in that particular collective. Classical MPI uses a communicator as the object that names such a participating set; its communicator size is the number of ranks in that set. MPI libraries already selected collective algorithms based on communicator size and message size (Thakur et al. 2005). GPU communication libraries inherit that algorithm-selection problem and add the further challenge of coordinating overlapping process groups without creating contention between concurrent collectives.

Table 6.1 previews the mapping from parallelism strategy to collective primitive. The primitive names are introduced formally in the next section; for now, read the table as a traffic map that says who must exchange data with whom.

Table 6.1: The Travel Manifest: How the high-level math of Chapter 5 manifests as low-level traffic patterns.

Parallelism Strategy	The Gradient’s Goal	Primary Primitive	Primary Constraint
Data Parallelism	Meet everyone, compute global average	AllReduce	Bandwidth (Large payloads)
FSDP/ZeRO	Find shards, reconstruct the whole	AllGather + ReduceScatter	Bandwidth (High frequency)
Tensor Parallelism	Quick handshake within the node	AllReduce	Latency (Speed is life)
Pipeline Parallelism	Handoff to the next neighbor	Point-to-Point (Send/Recv)	Latency (Sequential dependencies)
Expert Parallelism (MoE)	Targeted routing to a specialist	AllToAll	Latency + Contention

⁷ | **Mixture-of-Experts (MoE):** An architecture where each token activates only a subset of specialized subnetworks (experts), reducing per-token FLOPs while maintaining total model capacity. The systems trade-off is stark: MoE replaces the bandwidth-bound AllReduce of dense models with latency-bound AllToAll, shifting the communication bottleneck from β to α and creating $\mathcal{O}(N^2)$ contention that limits practical cluster size.

In this table, Expert Parallelism refers to the mixture-of-experts (MoE)⁷ architecture pattern. The mapping shows that different parallelism strategies impose fundamentally different communication patterns. Data parallelism and FSDP generate large, bandwidth-bound messages that benefit from ring-based algorithms and hierarchical decomposition. Tensor and pipeline parallelism generate small, latency-bound messages that benefit from tree-based algorithms and low-overhead software stacks. Expert parallelism generates all-to-all traffic patterns that stress the network’s bisection bandwidth. To reason quantitatively about these differences, we need a model of network performance.

6.2 Mapping the Terrain: Network Performance Modeling

A data center engineer cannot predict how long it takes to send ten megabytes across a cluster without knowing two distinct variables: the fixed startup tax and the per-byte transit fee. As the gradient begins its journey, it immediately encounters the physical reality of the data center network.

6.2.1 The alpha-beta cost model: Startup tax and transit fee

Every message our gradient sends obeys the linear cost model $T(n) = \alpha + n/\beta$ —a fixed startup tax plus a per-byte transit fee. Those two terms decide every algorithm choice in this chapter.

 Definition 6.2: α - β model (Hockney model)

α - β Model (Hockney Model) is the linear communication cost model $T(n) = \alpha + n/\beta$ that decomposes message transfer time into a fixed startup latency (α , the per-message overhead) and a message-size-dependent bandwidth term (n/β , proportional to bytes transferred), enabling algorithm designers to predict when message fusion or gradient compression will improve throughput (Hockney 1994).

1. **Significance:** For InfiniBand NDR at $\alpha \approx 2\mu\text{s}$ and $\beta \approx 50\text{ GB/s}$, the crossover size $n^* = \alpha \cdot \beta \approx 100\text{ KB}$. A 4 KB routing message is far below n^* , so the startup tax dominates; fusing 100 such messages into one 400 KB message reduces communication cost from $100\alpha = 200\mu\text{s}$ to one $\alpha + n/\beta \approx 10\mu\text{s}$, a $20\times$ improvement. A 140 GB gradient tensor is far above n^* , so bandwidth dominates and reducing payload bytes is the effective lever.
2. **Distinction:** Unlike idealized throughput models that treat bandwidth as the sole communication cost, the α - β model reveals that N small messages of size n/N cost up to $N\times$ more than one large message of size n when $n/N \ll n^*$, explaining why NCCL fuses small AllReduce calls and why MoE routing algorithms buffer tokens before launching collectives.
3. **Common pitfall:** A frequent misconception is that gradient compression always helps. If the compressed gradient size remains well above n^* , compression reduces the bandwidth term but leaves the latency term unchanged. Even shrinking a 70B model's gradient payload from 140 GB to 1.4 GB leaves the message firmly bandwidth-bound; it does not turn the operation into a low-latency exchange.

The two parameters have distinct physical meanings. Latency (α) is the fixed start-up cost to send a message regardless of size, covering software overhead (kernel launch, NCCL initialization), PCIe traversal, and network switching time. Bandwidth (β) is the sustained data transfer rate in bytes per second. The **critical message size** $n^* = \alpha \cdot \beta$ marks the crossover point: messages smaller than n^* are latency-bound; messages larger are bandwidth-bound. Section D.1 works this model through concrete message-size regimes and roofline analysis, so a reader who wants the full derivation behind the crossover can follow it there; here we establish the parameters and apply them directly.

Table 6.2 shows typical values for data center interconnects, and the critical-size column carries the load-bearing pattern: intra-node NVLink stays latency-bound up to several hundred kilobytes, whereas the inter-node fabrics cross over near 100 KB, so a message large enough to be bandwidth-bound inside a node can still be latency-bound once it travels between nodes.

Table 6.2: Interconnect Performance Parameters: Effective per-message launch latency (α , including the software stack), per-direction link bandwidth (β , the one-way deliverable rate that enters $T(n) = \alpha + n/\beta$; NVLink's datasheet 900 GB/s is the bidirectional total, so its β is the 450 GB/s one-way rate), and the computed crossover size $n^* = \alpha \cdot \beta$ at each row's α midpoint, where communication transitions from latency-bound to bandwidth-bound.

Interconnect	Latency (α)	Bandwidth (β)	Critical Size (n^*)
NVLink 4.0 (intra-node)	1–2 μs	450 GB/s	~0.7 MB
InfiniBand NDR 400 Gbps	1–3 μs	50 GB/s (per port)	~100 KB
InfiniBand HDR 200 Gbps	2–5 μs	25 GB/s	~87.5 KB
PCIe Gen5 (GPU CPU)	2–5 μs	64 GB/s	~224 KB
Ethernet 100 Gbps (RoCE)	5–10 μs	12.5 GB/s	~93.7 KB

Applying the critical message size formula to a concrete workload reveals which optimization strategy matters most:

Napkin Math 6.2: The critical message size

Problem: Consider a cluster using InfiniBand NDR 400 Gbps with $\alpha = 2 \mu\text{s}$ and $\beta = 50 \text{ GB/s}$. At what message size does optimizing for bandwidth start to matter more than optimizing for latency?

Math:

$$n^* = \alpha \cdot \beta = 2 \times 10^{-6} \text{ s} \times 5 \times 10^{10} \text{ B/s} = 100 \text{ KB}$$

Systems insight: Messages under 100 KB (like MoE tokens, pipeline activations) are **latency-bound**: buy lower-latency switches and reduce software overhead. Messages over 100 KB, such as large language model (LLM) gradients, are **bandwidth-bound**: buy more bandwidth and compress the data. Applying the wrong optimization wastes money without improving performance.

Small messages are latency-bound, large ones bandwidth-bound; the cost reverses.

The critical message size separates two distinct operating regimes. Below it, small messages such as MoE routing tokens or scalar reductions are latency-bound ($n < n^*$), where time is dominated by α and optimization focuses on fusion (batching small messages), topology (reducing hop count), and software-stack tuning (kernel bypass via RDMA). Above it, large messages such as LLM gradients or optimizer states are bandwidth-bound ($n \gg n^*$), where time is dominated by n/β and optimization shifts to compression (lower precision or sparsity), algorithm choice (Ring vs. Tree), and link aggregation (multi-rail NICs). The distinction between latency-bound and bandwidth-bound communication is the diagnostic skill to practice.

Checkpoint 6.1: Alpha-beta diagnostics

Verify your understanding of network performance regimes:

- ☐ **Bound regime:** Classify a 10 KB message sent over a link with $\alpha = 2 \mu\text{s}$ and $\beta = 10 \text{ GB/s}$ as latency-bound or bandwidth-bound.
- ☐ **Software overhead:** Determine which type of parallelism benefits more when “Software Overhead” (α) is reduced by half: Data Parallelism or Tensor Parallelism.
- ☐ **Critical message size:** Describe how the critical message size ($n^* = \alpha\beta$) changes when networking upgrades from 100 Gbps to 400 Gbps while software latency stays constant.
- ☐ **NIC scaling:** Assess the True or False claim that, in the bandwidth-bound regime, doubling the number of NICs per node effectively doubles the transmission speed for large tensors.

6.2.2 The LogP model

The α - β model assumes the processor is idle during communication. For pipelined systems where we overlap communication with computation, this assumption fails. The **LogP model** (Culler et al. 1993) extends α - β with four parameters:

- L_{lat} (**Latency**): The time for a message to traverse the network (similar to α).
- o (**Overhead**): The CPU/GPU time spent initiating or receiving a transfer. During this time, the processor cannot compute, making this the nonoverlappable cost. In a distributed training context, o is the aggregate of PyTorch or JAX dispatch overhead, CUDA kernel launch time, tensor memory registration with the RDMA stack, and occasionally Python Global Interpreter Lock (GIL) contention when the communication thread competes with the training loop. These software layers account for why measured NCCL overhead is 25–50 μs per collective even when the wire-level α is only 1–3 μs ; the NCCL comparison later in this section makes the gap concrete.
- g (**Gap**): The minimum time interval between consecutive message injections (inverse of message rate). This models link contention.
- N_{rank} (**Rank count**): The number of ranks in the communication group.

LogP distinguishes network latency (L_{lat} , which can be hidden) from processor overhead (o , which *cannot*). A system can overlap communication with computation only if the compute kernel runs longer than the overhead. A small overlap calculation makes this distinction concrete:

Napkin Math 6.3: Hiding communication behind computation

Problem: A training pipeline attempts to overlap gradient AllReduce with the next layer’s backward pass. The backward pass takes 500 μs . The AllReduce has network latency 100 μs but processor overhead $o = 50 \mu\text{s}$ to initiate and $o = 50 \mu\text{s}$ to receive. Can the communication be hidden?

Math:

1. **Overlappable portion:** Network latency $L_{\text{lat}} = 100 \mu\text{s}$ (data in flight while GPU computes).
2. **Non-overlappable portion:** $2o = 100 \mu\text{s}$ (GPU busy initiating/receiving).
3. **Compute available:** 500 μs .
4. **Hidden:** All 100 μs of L_{lat} can overlap with compute.
5. **Exposed:** The 100 μs of $2o$ overhead cannot overlap.

Result: Effective time is $100 \mu\text{s} + \max(500 \mu\text{s}, 100 \mu\text{s}) = 600 \mu\text{s}$. The network latency is hidden, but the processor overhead remains exposed. Figure 6.3 shows this overlap visually.

Systems insight: The α - β model captures the total communication time. The LogP model reveals *how much of it can be hidden*. When designing pipelined training, optimize for low o (kernel bypass, GPUDirect) rather than high β alone.

Figure 6.3: Communication-Computation Overlap: By pipelining collective operations with the backward pass, systems can hide network latency behind arithmetic execution. Overlap is successful only when the nonoverlappable overhead (o) is minimized, allowing the bulk transfer term to proceed while the GPU computes the next layer’s gradients.

The choice between models depends on the analysis context. The α - β model is the right tool for back-of-envelope calculations, algorithm selection (Ring vs. Tree), and cases where communication is *blocking* (synchronous barriers). Its strength is simplicity, since the two parameters can be measured

directly with a point-to-point bandwidth test and a zero-byte message latency test. Its weakness is the assumption that the processor is idle during communication, which makes it overly pessimistic when overlap is possible. The LogP model earns its extra parameters when the analysis turns to **pipelined execution**, compute-communication overlap, or debugging why a theoretically fast algorithm underperforms (often high o). Its distinction between network latency L_{lat} (which can be hidden) and processor overhead o (which cannot) determines whether a given overlap strategy will actually hide communication. The cost is that measuring o accurately requires profiling tools such as NVIDIA Nsight Systems, because o depends on the specific communication library and GPU driver stack.

In practice, most engineering calculations start with the α - β model for initial sizing and algorithm selection, then refine with LogP analysis when communication-computation overlap is the target optimization. Both models share a common limitation: they assume a single flow on a single link. Real communication patterns involve multiple simultaneous flows competing for shared bandwidth, which can cause congestion that neither model captures. For congestion-sensitive workloads (particularly AllToAll for MoE), empirical benchmarking on the target cluster remains the necessary validation step.

6.2.3 Putting the model to work: Llama 70B communication budget

The alpha-beta model becomes most valuable when applied to real training configurations. Consider a concrete scenario: training a Llama-class 70B parameter model using data parallelism across 128 GPUs spanning 16 nodes of 8 GPUs each. The gradient tensor is 140 GB in BF16 (70 billion parameters at 2 bytes each, common for Llama-class training). During each training step, this entire gradient must be synchronized across all workers.

The calculation uses the bandwidth hierarchy before the chapter formalizes it: reduce as much data as possible over the fast NVLink tier inside each node, send only the reduced shard over the slower InfiniBand tier, then reconstruct the result locally. The primitive names become precise in the hierarchy section; the engineering idea is already visible in the bandwidth budget.

Using BF16 gradients (a common practice that halves communication volume to 140 GB), the contrast is stark. Routing the full gradient over the slow inter-node fabric, as a flat Ring AllReduce does, costs roughly 5,557 ms. Confining most of the traffic to NVLink and sending only the reduced shard over InfiniBand cuts that to approximately 1200.8 ms. The difference is not marginal; it determines whether communication can be hidden behind computation or whether it becomes the critical path.

The per-phase breakdown behind these numbers (the intra-node reduction, the reduced inter-node exchange, and the intra-node redistribution) requires the collective primitives this section has not yet introduced. Section 6.5.1 names those primitives and works the full three-phase derivation; the budget here establishes only that the bandwidth hierarchy is worth respecting, and by how much.

6.2.4 Theory vs. practice: The NCCL reality gap

The bandwidth-latency trade-off (principle 11) provides useful first-order predictions, but real communication libraries introduce overheads that the idealized α - β model does not capture. NCCL, a widely used GPU communication library, adds protocol negotiation, memory registration, and internal pipelining that modify the effective α and β values (Jeagey 2017; NVIDIA 2026b). Table 6.3 compares one-message α - β payload predictions against measured NCCL performance for common message sizes on an 8-node DGX H100 cluster (64 GPUs, InfiniBand NDR 400G).

Table 6.3: α - β Predictions vs. Measured NCCL Performance: For small messages, NCCL’s protocol overhead (memory registration, channel setup, kernel launch) inflates the effective latency by 7–8 $\times$ over the bare-wire α . For large messages, NCCL achieves within 8–15 percent of theoretical bandwidth, validating the one-message payload model in the bandwidth-bound regime. Values are illustrative reference numbers for an effective NCCL payload-transfer model on 8-node DGX H100 clusters with InfiniBand NDR 400G; actual collective timings vary with algorithm, topology, NCCL version, and tuning.

Message Size	α - β Prediction	Measured NCCL	Ratio (Measured/Predicted)	Explanation
1 KB	~3.1 μ s	~25 μ s	~8.1 $\times$	NCCL protocol setup dominates

Message Size	α - β Prediction	Measured NCCL	Ratio (Measured/Predicted)	Explanation
64 KB	$\sim 4.4 \mu\text{s}$	$\sim 30 \mu\text{s}$	$\sim 6.9\times$	Still latency-bound; NCCL overhead
1 MB	$\sim 23.1 \mu\text{s}$	$\sim 40 \mu\text{s}$	$\sim 1.7\times$	Transitioning to bandwidth-bound
64 MB	$\sim 1.3 \text{ ms}$	$\sim 1.6 \text{ ms}$	$\sim 1.2\times$	NCCL approaches theoretical bandwidth
1 GB	$\sim 20 \text{ ms}$	$\sim 23 \text{ ms}$	$\sim 1.15\times$	Bandwidth-dominant; NCCL nearly optimal
10 GB	$\sim 200 \text{ ms}$	$\sim 215 \text{ ms}$	$\sim 1.07\times$	Large payloads saturate the wire

The table reveals two critical lessons. First, the α - β model underestimates small-message latency by 7–8 $\times$ because it accounts only for wire-level propagation, not the software stack overhead. For latency-sensitive operations (tensor parallelism AllReduce, MoE token routing), the effective α is 5–10 $\times$ higher than the physical wire latency. Second, for large messages the model is accurate to within 8–15 percent, confirming that bandwidth is the binding constraint and that NCCL’s internal optimizations (channel pipelining, kernel fusion) successfully saturate the available links.

This reality gap has practical consequences for algorithm selection. The crossover point between Ring and Tree AllReduce shifts upward in practice because the effective α is larger than the wire-level value. Engineers who use textbook α values will underestimate latency costs and may choose Ring when Tree would perform better. A robust practice is to measure the effective α on the specific cluster by benchmarking small-message AllReduce latency, then use that measured value in all subsequent calculations.

6.3 Choosing the Vehicle: Collective Operation Primitives

If a GPU simply opens a socket and sends a massive gradient to another GPU, the entire cluster will rapidly collapse into an unmanageable web of deadlocks and congestion. With the terrain mapped, the gradient must now choose its vehicle: strictly choreographed group exchanges known as collective operations, a vocabulary standardized by MPI and inherited by modern ML communication libraries (Message Passing Interface Forum 2015). Figure 6.4 illustrates four of the central primitives in this vocabulary: AllReduce, AllGather, ReduceScatter, and AllToAll. Each panel reads as a before-and-after across the process group, with one row per rank: blue cells mark the input each rank starts with, green cells mark the result it ends with, and orange marks the AllToAll routing that shuffles unique data between every pair of ranks. Two further primitives, Broadcast (rank 0 sends to all) and Reduce (all aggregate to rank 0), are foundational building blocks defined in the prose below and used implicitly in the figure’s compound patterns. Section D.2 formalizes the semantics and latency and bandwidth complexity of each primitive; the prose here introduces them through their workload use cases, and the reader who wants the formal complexity bounds before proceeding can establish them there first.

Definition 6.3: Collective operation

Collective Operation is a distributed communication pattern in which all processes in a group participate simultaneously to aggregate, broadcast, or redistribute data, with the correctness guarantee that each participant receives the result prescribed by the collective’s semantics regardless of message ordering or arrival time.

1. **Significance:** The right collective algorithm determines whether communication scales with cluster size or remains constant. Ring AllReduce achieves bandwidth-optimal $2(N-1)/N \times M/\beta$ per node (constant in N), while a naive reduce-then-broadcast approach costs $\mathcal{O}(N \times M/\beta)$, making it 500 $\times$ worse for $N = 1024$. Algorithm selection thus directly determines whether the BW term in the iron law is the training bottleneck.

2. **Distinction:** Unlike point-to-point communication (where one sender and one receiver exchange data independently), a collective operation coordinates the entire process group—every participant must invoke the collective before any can complete it, and the library guarantees a consistent result even when different processes contribute different data.
3. **Common pitfall:** A frequent misconception is that one collective algorithm suits all message sizes. Ring AllReduce achieves near-optimal bandwidth for large gradient tensors but has $\mathcal{O}(N)$ latency—for small messages like MoE routing decisions (~ 4 KB), a tree-based algorithm reduces latency to $\mathcal{O}(\log N)$ steps at the cost of suboptimal bandwidth utilization (the bandwidth-optimal recursive halving-doubling alternative is covered in section 6.4.5), requiring workload-specific algorithm selection rather than a single default.

Figure 6.4: Four Central Collective Primitives: Standardized patterns for group communication in distributed systems. (1) AllReduce: all aggregate and all receive the result. (2) AllGather: all send to all and concatenate. (3) ReduceScatter: all aggregate and results are distributed in shards. (4) AllToAll: every process sends unique data to every other process. The two foundational primitives Broadcast (rank 0 sends to all) and Reduce (all aggregate to rank 0) compose the patterns shown here and are defined in the surrounding prose.

The primitive choice is the first scaling decision because it fixes which ranks must coordinate, which data must move, and which communication term will dominate. Different model architectures stress different operations, and selecting the wrong primitive for a workload creates unnecessary bottlenecks.

6.3.1 The six core primitives

The six primitives in table 6.4 form a decision ladder: use the narrowest operation that preserves the model’s mathematics, because every broader pattern adds participants, barriers, or contention.

Table 6.4: The Six Collective Primitives: What each primitive computes, its primary use, and its communication cost, ordered from the narrowest pattern (Broadcast) to the most general (AllToAll).

Primitive	What it does	Primary use case	Communication cost
Broadcast	One sender transmits data to all receivers.	Distribute initial model weights from rank 0 at startup, across all parallelism strategies.	$\mathcal{O}(\log N)$ latency (tree); $\mathcal{O}(M)$ bandwidth.
Reduce	Aggregate data from all workers (sum, min, max) to a single root.	Aggregate validation metrics such as loss and accuracy to a logging process.	$\mathcal{O}(\log N)$ latency (tree); $\mathcal{O}(M)$ bandwidth.
AllReduce	Aggregate from all workers, then distribute the result to all ($y_i = \sum_{j=0}^{N-1} x_j$ for all i).	Data parallelism (section 5.3): synchronize gradients so every GPU computes the same update.	Ring is bandwidth-optimal at $2 \frac{N-1}{N} \frac{M}{\beta}$ but $\mathcal{O}(N)$ latency; Tree gives $\mathcal{O}(\log N)$ latency with worse bandwidth.
AllGather	Each worker’s data goes to all; the result concatenates every input ($x_i \rightarrow [x_0, \dots, x_{N-1}]$).	Sharded data parallelism (FSDP/ZeRO): collect sharded parameters before a forward or backward pass.	Ring $\frac{N-1}{N} \frac{M}{\beta}$; resident data grows from an M/N shard to the full M .
ReduceScatter	Reduce across workers, but scatter so each keeps a distinct chunk (worker i receives the i -th block of $\sum x_j$).	Sharded data parallelism: reduce gradients while keeping them sharded to save memory.	Ring $\frac{N-1}{N} \frac{M}{\beta}$; the inverse of AllGather.
AllToAll	The most general pattern: worker i sends a distinct chunk to each worker j , a distributed matrix transpose.	MoE routing tokens to experts; DLRM exchanging embedding lookups across workers.	$\frac{N-1}{N} M$ per worker, but $\mathcal{O}(N^2)$ logical connections make contention the scaling limit.

Ring achieves AllReduce’s bandwidth-optimal cost while Tree trades bandwidth for logarithmic latency; section D.2.1 develops the formal definition and a worked example comparing the two, so a reader who wants that derivation can take the full treatment there (Patarasuk and Yuan 2009; Thakur et al. 2005).

A key insight is that AllReduce can be decomposed into ReduceScatter followed by AllGather. This is not merely a mathematical equivalence; it is precisely how Ring AllReduce works internally (the Scatter-Reduce phase is a ReduceScatter, the AllGather phase is an AllGather). ZeRO-style sharding, realized in PyTorch as FSDP⁸, exploits this decomposition by AllGathering parameter shards before a module needs them and ReduceScattering gradients after backward so each rank retains only its shard for the optimizer step (Rajbhandari et al. 2020). This shards parameters, gradients, and optimizer state across workers, reducing persistent model-state memory roughly by $N\times$, while temporary full-parameter buffers and prefetching determine peak memory.

The same AllGather/ReduceScatter pair also appears in sequence parallelism: an AllGather reconstructs the activation view needed for a local operation, and a later ReduceScatter redistributes the result along the sequence dimension. That example will matter later because it shows that a primitive’s semantics stay fixed even when the tensor dimension being sharded changes.

This ladder matters because the primitive determines the synchronization shape before any algorithmic optimization begins. AllReduce creates global agreement, AllGather and ReduceScatter trade memory for repeated shard movement, and AllToAll replaces a bandwidth problem with fan-out and contention.

The contrast between AllToAll and AllReduce highlights a fundamental difference in how collective operations scale with cluster size.

Systems Perspective 6.1: AllToAll vs. AllReduce: Why scale differs

While AllReduce scales efficiently because it can be pipelined in a ring (where each node only talks to its neighbor), AllToAll is fundamentally harder to scale.

In an AllToAll, every process has a unique piece of data for every other process. This creates $\mathcal{O}(N^2)$ logical connections. At the hardware level, this leads to **network contention**: if 1024

⁸ | **FSDP (Fully Sharded Data Parallel)**: PyTorch’s fully sharded implementation follows the ZeRO-3 idea of sharding parameters, gradients, and optimizer states across N accelerators (Rajbhandari et al. 2020). The trade-off is communication frequency: full sharding adds layer-level AllGather and ReduceScatter operations instead of relying only on data parallelism’s step-level AllReduce, making it more sensitive to the α overhead.

GPUs all try to send data to different targets simultaneously, the “Fat-Tree” or “Spine” switches in the data center become the bottleneck.

This is why Expert Parallelism (MoE) and large-scale recommendation systems often hit a “communication wall” much earlier than standard data-parallel models. The algorithm choice (AllReduce vs. AllToAll) determines the scaling ceiling.

To make the AllToAll pattern concrete, consider a Mixture of Experts model with 64 experts distributed across 8 GPUs (8 experts per GPU). During each forward pass, a gating network assigns each input token to one or more experts. The tokens assigned to experts on remote GPUs must be physically moved to those GPUs before computation can proceed, and the results must be moved back afterward.

Napkin Math 6.4: AllToAll for MoE token routing

Problem: A MoE model processes a batch of 4096 tokens across 8 GPUs (512 tokens per GPU). Each token is a 2048-dimensional hidden state in BF16 (4.096 KB per token). The gating network assigns each token to exactly 1 of 64 experts (8 experts per GPU). Assuming uniform routing (each expert receives 64 tokens), how much data does each GPU send and receive?

Math:

Each GPU holds 512 tokens that need to reach 64 different experts across 8 GPUs. With uniform routing, each GPU sends 64 tokens to each of the other 7 GPUs (keeping 64 tokens local).

- Data per GPU-to-GPU transfer: 64 tokens $\times$ 4.096 KB/token = 262.144 KB
- Total data sent per GPU: 7 $\times$ 262.144 KB = 1.84 MB
- Total data received per GPU: 1.84 MB (symmetric)

Latency Analysis (InfiniBand NDR, $\alpha = 3 \mu\text{s}$, $\beta = 50 \text{ GB/s}$):

Each of the 7 transfers is a 262.144 KB message. From the α - β model: $T_{\text{transfer}} = 3 \mu\text{s} + 5 \mu\text{s} = 8 \mu\text{s}$ per transfer.

If serialized: $7 \times 8 \mu\text{s} = 56 \mu\text{s}$. If all 7 transfers run in parallel (full-duplex, non-blocking): $\approx 8 \mu\text{s}$.

Systems insight: The per-transfer sizes in this MoE example sit near the critical-message-size boundary, so startup overhead remains comparable to serialization time. This is why MoE scaling is often constrained by α (latency), fan-out, and contention rather than raw β (bandwidth) alone, and why MoE systems benefit from low-latency switches, RDMA, message fusion, and topology-aware routing. The AllToAll also runs twice per layer (once for token dispatch, once for result collection), doubling the startup tax.

In practice, MoE routing is rarely perfectly uniform. Popular experts receive more tokens than unpopular ones, creating load imbalance that translates to communication imbalance. If one expert receives $3\times$ more tokens than average, the GPU hosting that expert receives $3\times$ more incoming data, creating a hotspot that can stall the entire collective (since AllToAll is a barrier operation). Large MoE systems address this through auxiliary load-balancing losses that penalize the gating network for routing too many tokens to any single expert, and through capacity factors that cap the maximum number of tokens an expert can accept (dropping overflow tokens). These techniques trade a small amount of model quality for communication balance, which is the right trade-off at scale.

Table 6.5 maps these primitives to the parallelism strategies introduced in Chapter 5 and the lighthouse archetypes introduced in section 1.6.1.

Table 6.5: Collective Operation Selection Guide: Matching training strategies to their primary collective operations enables efficient distributed communication design. MoE and DLRM serve as canonical “lighthouse” workloads throughout this book, representing sparse expert architectures and recommendation systems respectively. Pipeline Parallelism uniquely relies on point-to-point rather than collective communication.

Training Strategy	Primary Collective	Bottleneck Characteristic
Data Parallelism	AllReduce	Bandwidth-bound (large gradients)
FSDP/ZeRO-3	AllGather, ReduceScatter	Bandwidth-bound, high frequency
Tensor Parallelism	AllReduce, AllGather	Latency-bound (requires NVLink)
Pipeline Parallelism	Point-to-Point (Send/Recv)	Latency-bound (microbatch handoffs)
Sequence Parallelism	AllGather, ReduceScatter	Bandwidth-bound (activation exchange)
MoE (Experts)	AllToAll	Latency-sensitive + contention
DLRM (RecSys)	AllToAll	Latency & Bandwidth (sparse lookups)

6.3.2 FSDP communication patterns

The FSDP/ZeRO strategy deserves special attention because its communication pattern differs fundamentally from standard data parallelism (Rajbhandari et al. 2020). In standard data parallelism, each GPU holds a complete copy of the model, computes gradients locally, and synchronizes via a single AllReduce at the end of the backward pass. Full sharding eliminates this redundancy by partitioning the model parameters across GPUs, so each GPU holds only its local shard outside the moments when a layer must be reconstructed.

Because each GPU now holds only $1/N$ of the parameters, it must reconstruct the full tensor before it can use a layer, and that reconstruction is what transforms the communication pattern. Before each layer’s forward pass, the GPU calls AllGather to collect the shards from all other GPUs. After the backward pass, the gradients are reduced and redistributed via ReduceScatter, so each GPU holds gradients only for its own parameter shard. The sharded parameters can then be discarded (freed from memory) until the next forward pass needs them.

The consequence is a displacement of overhead: sharding relieves the memory bottleneck but raises communication frequency. Standard data parallelism communicates once per training step (a single AllReduce of the full gradient). FSDP communicates twice per layer per step (AllGather in forward, ReduceScatter in backward), but each communication is smaller (only that layer’s parameters, sharded across ranks). For a model with N_L layers, FSDP issues $2N_L$ collective operations per step instead of 1; across all those operations, the total communication volume can be comparable to the single full-gradient AllReduce, but it is spread across many smaller operations.

The higher operation count makes FSDP more sensitive to latency (α) than standard data parallelism. If each of the $2N_L$ collectives pays the full NCCL startup overhead (25–50 μ s per operation from table 6.3), the aggregate overhead for a 100-layer model is 5–10 ms, which can represent a meaningful fraction of step time. FSDP implementations mitigate this through prefetching (launching the next layer’s AllGather while the current layer is computing) and communication stream pipelining (using dedicated CUDA streams for communication that overlap with compute streams).

Selecting the right collective algorithm at each invocation requires understanding these asymmetric patterns. The AllGather operations in FSDP are medium-sized (one layer’s parameters, typically 10–100 MB for transformer models) and latency-sensitive (because computation blocks until the full parameters are available). The ReduceScatter operations are of similar size but can overlap with the next layer’s backward computation. This asymmetry means the AllGather operations benefit more from low-latency algorithms (Tree or hybrid) while the ReduceScatter operations can use bandwidth-optimal algorithms (Ring) because their latency is hidden behind computation.

The collective primitives catalog above defines *what* must be communicated; the question now becomes *how* to execute these primitives efficiently on real networks. The most performance-critical primitive, AllReduce, admits multiple algorithmic implementations whose latency and bandwidth characteristics differ by orders of magnitude. The choice of algorithm can change AllReduce time by an order of magnitude, making this the single most consequential implementation decision in distributed training.

FSDP trades one step-level collective for two per-layer collectives.

6.4 Engineering the Flow: AllReduce Algorithms

A correct AllReduce must give all 1,000 GPUs the exact sum of all 1,000 one-gigabyte gradients, and the algorithm that delivers it sets the cluster’s scaling ceiling. The naive answer—every GPU sends to one central server, whose network card instantly saturates—fails first, which makes it the right place to start.

6.4.1 Naive approaches vs. the bandwidth bottleneck

Consider a naive implementation using a Parameter Server (Star topology). All N workers send their gradients to rank 0; rank 0 sums them and sends the result back. The constraint is rank 0’s bandwidth: it must receive $N \times M$ bytes and send $N \times M$ bytes, so the time grows as $T \propto N \times M / \beta$. At 1,000 GPUs, this makes the central rank the scaling bottleneck rather than the arithmetic.

This naive approach captures the pressure that early distributed ML frameworks had to manage: parameter-server systems receive, aggregate, and redistribute model updates through a server tier, while practical implementations shard the parameter space to spread that load (Dean et al. 2012; Li et al. 2014). Sharding reduces the per-server traffic from $N \times M$ to $N \times M / K_{\text{srv}}$ (where K_{srv} is the number of servers), but the server tier still grows as workers and model state grow, and it introduces additional complexity in parameter partitioning and consistency management.

The fundamental limitation is that any star-topology approach concentrates traffic at a central point. Regardless of how many servers participate, the aggregate traffic through the central tier scales as $\mathcal{O}(N \times M)$. To achieve true scalability, we need algorithms where the communication volume per node is constant regardless of N . This property, known as **bandwidth optimality**, is the design target for scalable collective algorithms.

War Story 6.1: When the parameter server became the bottleneck

Context: In 2017, Alexander Sergeev and Mike Del Balso’s team at Uber open-sourced Horovod as part of Uber’s Michelangelo ML platform, where TensorFlow training jobs needed to scale across many GPUs without forcing every model author to rewrite large portions of training code (Sergeev and Balso 2018).

Failure mode: TensorFlow’s stock distributed training relied on a parameter-server pattern that concentrated gradient traffic through a central tier and imposed non-negligible communication overhead. Scaling beyond a single node required heavy code modification, and the star-topology aggregation degraded as worker counts grew.

Consequence: Horovod adopted Baidu’s draft ring-allreduce implementation and wrapped efficient ring reduction behind a small API surface—just a few lines added to existing TensorFlow code (Gibiansky 2017; Sergeev and Balso 2018). The bandwidth bottleneck moved off the central server and onto bandwidth-optimal collective communication, and distributed training became practical for teams without distributed-systems expertise.

Systems lesson: A collective algorithm is also a developer interface. Scaling improves when the communication primitive is both bandwidth efficient and easy enough that teams actually use it correctly.

6.4.2 The bandwidth-optimal lower bound

Before examining specific algorithms, it is useful to establish a theoretical lower bound. In any correct AllReduce, every GPU starts with M bytes of local data and ends with M bytes of globally reduced data. Each byte of the final result incorporates information from all N GPUs, which means every GPU must receive at least $M \cdot (N - 1) / N$ bytes of “new” information (the contributions from all other GPUs). Symmetrically, each GPU must send at least $M \cdot (N - 1) / N$ bytes (its own contribution to the other GPUs’ results).

The minimum total transfer per GPU is therefore $2 \cdot M \cdot (N - 1) / N$ bytes (send plus receive). Dividing by the link bandwidth β gives the **bandwidth lower bound**:

$$T_{\text{bandwidth}}^{\min} = \frac{2(N-1)}{N} \cdot \frac{M}{\beta}$$

As N grows large, this approaches $2M/\beta$, which is independent of N . An algorithm that achieves this bound is bandwidth-optimal. Ring AllReduce achieves this bound exactly; simple tree variants do not (Patarasuk and Yuan 2009; Thakur et al. 2005). This distinction has practical consequences: on a 64-GPU cluster synchronizing a 1 GB gradient, the bandwidth difference between an optimal and a merely logarithmic algorithm amounts to several milliseconds per step, which accumulates to hours over a multi-day training run.

6.4.3 Ring AllReduce

Ring AllReduce⁹ arranges nodes in a logical ring ($0 \rightarrow 1 \rightarrow \dots \rightarrow N-1 \rightarrow 0$). It achieves bandwidth optimality by pipelining: every node sends and receives simultaneously on every link (Patarasuk and Yuan 2009).

The algorithm splits the vector of size M into N chunks and then alternates communication and local reduction in two named phases: Scatter-Reduce followed by AllGather. Algorithm 6.1 states the mechanics before the figure and trace make the same dataflow concrete.

Algorithm 6.1 Ring AllReduce

Require: N ranks in a logical ring; each rank i starts with tensor G_i of M bytes, split into N chunks

Ensure: every rank holds $G = \sum_{i=0}^{N-1} G_i$

- 1: assign the ring order $0 \rightarrow 1 \rightarrow \dots \rightarrow N-1 \rightarrow 0$
 - 2: **for** $N-1$ scatter-reduce steps **do**
 - 3: each rank sends one chunk (or partial sum) right, receives one from the left, and adds it into the matching local sum
 - 4: **end for**
 - 5: each rank now owns one fully reduced chunk of G
 - 6: **for** $N-1$ all-gather steps **do**
 - 7: each rank forwards a reduced chunk around the ring and stores the chunks it receives
 - 8: **end for**
 - 9: **return** the complete reduced tensor G , held on every rank
-

Across the $2(N-1)$ send/receive rounds each rank moves M/N bytes per round, for $2(N-1)M/N$ bytes sent and the same received: the bandwidth term reaches the information-theoretic lower bound, while the latency term grows as $2(N-1)\alpha$. The data flow during the Scatter-Reduce phase is illustrated in figure 6.5.

The key property visible in figure 6.5 is that every link carries data simultaneously in every step, leaving no link idle. This uniform link utilization is what makes Ring AllReduce bandwidth-optimal: each node sends exactly $2(N-1)/N \cdot M$ bytes total across both phases, matching the information-theoretic lower bound. Section D.3.1 works through side-by-side examples that compare Ring, tree, and recursive halving-doubling and show how the best algorithm shifts with message size, giving the reader concrete crossover numbers to weigh against the per-algorithm derivations developed here.

To make the ring algorithm concrete, consider a step-by-step trace with 4 GPUs reducing a vector of 4 elements by summation. Each GPU i starts with a local gradient vector $g_i = [a_i, b_i, c_i, d_i]$. The vector is split into 4 chunks (one per GPU), and the algorithm proceeds through two phases.

Example 6.1: Ring AllReduce: Step-by-step trace (4 GPUs)

Setup: 4 GPUs in a ring ($0 \rightarrow 1 \rightarrow 2 \rightarrow 3 \rightarrow 0$). Each GPU holds a vector of 4 values. We use concrete numbers for clarity:

- GPU 0: [1, 5, 3, 7]
- GPU 1: [2, 6, 4, 8]
- GPU 2: [3, 7, 5, 9]
- GPU 3: [4, 8, 6, 10]

⁹ | **Bandwidth-Optimal:** Ring AllReduce achieves the information-theoretic lower bound of $2(N-1)/N \cdot M/\beta$ bytes per node, meaning no correct AllReduce algorithm can move fewer bytes per node regardless of topology or strategy. This optimality holds because every GPU must receive $M(N-1)/N$ bytes of “new” information from other GPUs and contribute the same amount, and Ring saturates every link in every step.

Phase 1 — Scatter-Reduce

Each GPU sends its chunk to the next; partial sums accumulate over $N-1$ steps.

**Phase 2 — AllGather**

Each GPU forwards the now-reduced shard it received; after $N-1$ steps all chunks are complete everywhere.

Total bus traffic per GPU: $2 \cdot (N-1)/N \cdot S \rightarrow 2S$ as $N \rightarrow \infty$ (bandwidth-optimal)

Each phase requires $N-1$ send/receive steps. S = total tensor size.

Scatter-Reduce AllGather

Figure 6.5: Ring AllReduce Data Flow: Nodes arranged in a logical ring exchange chunks in two phases: a Scatter-Reduce phase (each node accumulates one chunk’s partial sum) followed by an AllGather phase (complete sums circulate to all nodes). The figure shows the ring laid out horizontally with a wrap-around bus closing the loop; every link is used simultaneously, achieving bandwidth optimality.

Expected result (element-wise sum): $[10, 26, 18, 34]$.

Each GPU “owns” one chunk: GPU 0 owns chunk A (element 0), GPU 1 owns chunk B (element 1), and so on.

Phase 1: Scatter-Reduce (3 steps)

Each GPU sends one chunk or partial sum to its right neighbor, which adds the received value to its local copy. Table 6.6 traces the three sequential steps across all four GPUs:

Table 6.6: Ring AllReduce Scatter-Reduce trace: Three sequential steps across 4 GPUs.

Step	GPU 0 sends	GPU 1 sends	GPU 2 sends	GPU 3 sends	After receive and add:
1	chunk A (1) → GPU 1	chunk B (6) → GPU 2	chunk C (5) → GPU 3	chunk D (10) → GPU 0	GPU 0: D=17, GPU 1: A=3, GPU 2: B=13, GPU 3: C=11
2	chunk D (17) → GPU 1	chunk A (3) → GPU 2	chunk B (13) → GPU 3	chunk C (11) → GPU 0	GPU 0: C=14, GPU 1: D=25, GPU 2: A=6, GPU 3: B=21
3	chunk C (14) → GPU 1	chunk D (25) → GPU 2	chunk A (6) → GPU 3	chunk B (21) → GPU 0	GPU 0: B=26, GPU 1: C=18, GPU 2: D=34, GPU 3: A=10

After Phase 1, each GPU holds the *complete sum* for exactly one chunk: GPU 0 has the global sum for element B (26), GPU 1 for C (18), GPU 2 for D (34), GPU 3 for A (10).

Phase 2: AllGather (3 steps)

Each GPU sends its fully reduced chunk around the ring so all GPUs receive all results. Table 6.7 shows the three forwarding steps that complete the collective:

Table 6.7: Ring AllReduce AllGather trace: Three sequential steps in which each GPU forwards its fully-reduced chunk around the ring.

Step	Action	Result
4	Each sends its complete chunk to right neighbor	Each GPU now has 2 of 4 final chunks
5	Continue forwarding	Each GPU now has 3 of 4 final chunks
6	Final forwarding	All GPUs hold [10, 26, 18, 34]

The total data movement per GPU is fixed by the ring schedule: in each of the $2(N-1) = 6$ steps, each GPU sends exactly $M/N = 1$ element. Total per GPU: $6 \times 1 = 6$ elements sent, 6 received.

The trace leaves two mechanics to verify before moving on: the $2(N-1)$ step count, and that every rank sends and receives in each step.

Checkpoint 6.2: Ring AllReduce mechanics

Verify your understanding of bandwidth-optimal reduction:

- ☐ **Step count:** Calculate the number of **sequential steps** required for a ring of N GPUs to complete the full AllReduce.
- ☐ **Bandwidth optimality:** Explain why Ring AllReduce is bandwidth-optimal, including how many times each byte of the total message M traverses the network per GPU.
- ☐ **Straggler impact:** Determine the impact on total collective completion time when one GPU in the ring is 50 percent slower than the others.
- ☐ **Send/receive duality:** Assess the True or False claim that every GPU is both a sender and a receiver in every step of Ring AllReduce.

The trace above illustrates the key property of Ring AllReduce: at every step, every link in the ring is active, with data flowing in the same direction. No GPU ever sits idle, and no link is underutilized. This uniform link utilization is what makes Ring bandwidth-optimal.

The performance follows directly from the algorithm structure. Each node sends and receives $\frac{M}{N}$ bytes in each of the $2(N-1)$ steps.

$$T_{\text{ring}} = \underbrace{2(N-1)\alpha}_{\text{Latency Term}} + \underbrace{2\frac{N-1}{N}\frac{M}{\beta}}_{\text{Bandwidth Term}}$$

- **Bandwidth:** As $N \rightarrow \infty$, the term approaches $2M/\beta$. This is theoretically optimal (each byte must be sent once and received once).
- **Latency:** The latency scales linearly with N . For 10,000 nodes, 20,000 sequential hops creates massive latency. This is why Ring is bad for small messages.

6.4.4 Tree AllReduce

Ring AllReduce pays a high price in latency for its bandwidth optimality. When a cluster grows to thousands of GPUs and the message size is moderate (a few megabytes), the $2(N-1)\alpha$ latency term dwarfs the bandwidth term, and the algorithm spends most of its time in sequential hops rather than in useful data transfer. To address this linear latency, Tree AllReduce uses a binary tree structure that works in two phases. In the reduce phase, leaves send to their parents, which sum the incoming values and pass them up, reaching the root in $\log_2 N$ steps. In the broadcast phase, the root sends the result back down to the leaves in another $\log_2 N$ steps.

Tree AllReduce has worse bandwidth efficiency because of link underutilization. In Ring AllReduce, every node sends and receives simultaneously, so all N links are active at every step. In Tree AllReduce, only a fraction of links are active at any time, and that fraction shrinks at every level. At the leaves, $N/2$ nodes send to $N/2$ parents, leaving half the nodes as idle receivers; at the next level up, $N/4$ nodes send to $N/4$ parents, leaving three-quarters idle; at the root, only two nodes communicate while the remaining $(N-2)$ sit idle. The result is that while Ring achieves near-100 percent link utilization for large messages on a balanced ring, a simple tree can leave many links idle and concentrate traffic near the root or interior links.

The resulting time complexity depends on the specific tree variant. A simple reduce-then-broadcast tree has logarithmic latency but nonuniform traffic and root/interior bottlenecks; recursive-doubling-style variants can incur $\mathcal{O}(\log N)$ full-message bandwidth per rank. The simplified model below captures the latency advantage and the potential bandwidth penalty of tree-like collectives:

$$T_{\text{tree-like}} \approx \underbrace{2\log_2 N \cdot \alpha}_{\text{Latency}} + \underbrace{2\log_2 N \frac{M}{\beta}}_{\text{Bandwidth penalty in full-message exchange variants}}$$

The latency term is logarithmic ($\mathcal{O}(\log N)$): for 1024 nodes, Ring needs 2046 steps while Tree needs only 20, and that $100\times$ reduction in steps makes Tree the preferred algorithm for latency-sensitive collectives such as tensor parallelism's per-layer AllReduce, where message sizes are small but frequency is high. The bandwidth term carries the penalty, because tree-like algorithms can underutilize links or concentrate traffic on interior links, and recursive-doubling-style full-message exchanges add a $\log_2 N$ bandwidth factor; these penalties make naive tree variants a poor choice for data parallelism's large gradient AllReduce, where bandwidth efficiency determines whether the network is saturated or partially idle.

This bandwidth penalty is catastrophic for large-scale data parallelism when the implementation repeatedly exchanges full messages or creates root/interior bottlenecks. For a 70B-parameter model's 140 GB gradient AllReduce across 1,000 GPUs, a bandwidth-inefficient tree-like variant can erase the latency advantage that motivated it. Optimized double-tree algorithms exist precisely to keep logarithmic latency without imposing that naive bandwidth penalty.

Tree AllReduce is, however, the correct choice when latency is the primary bottleneck, typically for smaller collectives with small message sizes. The canonical use case is a latency-sensitive AllReduce required by tensor parallelism, which operates on activations or weight gradients within a single layer. For an 8-GPU group inside a node communicating a small 1 MB tensor, the latency drops from Ring's $2(8-1)\alpha = 14\alpha$ to Tree's $2\log_2(8)\alpha = 6\alpha$. The bandwidth penalty is modest at that size, so reducing sequential startup steps can win.

6.4.5 Recursive halving-doubling (butterfly)

Ring and Tree represent two extremes of the latency-bandwidth trade-off: Ring is *bandwidth-optimal but latency-poor*, while Tree is *latency-optimal but bandwidth-poor*. A third approach combines the logarithmic latency of Tree with better bandwidth utilization. The **Recursive Halving-Doubling** algorithm (sometimes called the Butterfly algorithm) operates in $\log_2 N$ rounds. In each round k , every GPU exchanges data with a partner at distance 2^k in the logical numbering, and the message size halves (in the ReduceScatter phase) or doubles (in the AllGather phase).

In the ReduceScatter phase (first $\log_2 N$ rounds), GPU i partners with GPU $i \oplus 2^k$ (XOR of indices), and they exchange half of their current data. After receiving, each GPU sums its half with the received half, then discards the other half. After $\log_2 N$ rounds, each GPU holds M/N bytes of the fully reduced result. The AllGather phase reverses the process: in each round, partners exchange their reduced chunks, doubling the data each GPU holds until all GPUs have the complete result.

The performance of Recursive Halving-Doubling is:

$$T_{\text{butterfly}} = 2 \log_2 N \cdot \alpha + 2 \frac{N-1}{N} \cdot \frac{M}{\beta}$$

This achieves the best of both worlds: logarithmic latency ($\mathcal{O}(\log N)$, like Tree) and bandwidth-optimal data movement ($2(N-1)/N \cdot M/\beta$, like Ring). The catch is that it requires nonneighbor communication (GPU i must communicate with GPU $i \oplus 2^k$, which may be physically distant), and it requires N to be a power of two. For clusters where N is not a power of two, additional complexity is needed to handle the irregular cases.

Recursive halving-doubling is used in MPI-style collective implementations and is useful as a theoretical point in the latency-bandwidth trade-off (Thakur et al. 2005). NCCL's implementation families include ring, tree-derived, hierarchical, NVLink/NVSwitch-aware, and pattern-aware choices, with exact names and availability changing by version and topology (Jeaugey 2017; NVIDIA 2026b). The durable point is not the label on a particular release: practical communication libraries select algorithms through a topology-aware cost model because nonlocal communication patterns can create contention on shared network links that erodes theoretical advantages.

Sequence parallelism and Mixture of Experts routing expose the topology sensitivity of recursive halving-doubling most sharply. In sequence parallelism, AllGather reconstructs activation shards and ReduceScatter redistributes them along the sequence dimension—the inter-rank exchange schedule follows the same distance-doubling logic as the butterfly algorithm. In MoE routing, each token must reach any of N expert GPUs, creating the same fan-out pattern: a butterfly-style schedule produces cross-boundary pairings in the final round because token dispatch must traverse the full cluster diameter. The following eight-GPU ReduceScatter trace shows exactly how those long-distance crossings emerge.

To make this concrete, consider the ReduceScatter phase for 8 GPUs, which proceeds in $\log_2(8) = 3$ rounds. In round $k = 0$, each GPU i partners with GPU $i \oplus 1$, pairing neighbors: (0,1), (2,3), (4,5), (6,7). They exchange half their data and reduce. In round $k = 1$, the distance doubles: GPU i partners with GPU $i \oplus 2$, creating pairs (0,2), (1,3), (4,6), (5,7). In round $k = 2$, the distance doubles again: GPU i partners with GPU $i \oplus 4$, creating pairs (0,4), (1,5), (2,6), (3,7).

The problem with this pattern becomes clear on real hardware. The round $k = 2$ pairings force communication across physical boundaries. If GPUs 0–3 are on one node and 4–7 are on another, this final round creates cross-node traffic between the two nodes. For our 1,000-GPU cluster (approximated as 1,024 for the algorithm), the final round pairs GPU i with GPU $i \oplus 512$, forcing GPUs in the first half of the cluster to communicate with partners in the second half and potentially flooding the high-level network fabric that connects server racks. This topology-oblivious communication pattern is why Butterfly's theoretical optimality does not translate to practical superiority on large hierarchical clusters.

6.4.6 Double binary tree

NCCL can use a **Double Binary Tree** for many message sizes and topologies, which addresses the bandwidth inefficiency of a standard binary tree without requiring the nonlocal communication of

Butterfly (Jeauguey 2017; NVIDIA 2026b). The idea is to construct two independent binary trees that together cover all links, then run both trees simultaneously, each carrying half the data.

In a standard binary tree, at each level only half the links are active (the other half are idle because those nodes are receiving, not sending). By constructing a second, complementary tree (rooted at a different node, with edges that cover the links unused by the first tree), both trees can operate in parallel. Each tree carries $M/2$ bytes, and since their link utilization is complementary, the aggregate link utilization approaches 100 percent, matching Ring’s bandwidth efficiency while retaining Tree’s $\mathcal{O}(\log N)$ latency.

The combined performance is approximately:

$$T_{\text{double-tree}} \approx 2 \log_2 N \cdot \alpha + \frac{2M}{\beta}$$

In practice, the bandwidth term approaches $2M/\beta$ (optimal) while maintaining logarithmic latency. This makes Double Binary Tree a strong choice across a wide range of message sizes and cluster counts, which is why communication libraries select it in many configurations. The algorithm requires careful construction of the two complementary trees to ensure they do not create link contention, a problem that NCCL’s topology-aware graph search addresses during initialization.

The double binary tree’s broad competitiveness across message sizes explains why PyTorch DDP and FSDP bucket sizes (typically 25–100 MB) frequently fall into exactly the crossover territory where neither Ring nor pure Tree is clearly optimal. A bucket at 25 MB sits near the Ring-Tree crossover for medium-scale clusters, and a bucket at 100 MB begins to favor Ring on slow networks. Double binary tree handles this middle ground well, which is one reason NCCL dynamically selects it for many DDP/FSDP gradient synchronization calls rather than committing unconditionally to Ring.

Table 6.8 summarizes the AllReduce algorithm comparison and the performance characteristics of the four algorithms. As figure 6.6 illustrates, the choice between algorithms depends on message size: Tree dominates for small messages while Ring wins for large ones.

Table 6.8: AllReduce Algorithm Comparison: Each algorithm occupies a different point in the latency-bandwidth trade-off space. Ring and Butterfly achieve bandwidth optimality with different latency characteristics, while Double Binary Tree provides the best practical compromise.

Algorithm	Latency	Bandwidth	Bandwidth Optimal?	Constraint
Ring	$\mathcal{O}(N)\alpha$	$2 \frac{N-1}{N} \frac{M}{\beta}$	Yes	None
Tree	$\mathcal{O}(\log N)\alpha$	$\mathcal{O}(\log N) \frac{M}{\beta}$	No	None
Butterfly	$\mathcal{O}(\log N)\alpha$	$2 \frac{N-1}{N} \frac{M}{\beta}$	Yes	$N = 2^k$
Double Tree	$\mathcal{O}(\log N)\alpha$	$\approx \frac{2M}{\beta}$	Near-optimal	Complementary tree construction

6.4.7 The algorithm crossover point

The crossover point in figure 6.6, where Ring overtakes Tree, follows from setting $T_{\text{ring}} = T_{\text{tree}}$ and solving for M . The full time equations make the trade-off explicit:

$$T_{\text{ring}} = 2(N-1)\alpha + 2 \frac{N-1}{N} \frac{M}{\beta}$$

$$T_{\text{tree}} = 2 \log_2 N \cdot \alpha + 2 \log_2 N \cdot \frac{M}{\beta}$$

For large N , $(N-1) \approx N$ and $\frac{N-1}{N} \approx 1$, so the ring pays a latency term proportional to N while moving each byte close to the bandwidth limit:

$$T_{\text{ring}} \approx 2N\alpha + \frac{2M}{\beta}, \quad T_{\text{tree}} \approx 2 \log_2 N \cdot \alpha + \frac{2 \log_2 N \cdot M}{\beta}$$

Figure 6.6: Algorithm Crossover in Collective Communication: Performance analysis of Ring, Tree, and Double Binary Tree AllReduce algorithms across message sizes (1 KB to 10 GB) for a 256-GPU cluster with 200 Gbps interconnect.

The tree has the opposite shape: logarithmic startup cost, but each message byte moves through more stages. Setting the estimates equal isolates the message size where the cheaper latency path stops compensating for the extra bandwidth work:

$$\begin{aligned}
 2N\alpha + \frac{2M}{\beta} &= 2\log_2 N \cdot \alpha + \frac{2\log_2 N \cdot M}{\beta} \\
 \frac{2M}{\beta} - \frac{2\log_2 N \cdot M}{\beta} &= 2\log_2 N \cdot \alpha - 2N\alpha \\
 \frac{2M}{\beta}(1 - \log_2 N) &= 2\alpha(\log_2 N - N)
 \end{aligned}$$

Since $N \gg \log_2 N$ for large clusters, $(\log_2 N - N) \approx -N$ and $(1 - \log_2 N) \approx -\log_2 N$, yielding:

$$\begin{aligned}
 \frac{2M}{\beta}(-\log_2 N) &\approx 2\alpha(-N) \\
 M_{\text{crossover}} &\approx \frac{N \cdot \alpha \cdot \beta}{\log_2 N}
 \end{aligned}$$

For a rough upper-scale mental model, engineers sometimes drop the logarithmic factor:

$$M_{\text{crossover}} \approx N \cdot \alpha \cdot \beta$$

The log-aware crossover formula yields a useful intuition, not a hard selection rule. Above the crossover, message size dominates and Ring's bandwidth efficiency wins; below it, startup latency dominates and Tree's logarithmic depth wins.

For a cluster with $\alpha = 5 \mu\text{s}$, $\beta = 50 \text{ GB/s}$, and $N = 100$, the direct approximation gives:

$$M_{\text{crossover}} \approx \frac{100 \times 5 \cdot 10^{-6} \times 50 \cdot 10^9}{\log_2 100} \approx 3.8 \text{ MB}$$

In practice, NCCL’s algorithm selection is more nuanced than a simple two-way split. The Double Binary Tree algorithm offers logarithmic latency with near-optimal bandwidth, making it competitive with both Ring and Tree across a broad range of message sizes. NCCL also considers the number of channels (parallel communication streams), the network topology, and whether inter-node or intra-node links are being used. The effective selection logic resembles a multi-way decision tree indexed by (message size, GPU count, topology type) rather than a single crossover point.

Nevertheless, the crossover formula remains the essential mental model for understanding *why* libraries make the choices they do. When a library selects an unexpected algorithm, the crossover analysis provides the reasoning framework to evaluate whether the choice is correct or whether manual override is warranted. A concrete buffer-size calculation applies this framework to a realistic decision:

Napkin Math 6.5: The ring vs. tree crossover

Problem: A cluster synchronizes a 1 MB buffer across 64 GPUs. The network has latency $\alpha = 10 \mu\text{s}$ and bandwidth $\beta = 10 \text{ GB/s}$. Which algorithm performs better: Ring or Tree?

Math:

Latency:

1. **Ring Latency:** $2(N-1)\alpha = 2 \times 63 \times 10 \mu\text{s} = 1260 \mu\text{s}$.
2. **Tree Latency:** $2(\log_2 N)\alpha = 2 \times 6 \times 10 \mu\text{s} = 120 \mu\text{s}$.

Bandwidth (note the difference):

3. **Ring Bandwidth:** $2 \frac{N-1}{N} \frac{M}{\beta} \approx 2 \times \frac{1 \text{ MB}}{10 \text{ GB/s}} = 196.9 \mu\text{s}$ (optimal: each byte sent once).
4. **Tree Bandwidth:** $2 \log_2 N \cdot \frac{M}{\beta} = 12 \times \frac{1 \text{ MB}}{10 \text{ GB/s}} = 1200 \mu\text{s}$ (each level sends full message).

Table 6.9 sums the latency and bandwidth contributions into a head-to-head comparison:

Table 6.9: Ring vs. tree AllReduce timing for a 1 MB buffer on 64 GPUs: Latency, bandwidth, and total-time terms with $\alpha = 10 \mu\text{s}$ and $\beta = 10 \text{ GB/s}$.

Algorithm	Latency	Bandwidth	Total
Ring	1260 μs	196.9 μs	1456.9 μs
Tree	120 μs	1200 μs	1320 μs

Tree wins, but only by 9 percent. For this 1 MB message, we are near the crossover point.

Systems insight: Ring’s latency penalty ($10\times$ worse than Tree) nearly balances Tree’s bandwidth penalty ($6\times$ worse than Ring). The log-aware crossover estimate predicts $M_{\text{crossover}} \approx N\alpha\beta/\log_2 N = 64 \times 10 \mu\text{s} \times 10 \text{ GB/s}/6 \approx 1.1 \text{ MB}$. At 1 MB, we are just below crossover, so Tree wins. At 10 MB, Ring would dominate.

The crossover point sits inside the range that DDP and FSDP workloads traverse during normal training. A 1 MB message corresponds to gradients from a single feed-forward layer in a smaller transformer, or an MoE token-routing payload—Tree territory. A 10 MB DDP gradient bucket from a mid-size transformer layer sits near the crossover. A fused DDP bucket covering multiple layers reaches 50–300 MB; a full BF16 gradient tensor for a 70B parameters model reaches 1120 GB—both firmly in Ring territory. Most real training workloads sweep through this entire range as bucket sizes are tuned, and the crossover analysis sets the algorithmic boundary that separates bucket-level Tree operations from full-model Ring synchronizations.

The crossover analysis demonstrates that algorithm selection is not a static choice but depends on the specific combination of message size, cluster scale, and network parameters. In practice, communication libraries like NCCL maintain internal lookup tables that map message size, GPU count, topology, and protocol settings to selected algorithms such as Ring, Tree, or hybrid approaches.

Understanding the underlying crossover math allows engineers to predict when the library’s built-in choices may be suboptimal and to override them when necessary.

📌 Checkpoint 6.3: AllReduce algorithm selection

Verify your understanding of Ring vs. Tree AllReduce trade-offs:

- ❑ **Ring vs. Tree:** Explain why Ring AllReduce achieves bandwidth-optimal communication (approaching $2M/\beta$) while Tree AllReduce incurs $\mathcal{O}(\log N)$ bandwidth overhead.
- ❑ **Crossover point:** Calculate $M_{\text{crossover}}$ for a 256-GPU cluster with $\alpha = 5 \mu\text{s}$ and $\beta = 50 \text{ GB/s}$, then determine whether a 10 MB gradient buffer should use Ring or Tree.
- ❑ **Scatter-reduce trace:** Trace through the Scatter-Reduce phase of Ring AllReduce for 3 GPUs with a 3-element vector and verify that each GPU ends with the correct partial sum.
- ❑ **Latency limit:** Explain why Ring AllReduce’s $\mathcal{O}(N)$ latency makes it impractical for tensor parallelism, where message sizes are small and latency dominates.

6.5 Hierarchical Communication

The algorithms above assume a flat network where every link has the same bandwidth. Real data centers violate this assumption by an order of magnitude or more. Not all wires are created equal.

Hierarchical communication is the response to that inequality. Intra-node links are abundant and fast, inter-node links are scarce and expensive, and the algorithm must shrink payloads before they cross the scarce tier whenever possible. This is why the same AllReduce can be implemented as a local ReduceScatter, a cross-node reduction, and a local AllGather rather than as one flat exchange across every rank.

A GPU node delivers an order of magnitude more intra-node bandwidth (NVLink at 900 GB/s) than inter-node bandwidth (InfiniBand at 50 GB/s).

6.5.1 Hierarchical AllReduce

The algorithms above (Ring, Tree, Butterfly, Double Binary Tree) all assume a flat network where every link has the same bandwidth. This assumption holds within a single node (where all GPUs are connected by NVLink at equal bandwidth) but fails by $9\times$ in multi-node clusters. Real clusters are hierarchical networks, with fundamentally different bandwidths at each tier, as table 6.10 quantifies.

Table 6.10: The Bandwidth Hierarchy: Modern GPU clusters exhibit an order-of-magnitude bandwidth gap between intra-node and inter-node communication. Hierarchical algorithms exploit this gap. Relative speed compares per-direction rates (NVLink’s 450 GB/s one-way against InfiniBand’s 50 GB/s per port); the bandwidth column shows NVLink’s bidirectional datasheet total.

Tier	Interconnect	Bandwidth	Relative Speed
Intra-Node	NVLink 4.0	~900 GB/s	$9\times$ faster
Inter-Node	InfiniBand NDR 400G	~50 GB/s	$1\times$ (baseline)

A naive flat Ring AllReduce ignores this structure, potentially routing data across InfiniBand when NVLink would suffice and wasting the scarce inter-node bandwidth. **Hierarchical AllReduce** decomposes the global operation into three phases that respect the bandwidth hierarchy, as shown in figure 6.7.

The three-phase decomposition in figure 6.7 confines the expensive inter-node traffic to Phase 2, where each GPU transmits only M/G bytes instead of M . With $G = 8$ GPUs per node (a typical DGX configuration), this reduces inter-node traffic by $8\times$, effectively multiplying the scarce InfiniBand bandwidth by the number of GPUs per node.

The phases form one causal chain:

Hierarchical collectives shrink payload before it crosses slow tiers.

Figure 6.7: Hierarchical AllReduce: Three-phase decomposition that exploits the intra-node/inter-node bandwidth gap. Phase 1 performs intra-node aggregation over NVLink (an NVLink ring acting as a ReduceScatter that leaves each GPU holding a node-shard partial sum), reducing inter-node traffic by a factor of G (GPUs per node). Phase 2 runs an AllReduce across corresponding GPUs using InfiniBand. Phase 3 completes intra-node distribution over NVLink (the AllGather that returns each GPU to the full result). The figure labels these phases by their NVLink/IB mechanics; the prose below names the corresponding collective primitives.

1. **Intra-node ReduceScatter over NVLink:** A local reduction among the G GPUs in each node leaves each GPU with $1/G$ of the partially reduced data, using only abundant intra-node bandwidth.
2. **Inter-node AllReduce over InfiniBand:** Each GPU sends its node shard across corresponding GPU positions, transmitting M/G bytes instead of M .
3. **Intra-node AllGather over NVLink:** Each node redistributes the final shards internally, completing the result without consuming additional inter-node bandwidth.

A simple 8-node budget makes this bandwidth multiplication concrete:

Napkin Math 6.6: The hierarchical bandwidth multiplier

Problem: A cluster has 8 nodes, each with 8 GPUs (64 total). The system must AllReduce a 1 GB gradient buffer. Compare flat Ring AllReduce vs. Hierarchical AllReduce.

Flat ring AllReduce (ignoring hierarchy):

- Each GPU sends ~2 GB total (the bandwidth-optimal Ring AllReduce formula).
- The ring crosses node boundaries multiple times.
- **Effective bandwidth:** Limited by the slowest link = 50 GB/s (InfiniBand).
- **Time:** $\approx 2 \times 1 \text{ GB} / 50 \text{ GB/s} = 40 \text{ ms}$ (bandwidth term dominates).

Hierarchical AllReduce (3-step decomposition):

1. **Intra-node ReduceScatter:** Each GPU sends 875 MB at 450 GB/s per direction $\rightarrow \sim 1.94 \text{ ms}$

2. **Inter-Node AllReduce:** Each GPU AllReduces a $1\text{ GB}/8 = 125\text{ MB}$ shard over InfiniBand; Ring moves roughly $2(N-1)/N$ times that payload, and after adding the small latency term the phase takes $\sim 4.42\text{ ms}$ at 50 GB/s (Only $1/8$ of the data crosses InfiniBand!)
3. **Intra-node AllGather:** Each GPU receives 875 MB at 450 GB/s per direction $\rightarrow \sim 1.94\text{ ms}$
4. **Total time:** $\approx 1.94\text{ ms} + 4.42\text{ ms} + 1.94\text{ ms} = 8.3\text{ ms}$

Systems insight: Hierarchical AllReduce achieves a $4.8\times$ speedup by reducing the inter-node payload from 1 GB to 125 MB per GPU before the Ring traffic multiplier. With 8 GPUs per node, we effectively get $8\times$ the apparent inter-node bandwidth. This is why NVIDIA's NCCL and similar libraries often select hierarchical algorithms on multi-node clusters when the topology supports them.

These three phases confine most traffic within each node before crossing the slower inter-node fabric, and the same idea generalizes beyond two levels. Large clusters with multiple racks connected through spine switches introduce a third bandwidth tier (rack-to-rack at reduced bisection bandwidth). At 128 GPUs arranged as 4 racks of 4 nodes of 8 GPUs with $2:1$ cross-rack oversubscription, applying the same decomposition at each tier shrinks the cross-rack payload per GPU by $32\times$ compared to the original gradient—roughly 15 ms total versus 160 ms for flat AllReduce. The hierarchical decomposition concentrates traffic where bandwidth is abundant and minimizes traffic where bandwidth is scarce.

6.5.2 In-network reduction: SHARP and beyond

The contrast in figure 6.8 shows the next step: move the reduction work from endpoint GPUs into the switch ASIC so packets are aggregated while they traverse the fabric.

Hierarchical AllReduce reduces the volume of cross-node traffic, but the aggregation still requires multiple network round-trips. NVIDIA's **Scalable Hierarchical Aggregation and Reduction Protocol (SHARP)**¹⁰ implements this idea: instead of gradients traveling to a destination GPU for summation, the InfiniBand switch aggregates partial sums as data packets pass through it.

The benefit is twofold. First, SHARP reduces endpoint memory traffic and can reduce pressure on upper-level links by aggregating packets before they leave a switch tier. In a software-based tree reduction, data arrives at a GPU, is written to memory, summed with local data, and then transmitted to the next level. With SHARP, the switch combines incoming packets in flight and forwards the aggregate for the reduction tree. Second, SHARP eliminates the store-and-forward path through intermediate GPUs. Each software hop adds the full α/β cost; with in-switch aggregation, the reduction happens inside the switch ASIC rather than in endpoint memory.

The practical impact is most pronounced for message sizes where aggregation latency contributes meaningfully to total AllReduce time. For very large messages, bandwidth dominates regardless of algorithm, and SHARP's latency reduction becomes proportionally smaller. For very small messages, fixed switch-processing overhead can limit the benefit. Graham et al. (2020) report multi-fold reduction-bandwidth improvements and smaller application-level gains for PyTorch workloads when SHARP Streaming-Aggregation is enabled on HDR/Quantum InfiniBand switches.

Strong scaling campaigns—training a fixed model across more accelerators without proportionally growing batch size—are precisely the workloads where SHARP's latency reduction translates into step-time reduction. As the per-accelerator batch shrinks, each gradient tensor stays large (proportional to model size) but the backward pass per accelerator shortens, so communication dominates an increasing fraction of step time and the latency term α in the ring formula hits the bottleneck. In-switch aggregation cuts directly into that latency cost. Switch ASIC vendors have explicitly extended InfiniBand ASICs to support ML-native datatypes, including FP16 and BF16, confirming that SHARP is co-evolving with ML workload requirements rather than serving only the legacy HPC floating-point operations that motivated its original design. An ML system team choosing SHARP infrastructure for a scaling campaign should verify FP16/BF16 aggregation support in the specific switch generation, since earlier ASICs supported only FP32 and INT32.

10 | **SHARP (Scalable Hierarchical Aggregation and Reduction Protocol):** In-network computing on Quantum InfiniBand switches that performs reduction operations (such as sum, min, and max) as packets traverse an aggregation tree (Graham et al. 2020). Graham et al. report substantially higher reduction bandwidth than host-based algorithms and describe switch-resource limits on outstanding aggregation groups and trees, which can create contention when many collectives compete for the same in-network resources.

Figure 6.8: In-Network Reduction (SHARP): Side-by-side comparison split by a vertical divider. The left side shows a traditional tree AllReduce performing reduction at intermediate GPUs, incurring multiple store-and-forward delays. The right side shows SHARP offloading the reduction to the network switch ASIC, allowing partial sums to be aggregated at line rate as packets traverse the switch. This eliminates GPU memory traffic and store-and-forward latency, significantly accelerating small-to-medium message collectives.

SHARP does impose constraints. The switch must support the specific reduction operation (typically limited to sum, min, and max on floating-point and integer types). The number of concurrent SHARP aggregation trees is limited by switch resources, so large clusters with many simultaneous training jobs may exhaust SHARP capacity. Additionally, SHARP requires InfiniBand infrastructure; it is not available on Ethernet-based fabrics.

6.5.3 Topology-aware routing

Hierarchical AllReduce reduces inter-node traffic, and SHARP eliminates some of it entirely, but neither technique addresses a subtler problem: how the logical communication pattern maps to the physical network topology. A Ring AllReduce among 64 GPUs creates a logical ring, but which physical links carry each hop determines whether the ring achieves peak bandwidth or creates congestion. Two runs of the same training job on the same hardware can differ by $2\times$ in communication throughput depending on how ranks are assigned to GPUs and how the resulting traffic pattern interacts with the network’s physical structure.

Communication libraries like NCCL perform **topology detection** at initialization, running graph search algorithms to discover the physical network structure and find high-bandwidth communication paths (NVIDIA 2026b). The library must determine, for each pair of ranks, whether the peer sits on a local NVLink switch or 100 meters away across an InfiniBand fabric, because the same collective algorithm can differ by $2\times$ or more in throughput depending on how logical ranks map to physical hardware.

The topology detection process begins with hardware enumeration. NCCL queries the PCIe bus to discover GPU placement, NVLink connectivity between GPUs, and NIC-to-PCIe-switch affinity. From this information, it constructs an internal graph where nodes represent GPUs and edges represent physical links with annotated bandwidth and latency. A graph search algorithm then finds communication paths that maximize aggregate bandwidth while minimizing the number of cross-

domain hops (transitions between NVLink, PCIe, and InfiniBand domains). This topology-aware path selection is what allows NCCL to approach theoretical peak bandwidth on well-configured systems, while topology-unaware implementations can leave a large fraction of bandwidth unused.

6.5.3.1 Torus topology (TPU pods)

The dimension-ordered reduction in figure 6.9 shows why torus fabrics use the physical mesh directly instead of pretending the pod is a flat all-to-all network.

Figure 6.9: Dimension-Ordered Reduction on Torus Topology: In a 2D torus mesh (a simplified representation of 3D TPU pods), AllReduce is decomposed into two sequential steps along the X and Y dimensions. By reducing along one dimension at a time, the system minimizes network diameter and avoids link contention, ensuring that each direct neighbor link operates at full bandwidth.

Google’s Tensor Processing Unit (TPU) pods use a 3D torus topology where each TPU connects directly to 6 neighbors ($\pm X, \pm Y, \pm Z$); figure 6.9 depicts the same dimension-ordered idea as a 2D simplification. Unlike the hierarchical fat-tree topology of InfiniBand clusters, the torus provides uniform, direct connectivity: every TPU chip has the same number of links (6) and the same per-link bandwidth, regardless of its position in the mesh. The optimal AllReduce strategy for this topology is **dimension-ordered reduction**:

1. Reduce along X for each fixed (Y, Z) line, producing partial sums over the X dimension
2. Reduce those partials along Y for each fixed (X, Z) line, producing partial sums over the $X \times Y$ plane
3. Reduce those partials along Z for each fixed (X, Y) line to complete the global result

Each dimension-ordered reduction is itself a Ring AllReduce along one axis-aligned torus ring. For a pod with $X \times Y \times Z$ TPUs, the first step runs independent X-dimension rings, one for each fixed (Y, Z) coordinate, so each participant receives a partial sum over that X line. The second step runs Y-dimension rings to combine those X partials across Y, and the third step runs Z-dimension rings to complete the global reduction. This cascading reduction achieves total bandwidth cost $2M/\beta$ (same as a single Ring) but with latency proportional to $2(X + Y + Z)$ rather than $2(X \times Y \times Z)$, because each dimension’s ring is shorter than a global ring.

Dimension-ordered reduction minimizes network diameter and ensures each link carries traffic in only one direction at a time, avoiding congestion. The torus topology also provides natural fault

tolerance through alternate routing paths: if one link in the X-dimension fails, traffic can detour through the Y or Z dimensions (at the cost of increased latency). Google’s Accelerated Linear Algebra (XLA) compiler generates dimension-ordered collectives automatically when targeting TPU pods, abstracting the topology details from the user.

6.5.3.2 Rail-optimized routing (NVIDIA DGX)

In NVIDIA DGX systems, each GPU has its own dedicated NIC (network interface card). Rail-optimized routing exploits this by ensuring that GPUs at the same position within their respective nodes communicate only with each other:

- GPU 0 on Node A talks only to GPU 0 on Node B, Node C, and so on.
- GPU 1 on Node A talks only to GPU 1 on other nodes.
- And so on for GPUs 2–7.

This creates 8 independent “rails” of communication that operate in parallel without contention, as table 6.11 illustrates.

Table 6.11: Rail-Optimized Traffic Distribution: Each rail carries 1/8 of the total traffic independently.

Rail	Participants	Traffic
Rail 0	Node0-GPU0 Node1-GPU0 Node2-GPU0 ...	$M/8$ each
Rail 1	Node0-GPU1 Node1-GPU1 Node2-GPU1 ...	$M/8$ each
...	...	...
Rail 7	Node0-GPU7 Node1-GPU7 Node2-GPU7 ...	$M/8$ each

Rail alignment is critical because without it, all 8 GPUs on a node might try to send to the same remote GPU simultaneously, creating $8\times$ contention on a single NIC. Rail-aligned routing ensures each NIC handles exactly 1/8 of the traffic, achieving full bisection bandwidth utilization.

Rail-optimized routing and hierarchical AllReduce reinforce each other. In the hierarchical decomposition described earlier, Step 2 (inter-node AllReduce) naturally aligns with rail topology. GPU i on each node communicates only with GPU i on other nodes, which is precisely the rail pattern. This alignment is not coincidental; NVIDIA designed the DGX hardware with rail-optimized communication in mind, and NCCL’s hierarchical algorithms can exploit this structure when the topology is detected and ranks are mapped correctly. When the logical communication pattern matches the physical topology, each NIC carries its intended share of traffic and the cluster can approach its theoretical peak bisection bandwidth.

Misalignment between logical and physical topology is a common source of performance degradation that is difficult to diagnose without careful profiling. If process ranks are assigned arbitrarily (for example, by the job scheduler without topology awareness), the hierarchical AllReduce may route cross-node traffic through the wrong NICs, creating hotspots that reduce effective bandwidth by $2\text{--}4\times$. Large deployments use topology-aware rank assignment (configured through NCCL’s `CUDA_VISIBLE_DEVICES` and the scheduler’s GPU binding policies) to ensure alignment.

The hierarchical approach, combined with topology-aware routing, represents the culmination of the algorithms explored in this section: the α - β model identifies the bottleneck (inter-node bandwidth), hierarchical decomposition reduces traffic across that bottleneck, and rail optimization ensures the reduced traffic flows without contention. Together, these techniques close the gap between theoretical peak bandwidth and achieved bandwidth on well-configured clusters.

6.6 Gradient Compression Under Bandwidth Scarcity

Even after topology tuning and algorithm selection, a system may remain bandwidth-bound because the physical fabric cannot move gradient payloads fast enough. In that regime, sending fewer bits becomes a deliberate design choice rather than a universal last resort. The previous section attacked the communication bottleneck from the scheduling and topology side; payload compression attacks the same bottleneck by changing what crosses the fabric.

The bandwidth wall arises most acutely in two scenarios: training across data centers connected by wide-area networks (where bandwidth is 10–100 $\times$ lower than InfiniBand), and training on cloud instances with commodity Ethernet networking where RDMA is unavailable or constrained. In these bandwidth-constrained settings, gradient compression techniques can reduce communication volume by 4–1000 $\times$, at the cost of introducing noise into the optimization process. The central tension is between bandwidth reduction and the noise tolerance of the optimization process—how much compression the optimizer can absorb before convergence is compromised.

6.6.1 Quantization: Reducing precision

Quantization is the least disruptive compression lever when bandwidth is binding because it keeps every gradient element but reduces the bits used to represent it. Most gradients are computed in FP32 (32-bit floating point) or BF16 (16-bit brain float), so reducing bit-width directly reduces communication volume. The useful question is how much gradient fidelity the optimizer can absorb, and the progression from mild to aggressive quantization illustrates the trade-off between compression ratio and gradient fidelity:

1. **FP16 (16-bit)**: A common baseline for accelerator training. Half the bits of FP32, with minimal impact on convergence for many models. Provides 2 $\times$ compression over FP32.
2. **INT8 (8-bit)**: Quantize each gradient vector to 256 discrete levels. This requires computing a scaling factor per tensor: $g_{\text{int8}} = \text{round}(g/s)$ where $s = \max(|g|)/127$. The receiver reconstructs $\hat{g} = g_{\text{int8}} \times s$. Provides 4 $\times$ compression over FP32 but introduces quantization noise proportional to the gradient magnitude.
3. **1-bit SGD**: The extreme case: transmit only the sign of each gradient element (+1 or -1). The receiver reconstructs using a learned or adaptive scaling factor. This achieves 32 $\times$ compression over FP32 but introduces substantial noise that can degrade convergence without additional mechanisms (Seide et al. 2014; Karimireddy et al. 2019).

6.6.1.1 Block quantization for gradient communication

The quantization progression above uses a single scaling factor per entire tensor, which implicitly assumes the gradient distribution is uniform across the tensor. In practice, gradient distributions are highly nonuniform: attention layers produce gradients with heavy tails, embedding layers produce extremely sparse gradients, and normalization layers produce gradients concentrated near zero. A single scaling factor per tensor is suboptimal when gradient distributions vary across the tensor. Regions with small gradients lose most of their information when quantized with a scaling factor dominated by the tensor’s maximum value. **Block quantization** addresses this by dividing the gradient tensor into blocks of b_{block} elements (typically $b_{\text{block}} = 64$ or 128) and computing an independent scaling factor per block. Each block’s scaling factor adapts to the local gradient distribution, reducing quantization error at the cost of transmitting $d_{\text{grad}}/b_{\text{block}}$ additional scaling factors.

For a gradient vector of dimension d_{grad} quantized to INT8 with block size b_{block} , the message size is $d_{\text{grad}} \times 1$ byte for the quantized values plus $(d_{\text{grad}}/b_{\text{block}}) \times 4$ bytes for the FP32 scaling factors, or $d_{\text{grad}} + 4d_{\text{grad}}/b_{\text{block}}$ bytes in total. The effective compression is therefore $4d_{\text{grad}}/(d_{\text{grad}} + 4d_{\text{grad}}/b_{\text{block}}) = 4b_{\text{block}}/(b_{\text{block}} + 4)$, which for $b_{\text{block}} = 128$ reaches 3.88 $\times$, close to the theoretical 4 $\times$. The quality gain comes from replacing the global error bound: block quantization reduces the maximum quantization error from $s \cdot 0.5$, where s is the global scaling factor, to $s_b \cdot 0.5$, where s_b is the block-local scaling factor, which for the heavy-tailed gradient distributions common in attention layers can cut quantization error by 2–5 $\times$ compared to per-tensor quantization.

Interfaces that fuse quantize-reduce operations make block quantization practical in communication compression, but each reduction in bit-width introduces quantization noise. This noise acts as a biased perturbation to the true gradient direction. For aggressive quantization (INT8 and especially 1-bit), the systematic bias can prevent convergence unless the system carries an error-feedback correction across steps. Quantization should therefore move only as far down the precision ladder as the convergence budget permits.

6.6.2 Sparsification: Transmitting only important gradients

Quantization attacks communication volume by reducing the number of bits per gradient element while transmitting every element. An orthogonal approach, **sparsification**, attacks the problem from the other direction: keep full precision but transmit only a subset of gradient elements, setting the rest to zero.

6.6.2.1 Top-k sparsification

The most common method is **Top-k compression**: for a gradient vector $g \in \mathbb{R}^{d_{\text{grad}}}$, transmit only the K_{top} elements with the largest absolute magnitude, setting the rest to zero (Aji and Heafield 2017; Lin et al. 2018):

$$\text{TopK}(g) = g \odot \mathbf{1}_{|g| \geq |g|_{(K_{\text{top}})}}$$

where $|g|_{(K_{\text{top}})}$ is the K_{top} -th largest element by magnitude. With $K_{\text{top}} = 0.001 \times d_{\text{grad}}$ (keeping only 0.1 percent of elements), this achieves $1000\times$ compression.

The compression headline must be discounted by the cost of encoding the sparse representation. Transmitting a sparse gradient requires sending both the nonzero values and their indices. For a gradient vector of dimension d_{grad} with K_{top} nonzero elements, the encoded message contains K_{top} values (each in FP32 or FP16) plus K_{top} indices (typically INT32). The total message size is $K_{\text{top}} \times (4 + 4) = 8K_{\text{top}}$ bytes for FP32 values with INT32 indices. The effective compression ratio is therefore $4d_{\text{grad}}/(8K_{\text{top}}) = d_{\text{grad}}/(2K_{\text{top}})$.

For $K_{\text{top}} = 0.001d_{\text{grad}}$, the encoded message yields a compression ratio of $500\times$, not the $1000\times$ suggested by the kept-element fraction alone, because the index overhead is significant. Reducing the index size to INT16 (for $d_{\text{grad}} < 65536$) or using run-length encoding for structured sparsity patterns can improve the effective ratio.

Top-k is not the only sparsification rule. **Random-k sparsification** selects K_{rand} elements uniformly at random and scales them by $d_{\text{grad}}/K_{\text{rand}}$ to maintain an unbiased gradient estimate. Random-k has the advantage of being an unbiased compressor even without error feedback, because $\mathbb{E}[\text{RandomK}(g)] = g$. However, it introduces higher variance than Top-k because it discards large gradients with the same probability as small ones. In practice, Top-k with error feedback converges faster than Random-k for the same compression ratio, because Top-k preserves the most informative gradient components at each step.

6.6.2.2 The convergence problem

Naively discarding small gradients creates a systematic bias. If a parameter consistently receives small gradients (e.g., 0.01 per step), it will not be updated because 0.01 is always below the Top-k threshold. Over thousands of steps, these “lost” gradients accumulate to a significant error that prevents the model from converging to the true optimum.

The problem is not merely practical; it is a fundamental mathematical obstacle. Without correction, sparsified SGD is a *biased estimator* of the true gradient, and biased gradient descent can converge to arbitrarily wrong solutions. The same problem afflicts aggressive quantization: rounding gradients to INT8 or 1-bit introduces a systematic rounding error that accumulates across training steps. Error feedback addresses this accumulation for quantized gradients (Seide et al. 2014) and for sparsified gradients (Stich et al. 2018; Karimireddy et al. 2019).

6.6.3 Error feedback: The memory of the journey

We solve the conflict between compression and convergence with error feedback. The system applies the compressor immediately to recover bandwidth, then stores the discarded residual in a local accumulator and re-injects it into the next gradient. *The error is deferred, not destroyed.* We maintain a local error accumulator e_t that stores the compression residual.

Error feedback carries the residual into the next compressed step.

Definition 6.4: Error feedback mechanism

Error Feedback is a distributed-training technique for gradient compression that maintains a per-worker residual accumulator e_t , re-injecting the compression error back into the next gradient update so that information deferred by the compressor is never permanently discarded.

1. **Significance:** Top-k sparsification at 1 percent keeps only the largest 1 percent of gradient values by magnitude, reducing AllReduce data volume from 140 GB to 1.4 GB for a 70B model—a $100\times$ payload reduction before sparse-index overhead. Without error feedback, the discarded 99 percent of gradient values create a biased update that can harm convergence; with error feedback, the residual accumulates until deferred components cross the compression threshold in later steps, recovering the convergence guarantees analyzed for memory/error-feedback variants under their assumptions (Stich et al. 2018; Karimireddy et al. 2019).
2. **Distinction:** Unlike lossy compression (which permanently discards sub-threshold gradient components), error feedback is a delayed transmission strategy: the residual e_t telescopes across steps so that $\frac{1}{K} \sum_{t=1}^K v_t \rightarrow \frac{1}{K} \sum_{t=1}^K g_t$ as $K \rightarrow \infty$, making the long-run average of transmitted gradients equal to the true gradient average.
3. **Common pitfall:** A frequent misconception is that error feedback is automatic whenever a compressor is used. It is not: the training system must explicitly preserve and reinject the residual. Without that residual path, Top-k and 1-bit quantization introduce systematic bias that can accumulate across steps (Karimireddy et al. 2019).

Error feedback preserves cumulative gradient information over time. Consider what happens over K steps:

$$\sum_{t=1}^K v_t = \sum_{t=1}^K [(g_t + e_t) - e_{t+1}] = \sum_{t=1}^K g_t + e_1 - e_{K+1}$$

If the error accumulator remains bounded (which it does for reasonable compression schemes), then as $K \rightarrow \infty$:

$$\frac{1}{K} \sum_{t=1}^K v_t \rightarrow \frac{1}{K} \sum_{t=1}^K g_t$$

The long-run average of transmitted gradients equals the long-run average of true gradients. No gradient information is permanently lost; it is merely delayed. Small gradients that are repeatedly dropped eventually accumulate in e_t until they exceed the compression threshold and get transmitted.

The telescoping property of compression error across time is why error feedback can transform a biased compressor into a convergent training method. Theoretical analyses show convergence guarantees for sparsified SGD with memory and for EF-SGD with broad compression operators under their stated assumptions (Stich et al. 2018; Karimireddy et al. 2019). A short trace shows how error feedback preserves gradient information that naive compression would lose. Table 6.12 runs the trace for a greedy compressor with no residual path, transmitting only values ≥ 0.5 :

Table 6.12: Naive compression trace (no error feedback): Five-step worked trace showing how a greedy 1-bit quantizer transmits zero whenever individual gradients fall below the threshold.

Step	True Gradient g_t	Transmitted v_t	Cumulative Transmitted	Cumulative True
1	0.4	0	0	0.4
2	0.3	0	0	0.7
3	0.2	0	0	0.9
4	0.4	0	0	1.3
5	0.3	0	0	1.6

The error-feedback trace in table 6.13 runs the same sequence with a residual accumulator e_t that re-injects the discarded remainder into the next step. The example below works through both traces to show that the deferred information is conserved rather than lost.

 Example 6.2: Error feedback mechanism

Problem: A single parameter receives small gradients (all below 0.5) over five training steps. A greedy compressor transmits only values ≥ 0.5 (rounding to nearest integer: values in $[0, 0.5) \rightarrow 0$, values in $[0.5, 1.5) \rightarrow 1$, etc.). After five steps, how much gradient information does naive compression lose, and how does an error-feedback accumulator recover it?

Naive compression outcome: In table 6.12, after 5 steps the system has transmitted 0 but the true cumulative gradient is 1.6. The parameter never updates, and 100 percent of gradient information is lost.

Error-feedback outcome: In table 6.13, the accumulator e_t telescopes the residual across steps. After 5 steps, the system has transmitted 2 with a remaining error of -0.4 . The true cumulative is 1.6, so transmitted + error = $2 + (-0.4) = 1.6$ ✓

Systems insight:

1. **No information is lost:** The sum (transmitted + error buffer) always equals the cumulative true gradient.
2. **Small gradients accumulate:** Individual gradients of 0.3–0.4 were too small to transmit alone, but they accumulated until crossing the threshold.
3. **Error oscillates around zero:** The error buffer e_t does not grow unboundedly; it oscillates as gradients are “paid back” through transmission.
4. **Convergence preserved:** Over time, the model receives approximately the correct total gradient, with some delay.

Table 6.13: Error-feedback compression trace: Same five-step sequence under error-feedback compression.

Step	g_t	e_t	$g_t + e_t$	v_t	$\begin{matrix} e_{t+1} = \\ (g_t + e_t) - v_t \end{matrix}$	Cumulative v
1	0.4	0	0.4	0	0.4	0
2	0.3	0.4	0.7	1	-0.3	1
3	0.2	-0.3	-0.1	0	-0.1	1
4	0.4	-0.1	0.3	0	0.3	1
5	0.3	0.3	0.6	1	-0.4	2

6.6.4 1-bit Adam: Compression-aware optimization

Error feedback restores convergence guarantees for any compression scheme, but it treats the optimizer as a black box. The gradient is compressed, transmitted, decompressed, and then fed to the optimizer as if nothing happened. This separation leaves performance on the table: the optimizer maintains internal state (momentum, variance estimates) that contains information about the gradient distribution, yet compression ignores this state entirely. The decision is whether compression should operate on raw gradients or on the optimizer state that already summarizes them.

A more integrated approach, pioneered by Microsoft’s DeepSpeed team, compresses the *optimizer’s communication* rather than the *raw gradients*. **1-bit Adam** (Tang et al. 2021) observes that the Adam optimizer maintains two momentum states (m_t and v_t) that change slowly between steps. Rather than communicating the full gradient and reconstructing Adam states independently on each worker, 1-bit Adam communicates only the sign of the momentum (1 bit per parameter) plus a per-tensor scaling factor.

The algorithm proceeds in two phases. During a *warmup phase* (typically 15–20 percent of training), standard Adam runs with full-precision communication to establish stable momentum estimates.

Once the momentum variance stabilizes (indicated by the ratio $\text{Var}(m_t)/\mathbb{E}[|m_t|]^2$ falling below a threshold), the algorithm switches to *compressed mode*. In compressed mode, each worker computes its local Adam update, extracts the sign of the momentum difference since the last communication, and transmits 1 bit per parameter plus a single FP32 scaling factor per tensor.

The theoretical justification rests on the observation that Adam’s adaptive learning rates concentrate gradient information into the magnitude of the momentum terms. Once these magnitudes stabilize, the *direction* (sign) carries most of the information, while the *magnitude* can be approximated by a single scaling factor. Error feedback is applied to the sign compression to ensure no directional information is permanently lost.

The 1-bit Adam paper reports up to $5\times$ communication-volume reduction while matching the convergence speed of uncompressed Adam, with experiments up to 256 GPUs showing up to $3.3\times$ higher throughput for BERT-Large pretraining and up to $2.9\times$ higher throughput for SQuAD fine-tuning (Tang et al. 2021). The practical lesson is narrower than “compression always wins”: the compression overhead must remain small compared with the communication time saved.

The success of 1-bit Adam illustrates a broader principle: compression is most effective when it is co-designed with the optimization algorithm. Compressing raw gradients discards information indiscriminately. Compressing optimizer states exploits the structure of the optimization trajectory, achieving higher compression ratios with less convergence impact.

Napkin Math 6.7: The payback of compression

Problem: A training job takes 40 ms to synchronize a gradient buffer. The system implements 1-bit Adam, which reduces communication volume by $32\times$ but adds 2 ms of CPU/GPU overhead for the compression logic. Scaling factors, optimizer-state coordination, and protocol overhead reduce the realized network gain to $8\times$ effective throughput. What is the actual communication speedup?

Math:

1. **Compressed communication time:** 40 ms divided by $8 = 5$ ms.
2. **Total new time:** 5 ms (comm) + 2 ms (overhead) = 7 ms.
3. **Effective speedup:** 40 ms divided by 7 ms $\approx 5.7\times$.

Systems insight: Compression is a trade of *compute for bandwidth*. It pays off only when $T_{\text{overhead}} < T_{\text{comm}}(N) \times (1 - 1/\text{Ratio})$. In this case, spending 2 ms to save 35 ms of network time is an exceptional trade. However, on a high-speed NVLink network where $T_{\text{comm}}(N)$ is only 1 ms, this same compression logic would slow down training. Always profile the network before adding compression.

The payoff calculation makes compression a conditional optimization: it must save enough communication time to cover both encoding overhead and convergence risk.

Checkpoint 6.4: Gradient compression decisions

Verify your understanding of when and how to apply gradient compression:

- ☐ **Error feedback:** Explain why 1-bit SGD without error feedback causes divergence while 1-bit Adam with warmup converges, comparing how each method handles information loss.
- ☐ **Compression payoff:** Determine whether applying $4\times$ gradient compression improves total step time when the backward pass takes 800 ms and AllReduce takes either 200 ms or 2000 ms.
- ☐ **Error accumulator:** Derive the steady-state behavior of the error accumulator e_t when the true gradient is constant at $g = 0.3$ and the compression threshold is 0.5.

- **Top-k vs. quantization:** Choose between Top-k sparsification and quantization for a workload, accounting for compression ratio and sparse-index encoding overhead.

6.6.5 Compression trade-offs: Bandwidth vs. convergence

Gradient compression is not free; it trades reduced communication for increased variance or bias in the optimization process. The comparison in table 6.14 summarizes the source-backed patterns from quantization, sparsification, error-feedback, and optimizer-aware compression work (Seide et al. 2014; Aji and Heafield 2017; Lin et al. 2018; Stich et al. 2018; Karimireddy et al. 2019; Tang et al. 2021).

Table 6.14: Gradient Compression Methods: Compression-ratio versus convergence-impact trade-off for the four canonical gradient compressors. The right choice depends on whether bandwidth or convergence speed is the binding constraint; aggressive compressors only pay off once communication dominates iteration time.

Method	Compression Ratio	Convergence Impact	Best Use Case
FP16	2×	Negligible	Common accelerator baseline
INT8 + Error FB	4×	Minor slowdown (~5–10%)	Bandwidth-constrained clusters
Top-k (1%) + Error FB	100×	Moderate slowdown (~10–20%)	Cross-data center training
1-bit + Error FB	32×	Significant slowdown (~20–30%)	Extreme bandwidth constraints

6.6.5.1 When to use compression

The decision rule is not the compression ratio alone. Compression is worthwhile only when the wall-clock time saved per step exceeds the encoding overhead and the extra steps caused by slower convergence. Aggressive compression pays off when communication time dominates compute time (a high $T_{\text{comm}}(N)/(T_{\text{compute}}/N)$ ratio), which typically occurs with smaller models on large clusters; when compute time dominates instead, the convergence slowdown is not worth the savings because the system is not bottlenecked on communication. Independently of that ratio, any lossy compression beyond FP16 should carry error feedback unless the optimizer analysis and convergence tests justify omitting it, since without correction convergence can fail.

The α - β analysis from section 6.2 helps determine when compression pays off: if the gradients are large enough to be bandwidth-bound ($M > n^*$), compression directly reduces wall-clock time. If they are latency-bound ($M < n^*$), compression will not help because the latency term dominates regardless of message size.

The decision of whether compression is worthwhile requires comparing the communication time savings against the convergence penalty. Consider a concrete scenario: a training run requires 100,000 steps to converge without compression, with each step taking 500 ms (300 ms compute, 200 ms communication). The total training time is 50,000 seconds. Applying INT8 compression with error feedback reduces communication time by 4× (from 200 ms to 50 ms per step) but increases the required steps by 10 percent (from 100,000 to 110,000). The new total time is $110,000 \times 0.35 = 38,500$ seconds, a 23 percent improvement. The compression is worthwhile because the per-step communication savings (150 ms) outweigh the additional steps required.

Now consider the same model on a faster network where communication takes only 30 ms per step. Compression reduces this to 7.5 ms (saving 22.5 ms per step) but still adds 10 percent more steps. The new total time is $110,000 \times 0.3075 = 33,825$ seconds vs. $100,000 \times 0.33 = 33,000$ seconds without compression. The compression increases total training time by 2.5 percent, because the per-step savings (22.5 ms) are too small relative to the convergence penalty (10,000 extra steps at 307.5 ms each). This example illustrates why compression should only be applied when the communication-to-computation ratio ($T_{\text{comm}}(N)/(T_{\text{compute}}/N)$) exceeds a threshold that depends on the specific convergence penalty of the chosen method.

6.7 The Communication Library Landscape

Writing a highly optimized, topology-aware, hierarchical Ring AllReduce from scratch in C++ would take a dedicated team of engineers months of effort. The engineering decision is which library

preserves the chapter’s model, topology, and overlap assumptions on the target hardware. The preceding sections developed three complementary strategies for taming communication cost; production libraries realize those strategies through four decision axes: the device memory path, topology awareness, portability, and observability.

6.7.1 NCCL: Why it is central to NVIDIA GPU workloads

NVIDIA Collective Communications Library (NCCL)¹¹ is central to many NVIDIA multi-GPU training deployments because it turns the collective algorithms above into GPU-resident data movement (Jeaughey 2017; NVIDIA 2026b). Its adoption stems from three GPU-specific optimizations that MPI and Gloo cannot replicate without hardware vendor support. Kernel fusion folds the reduction operator (sum, average) directly into the memory-copy kernel, so instead of copying data to a buffer, reducing, then copying the results back, NCCL reduces during the transfer and eliminates the intermediate memory traffic that would otherwise cap HBM bandwidth utilization. Channel pipelining opens multiple parallel communication channels to saturate every network interface at once, so a DGX node with 8 NICs reaches $8\times$ the bandwidth of a single-channel implementation. GPUDirect RDMA lets the network card read directly from GPU memory over PCIe, bypassing the CPU entirely; without it, data would traverse GPU $\rightarrow$ CPU memory $\rightarrow$ NIC $\rightarrow$ network, adding microseconds of latency and consuming CPU cycles. Together these explain why NCCL is usually the first backend to benchmark for NVIDIA GPU collectives before falling back to generic MPI implementations.

Beyond raw performance, NCCL’s topology auto-discovery is a critical differentiator. The topology-detection phase from section 6.5.3 is, in NCCL, driven by NVIDIA Management Library (NVML) queries and PCI bus enumeration of NVLink connectivity and NIC placement. The library-specific payoff is hardware-aware algorithm selection: on a DGX H100 with NVSwitch, NCCL recognizes that all 8 GPUs are fully connected and selects NVSwitch-based algorithms that differ from the ring algorithms used on systems with point-to-point NVLink connections.

NCCL also implements automatic algorithm selection based on message size and GPU count. Internally, it maintains tuning logic that maps message size, GPU count, and topology to a selected algorithm or protocol family. Users can override or inspect some built-in choices through documented environment variables such as `NCCL_ALGO`, `NCCL_PROTO`, and `NCCL_DEBUG` when benchmarking reveals suboptimal choices for specific workloads (NVIDIA 2026b). The debug output provides essential visibility for performance debugging.

A newer NCCL capability is limited support for user-defined reduction operators, such as the documented premultiplied-sum reduction for a communicator and datatype (NVIDIA 2026b). This support is narrower than MPI-style arbitrary reductions and custom datatypes, so application-specific aggregation such as outlier clipping usually still requires separate kernels or framework-level logic.

Despite its adoption, NCCL is not without limitations. It is open source but tightly coupled to NVIDIA GPUs and networking, and cannot be used as the native collective library on AMD or Intel accelerators. For organizations building multi-vendor infrastructure or requiring full control over the communication stack, these limitations motivate the use of alternative libraries.

6.7.2 MPI: The HPC foundation

The Message Passing Interface (MPI)¹² standardized collective operations decades before deep learning existed. The MPI Forum’s standards history records Version 1.0 in May 1994, defining a vendor-neutral API for point-to-point messaging, collective operations, and process management that became the lingua franca of high-performance computing (Message Passing Interface Forum 2015, 1993). MPI remains relevant for ML systems when portability, CPU-side coordination, or HPC integration is the binding requirement.

For CPU-based distributed computing, MPI implementations (OpenMPI, MPICH, Intel MPI) are mature and well-optimized, with decades of performance tuning across diverse network fabrics. HPC facilities that predate the GPU training era often have MPI deeply integrated into their job schedulers and resource managers, making MPI the path of least resistance for deploying ML workloads on these systems.

¹¹ | **NCCL (NVIDIA Collective Communications Library)**: NCCL can approach theoretical peak bandwidth on well-configured NVIDIA clusters by combining GPU-resident collectives, GPUDirect RDMA, and topology-aware path selection (Jeaughey 2017; NVIDIA 2026b). Its NVIDIA-specific design creates a vendor lock-in trade-off: organizations can gain a tuned collective backend for NVIDIA GPU fabrics but lose portability to AMD (RCCL) or Intel (oneCCCL) hardware.

¹² | **MPI (Message Passing Interface)**: Standardized in June 1994 after a three-year community effort, MPI defined the collective operations (AllReduce, Broadcast, Scatter) that ML frameworks later adopted wholesale. For GPU training, standard MPI requires explicit device-to-host copies that negate GPUDirect benefits, which is why NCCL displaced it for GPU collectives while MPI persists for job launch (`mpirun`) and CPU-side coordination.

MPI's specification includes features that NCCL lacks, most notably **persistent collectives** and **non-blocking collective operations** with fine-grained completion semantics. Persistent collectives (introduced in MPI 4.0) allow applications to “preregister” a collective operation, amortizing the setup overhead across thousands of invocations. This is valuable for training loops where the same AllReduce shape repeats at every step. Non-blocking collectives (MPI_Iallreduce) provide explicit request handles that can be tested for completion, enabling more flexible overlap patterns than NCCL's asynchronous operations.

MPI also provides **one-sided communication** (MPI_Put, MPI_Get, MPI_Accumulate) that maps naturally to RDMA hardware. These operations allow a process to read from or write to another process's memory without the remote process explicitly participating, enabling communication patterns that are difficult to express with collective operations alone. Parameter server architectures and certain asynchronous training algorithms benefit from one-sided semantics.

The primary limitation for ML practitioners is GPU-awareness. Standard MPI implementations assume host memory buffers. Calling MPI_Allreduce on GPU memory typically requires explicit device-to-host copies, which negate the performance advantage of keeping data on the GPU. CUDA-aware MPI extensions (available in OpenMPI and MVAPICH2) can accept GPU pointers directly, but their internal implementations rarely match NCCL's kernel fusion and channel pipelining optimizations. The practical guidance is hardware-specific: use NCCL for NVIDIA GPU-to-GPU collective operations when the hardware stack supports it, and use MPI for CPU collective operations, process management (`mpirun`, `mpiexec`), or cross-platform portability across non-NVIDIA hardware.

6.7.3 Gloo: Cross-platform flexibility

Gloo is Meta's open-source collective communication library, integrated into PyTorch as a backend option alongside NCCL. While NCCL is often the primary choice for performance-critical NVIDIA GPU training, Gloo fills a complementary role in the PyTorch ecosystem: it preserves distributed semantics when portability matters more than saturating GPU interconnects.

Gloo's primary strength is its portability. It supports Linux, macOS, and Windows without requiring CUDA or any vendor-specific runtime. This makes Gloo the natural choice for development and debugging workflows where engineers prototype distributed training logic on laptops or CI servers before deploying to GPU clusters. Gloo's TCP/IP transport works over any network stack, including the loopback interface for single-machine multi-process testing, eliminating the infrastructure requirements that NCCL imposes.

For CPU-only training (data preprocessing pipelines, feature engineering, CPU-based model architectures), Gloo's implementations are competitive with MPI for small-to-medium cluster sizes. Gloo optimizes for the common case in PyTorch distributed training: process groups that perform AllReduce and Broadcast on tensors stored in CPU memory. Its shared-memory transport enables high-bandwidth intra-node communication without network overhead, achieving near-memcpy throughput for local process groups.

Gloo also serves as a fallback backend in PyTorch's `torch.distributed` module. When NCCL is unavailable or inappropriate (non-NVIDIA hardware, missing drivers, unsupported platforms), PyTorch configurations can use Gloo for collective operations. This fallback behavior is valuable for mixed-vendor environments and for ensuring that distributed training code remains portable across hardware configurations.

The primary limitation is performance on GPU clusters. Gloo lacks kernel fusion, GPUDirect RDMA, and NVLink-aware routing, so GPU tensor collectives require explicit device-to-host copies. On NVIDIA GPU clusters, Gloo can achieve far less bandwidth than NCCL for large-message AllReduce operations. For latency-sensitive small-message operations, the gap widens further because Gloo cannot bypass the OS kernel for GPU memory access. The guidance for practitioners is straightforward: use Gloo for development, CPU workloads, and portability; switch to a hardware-optimized backend for performance-critical GPU training.

6.7.4 Library selection guide

The selection matrix in table 6.15 summarizes those axes. The point is not to memorize library names; it is to choose the backend whose memory path, topology model, portability constraints, and debugging visibility match the job.

Table 6.15: Communication Library Selection: Choose based on hardware and workload requirements. Many NVIDIA GPU training deployments use NCCL; Gloo serves as a portable fallback.

Scenario	Recommended Library	Rationale
Multi-GPU training (NVIDIA)	NCCL	GPUDirect, kernel fusion, NVLink-aware
CPU-only distributed training	Gloo or MPI	Mature CPU optimizations
Development/debugging	Gloo	Cross-platform, no CUDA dependency
Mixed vendor GPUs	Gloo (fallback)	NCCL is NVIDIA-specific
HPC integration	MPI + NCCL	MPI for job launch, NCCL for GPU collectives

The table follows directly from the chapter’s cost model. A backend is not faster in the abstract; it is faster when its memory path avoids host copies, its topology model matches the fabric, and its failure signals expose the part of α , β , or processor overhead that limits the job.

6.7.5 Vendor-specific libraries

The three libraries above do not exhaust the communication landscape because the same collective algorithm has different effective α , β , and topology constraints on different accelerator platforms. The pattern is consistent: use the backend that understands the device memory path and interconnect on the hardware actually running the job. AMD’s **RCCL (ROCm Communication Collectives Library)** mirrors NCCL’s API for AMD GPUs and optimizes collectives for the ROCm stack and Infinity Fabric, but benchmarked RCCL deployments may achieve only 70–85 percent of comparable NCCL bandwidth when intra-node fabric maturity or software tuning lags the NVIDIA stack. Intel’s **oneCCL (oneAPI Collective Communications Library)** targets Intel accelerator and CPU deployments with its own topology-aware collectives.

The broader pattern is a standardized front-end API with hardware-specific backends underneath it. PyTorch’s `torch.distributed` module routes collective calls to NCCL, RCCL, oneCCL, or Gloo based on the configured process group and available backend. In practice, teams often mix backends rather than choosing one globally: a GPU process group may use NCCL for gradient AllReduce while a CPU-side coordination group uses Gloo for barriers, scalar broadcasts, or sampler state. The chapter’s algorithms remain universal, but the efficient execution plan is hardware-specific. When that plan underperforms, the communication backend also becomes the diagnostic starting point.

 Systems Perspective 6.2: Debugging communication bottlenecks

When a distributed training job runs slower than expected, the communication library provides the first diagnostic signals because it exposes the selected algorithm, measured bandwidth, rank mapping, and overlap behavior. A systematic workflow isolates whether the bottleneck is in computation, communication, or their interaction:

1. **Profile with NCCL debug logging:** Set `NCCL_DEBUG=INFO` to see which algorithm (Ring, Tree) and protocol (Simple for bulk bandwidth, LL/LL128 as lower-latency protocols for small messages) NCCL selects for each collective. Unexpected algorithm choices often indicate topology mis-detection.
2. **Measure bare collective performance:** Run NCCL's built-in benchmarks (`nccl-tests`) with the cluster's exact topology to establish the achievable bandwidth baseline. If `nccl-tests` achieves 90 percent of theoretical bandwidth but the training job achieves only 50 percent, the bottleneck is in how the training framework invokes collectives, not in the communication library itself.
3. **Check for stragglers:** Use `torch.cuda.synchronize()` before and after each collective to measure per-operation time. A collective that takes $2\times$ longer than expected often indicates one GPU is delayed (thermal throttling, ECC error recovery, or unbalanced data loading), which stalls the entire barrier.
4. **Verify overlap effectiveness:** Use NVIDIA Nsight Systems to visualize the timeline of compute kernels and communication operations on the same axis. Effective overlap

shows communication operations running in parallel with backward pass kernels. Poor overlap shows gaps where the GPU is idle during communication.

5. **Isolate network vs. host overhead:** If `nccl-tests` shows low bandwidth, the issue is network-level (bad cables, congestion, misconfigured routing). If `nccl-tests` shows full bandwidth but training is slow, the issue is host-level (insufficient overlap, small bucket sizes, CPU bottlenecks in data loading).

Once the backend is correctly matched to the hardware and measured against a bare collective baseline, the remaining exposed communication time must be hidden behind computation.

6.8 Communication-Computation Overlap

A 20-millisecond network delay can effectively disappear—not by upgrading the physical network, but by hiding the communication behind arithmetic. The preceding sections reduced communication cost through algorithm choice, topology awareness, and payload compression. Overlap attacks the residual by changing when communication happens.

6.8.1 Layer-by-layer overlap

Gradient computation during the backward pass proceeds layer by layer, from the output layer back to the input layer. The gradient for layer ℓ is available as soon as that layer’s backward pass completes, even while layers $\ell - 1, \ell - 2, \dots$ are still computing. This creates an opportunity: begin communicating the gradient for layer ℓ immediately, while the GPU computes the gradient for layer $\ell - 1$.

In PyTorch’s `DistributedDataParallel` (DDP), this overlap is implemented through **gradient hooks**. Each parameter registers a hook that fires when its gradient is ready. The hook triggers an asynchronous AllReduce for that parameter’s gradient bucket. Meanwhile, the backward pass continues computing gradients for earlier layers. If the backward computation for the remaining layers takes longer than the AllReduce (the common case for large models), the communication is completely hidden.

The effectiveness of this overlap depends on the relative sizes of computation and communication at each layer. For transformer models, the largest gradient tensors belong to the attention and feed-forward weight matrices, which are also the most computationally expensive layers. This favorable correlation means that the layers with the most data to communicate are also the layers with the most computation behind which to hide that communication.

The overlap strategy interacts with the algorithm choice from the previous sections. Ring AllReduce, with its higher latency but optimal bandwidth, benefits more from overlap than Tree AllReduce, because Ring’s latency penalty (which would otherwise dominate for medium-sized messages) can be hidden behind computation. This is one reason why NCCL may select Ring even below the theoretical crossover point when it detects that the framework supports asynchronous operation: the latency disadvantage of Ring is neutralized by overlap, while its bandwidth advantage remains.

A critical synchronization barrier limits this overlap: the optimizer step *cannot* begin until all gradients are reduced. The gradients for the final layers processed (closest to the input) expose their communication latency because no subsequent backward computation remains to mask them.

6.8.2 Bucket fusion

The layer-by-layer overlap described earlier assumes that each layer’s gradient is communicated as a single message. In reality, a transformer layer contains dozens of individual parameter tensors (query, key, value projection matrices, output projection, layer norm parameters, feed-forward weights, and biases). Launching a separate AllReduce for every individual parameter would create thousands of small-message collectives, each paying the full α overhead. To avoid this, DDP uses **bucket fusion** to group parameters into buckets (often configured around tens of megabytes, with 25 MB a common PyTorch reference point) and launches one AllReduce per bucket. The bucket size represents a trade-off: larger buckets amortize α overhead but delay the start of communication (because the bucket cannot be sent until all its parameters have computed gradients). Smaller buckets start communication earlier but pay more α overhead.

The optimal bucket size depends on the model architecture and network characteristics. For models with many small layers (such as deep residual networks), smaller buckets (5–10 MB) improve overlap by starting communication sooner. For models with a few large layers (such as large language models with multi-gigabyte embedding tables), larger buckets (50–100 MB) are preferable because the large layers dominate both computation and communication time. PyTorch’s `bucket_cap_mb` parameter in DDP allows tuning this trade-off.

The order in which parameters are added to buckets determines overlap effectiveness. DDP assigns parameters to buckets in reverse order of their use in the forward pass, which corresponds to the order in which gradients become available during the backward pass. This reverse-order assignment ensures that the first bucket to fill (and thus the first AllReduce to launch) contains the parameters from the last layers of the forward pass, which are the first layers of the backward pass. This ordering maximizes the overlap window: the earliest buckets have the most subsequent computation behind which to hide their communication.

6.8.3 Overlap limits: When hiding fails

Communication-computation overlap has fundamental limits. The LogP model’s overhead parameter o represents the irreducible GPU time consumed by initiating and completing transfers. Even with perfect overlap, the GPU must spend at least $2o$ per AllReduce operation on initiation and completion. If the model has many layers but each layer’s backward pass is short (less than o), the GPU spends more time on communication overhead than on computation, and overlap provides no benefit.

Additionally, the first and last layers of the backward pass cannot overlap. The first layer to complete (the output layer) has no prior communication to overlap with. The last layer to communicate (the input layer) has no subsequent computation to overlap with. For shallow models (2–3 layers), these boundary effects consume a significant fraction of the total time, limiting the achievable overlap to 50–60 percent. For deep models (dozens of layers or more), the boundary effects are negligible, and overlap can hide 90–95 percent of communication time.

A third limitation arises from memory pressure. Overlapping communication with computation requires maintaining additional GPU memory buffers: the gradient being communicated must remain in memory while the backward pass continues producing new gradients for earlier layers. For FSDP workloads, where memory optimization is the primary motivation, this additional buffer requirement can conflict with the memory savings that FSDP provides. The engineering challenge is to find the sweet spot where overlap is aggressive enough to hide communication but not so aggressive that it pushes the GPU into out-of-memory territory. PyTorch FSDP settings such as `limit_all_gathers`, `backward_prefetch`, `forward_prefetch`, and resharding or prefetch choices provide knobs for this trade-off.

A realistic training configuration shows how much communication remains exposed after overlap.

Napkin Math 6.8: Overlap budget for a 7B transformer

Problem: A 32-layer transformer model (7B parameters) is trained on 64 GPUs. Each layer’s backward pass takes 15 ms. For this overlap budget, the communication bucket uses conservative FP32-gradient accounting, so the hierarchical AllReduce for each layer’s gradients (~880 MB per layer) takes 26.4 ms using 100 MB buckets. What is the step time with and without overlap?

Without overlap (sequential):

$$T_{\text{sequential}} = T_{\text{backward}} + T_{\text{comm}}(N) = 480 \text{ ms} + 32 \times 26.4 \text{ ms} = 1324.8 \text{ ms}.$$

With overlap (pipelined):

Each layer’s AllReduce (26.4 ms) runs in parallel with the next layer’s backward pass (15 ms). Since $26.4 \text{ ms} > 15 \text{ ms}$, there is 11.4 ms of exposed communication per layer that cannot be hidden.

$$T_{\text{pipelined}} = T_{\text{backward}} + T_{\text{first layer comm}} + (N_L - 1) \times T_{\text{exposed}} = 859.8 \text{ ms}.$$

Systems insight: Overlap reduces total step time by 35.1 percent. The remaining exposed communication comes from the AllReduce being slower than the per-layer backward pass. To eliminate this residual, either increase the backward pass computation (larger batch size) or reduce AllReduce time (more aggressive compression, better topology). The overlap is most effective when $T_{\text{backward per layer}} > T_{\text{AllReduce per layer}}$.

The combination of hierarchical AllReduce (reducing the volume of data to communicate), rail-optimized routing (maximizing the throughput of each communication operation), and layer-by-layer overlap (hiding the remaining communication behind computation) forms a common communication optimization stack for distributed training. Each technique addresses a different term in the performance equation: hierarchical algorithms reduce M , topology-aware routing maximizes effective β , and overlap amortizes α by running communication concurrently with computation. When all three are applied together, the communication overhead for a well-configured system can fall to 5–15 percent of total step time, down from the 50–80 percent that a naive flat, synchronous approach would impose.

Even the intra-node base case shows this stack succeeding before any of the multi-node machinery is needed: a 70B-parameter model on a single node of 8 NVLink-connected GPUs must AllReduce 140 GB of FP16 gradients per step, which Ring AllReduce on NVLink completes in roughly 0.3 seconds against a 2.1-second per-step compute budget, comfortably overlapped at about 15 percent of compute time. That quantitative success sets up the pitfalls below, because each one begins by optimizing the wrong term, choosing the wrong primitive, or trusting a topology assumption that no longer matches the workload.

6.9 Fallacies and Pitfalls

Communication optimization attracts persistent misconceptions because the interaction between latency, bandwidth, topology, and compression creates nonobvious failure modes that simple mental models miss.

Fallacy: *Bandwidth is the only metric that matters.*

For small messages (pipeline parallelism activations, MoE tokens), latency (α) dominates. Buying 400G networking will not help if the message takes 5 μs to serialize in software. The critical message size $n^* = \alpha \cdot \beta$ determines which metric to optimize: below n^* , reduce latency; above it, increase bandwidth.

Pitfall: *Assuming AllReduce works for everything.*

AllReduce creates a global barrier and assumes all participants contribute identical data shapes. In Expert Parallelism (MoE) and Recommendation Systems, where each worker needs to send distinct data to every other worker, AllReduce is fundamentally wrong. These workloads require AllToAll, which has $\mathcal{O}(N^2)$ logical connections and hits network contention limits at much smaller cluster sizes.

Fallacy: *Pipeline parallelism eliminates communication overhead.*

Pipeline parallelism replaces AllReduce with point-to-point activation transfers between adjacent stages, and the per-message cost is genuinely cheaper. Pipeline introduces a different overhead: bubble idleness. With p pipeline stages, at least $(p-1)/(p-1+m)$ of GPU-time is idle while the pipeline fills and drains, where m is the number of microbatches. For deep pipelines ($p \geq 8$), this requires $m \geq 32$ microbatches to keep the bubble below 20 percent, which constrains batch size, activation memory, and convergence. The choice between data parallelism and pipeline parallelism is not “communication vs. no communication” but a trade between bandwidth-bound AllReduce and time-bound bubble overhead.

Pitfall: *Using Ring AllReduce by default without checking message size and topology.*

Ring achieves bandwidth-optimal $2 \frac{N-1}{N} \frac{M}{\beta}$ but pays $\mathcal{O}(N)$ latency. For a 1 MB gradient across 64 GPUs with $\alpha = 10 \mu\text{s}$, Tree AllReduce wins because Ring’s 1,260 μs latency penalty exceeds Tree’s 1,000 μs bandwidth penalty. The log-aware crossover estimate $M_{\text{crossover}} \approx N\alpha\beta / \log_2 N$ determines when to switch algorithms; $N\alpha\beta$ is only a coarse upper-scale heuristic.

Fallacy: *Gradient compression is safe without error feedback.*

Top-k sparsification can achieve 99 percent compression, but naively discarding small gradients causes divergence. Without error feedback ($e_{t+1} = (g_t + e_t) - v_t$), gradients below the threshold are lost forever, accumulating systematic bias that eventually destabilizes training.

Pitfall: *Evaluating gradient compression by communication speedup alone.*

A compression scheme that achieves $100\times$ communication speedup is worthless if it degrades model quality enough to require $2\times$ more training iterations to reach the target accuracy. The right metric is *time-to-accuracy*, not *time-per-iteration*. Communication microbenchmarks measure time-per-iteration, while the engineering decision depends on time-to-accuracy, and the two diverge whenever compression introduces gradient bias or variance that slows convergence. Validate compression on the target convergence benchmark with the deployment training schedule, not on a synthetic AllReduce microbenchmark alone.

Fallacy: *Async collectives always hide latency.*

Python's `dist.all_reduce(..., async_op=True)` only returns control to the CPU. The LogP model distinguishes network latency L_{lat} (overlappable) from processor overhead o (nonoverlappable). If the GPU compute kernel is shorter than the communication overhead, the GPU still stalls. Communication can only be hidden when $T_{\text{compute}} > o$.

Pitfall: *Silent data corruption in the network.*

Networks are not perfect. A bad cable, faulty NIC, or firmware bug can corrupt data below the level where the training framework sees an explicit error. At 10,000 nodes running 24/7, even very rare bit errors can appear often enough to matter. The communication-specific lesson is that bandwidth tuning is incomplete without end-to-end validation: checksums, collective result checks, gradient-norm sanity tests, and fault-tolerance mechanisms must catch corrupted gradients before they become model updates.

Fallacy: *Flat AllReduce is good enough for multi-node training.*

A flat Ring AllReduce treats all links as equal, routing data across 50 GB/s InfiniBand when 900 GB/s NVLink is available within the node. For an 8-node cluster with 8 GPUs per node, hierarchical AllReduce reduces inter-node traffic by $8\times$ compared to flat Ring, achieving about $4.8\times$ in the worked example above. Ignoring the bandwidth hierarchy leaves the majority of intra-node bandwidth unused while overloading the scarce inter-node bandwidth.

Pitfall: *Using the ring AllReduce formula for intra-node communication.*

The ring AllReduce cost model assumes a logical ring topology, which matches the inter-node communication pattern across InfiniBand. It does not match intra-node communication. Within a DGX-class node, GPUs talk through NVLink and NVSwitch, which provides all-to-all connectivity rather than a ring. The actual intra-node AllReduce often uses a single-step reduce through the NVSwitch crossbar, with latency closer to a single hop than to the $\mathcal{O}(N)$ ring cost. Capacity planning that applies the ring formula uniformly overstates intra-node communication time by an order of magnitude and pushes the parallelism boundary outward unnecessarily. Use the crossbar model inside the node, the ring or tree model across nodes, and the hierarchical sum for global AllReduce.

Fallacy: *Rank-to-GPU mapping does not affect collective performance.*

If the job scheduler assigns ranks to GPUs without considering the physical topology, hierarchical AllReduce and rail-optimized routing may route traffic suboptimally. A common symptom is that `nccl-tests` achieves full bandwidth on the cluster, but the actual training job achieves only 50–60 percent because ranks are assigned across nodes in a way that prevents rail alignment. Verify that rank assignment matches the expected topology (e.g., ranks 0–7 on Node 0, ranks 8–15 on Node 1) before benchmarking communication performance.

Pitfall: *Benchmarking collectives without recording placement context.*

A collective benchmark is not reusable evidence unless it records rank order, NIC rail binding, NCCL topology configuration, and node allocation. Without that context, teams compare results from different physical layouts and mistake placement differences for library or hardware regressions.

6.10 Summary

Communication is the friction of scale. Computation is local, but learning is global, and the $\alpha\text{-}\beta$ and LogP models transform communication bottleneck analysis from guesswork into quantitative engineering. The critical message size $n^* = \alpha \cdot \beta$ separates latency-bound from bandwidth-bound regimes, and the gap between theoretical predictions and measured NCCL performance reveals

that software stack overhead inflates small-message latency by 5–10 $\times$, shifting algorithm crossover points in practice.

The Collective Primitives (AllReduce, AllGather/ReduceScatter, AllToAll) map directly to parallelism strategies, and each primitive determines a distinct scaling ceiling. AllReduce workloads are bandwidth-bound and scale gracefully, while AllToAll workloads are contention-bound and hit practical limits at smaller cluster sizes.

The Ring and Tree AllReduce algorithms occupy opposite ends of the latency-bandwidth trade-off, with the log-aware crossover estimate $M_{\text{crossover}} \approx N\alpha\beta/\log_2 N$ determining which is optimal for a given configuration. Hierarchical AllReduce and Rail-Optimized Routing exploit the bandwidth hierarchy of GPU clusters to multiply effective inter-node bandwidth, while in-network reduction (SHARP) reduces host-visible communication by performing part of the aggregation inside network switches.

When even the fastest wires are not enough, gradient compression provides the final squeeze. Quantization, sparsification, and compression-aware optimizers like 1-bit Adam reduce communication volume by 4–1000 $\times$. Error feedback ensures that while the journey may be compressed or delayed, no vital information is permanently lost, preserving the mathematical truth of the model’s convergence. Finally, communication-computation overlap through layer-by-layer pipelining and bucket fusion hides the remaining communication time behind useful computation, reducing the effective communication overhead to 5–15 percent of total step time in well-configured systems.

The communication traffic patterns differ fundamentally across the Lighthouse Archetypes.

Lighthouse 6.1: Communication archetype patterns

The “Travel Manifest” for a gradient depends on the system’s objective function and constraint regime. Each lighthouse archetype faces a distinct communication challenge, and the techniques developed in this chapter map to those challenges differently, as table 6.16 summarizes.

Table 6.16: Archetype-to-collective mapping: Each lighthouse archetype’s communication pattern is determined by its dominant bottleneck.

Archetype	Primary Collective	Dominant Friction	Optimization Strategy
Archetype A (GPT-4/Llama-3)	AllReduce	Bandwidth (β)	Hierarchical AllReduce; Rail-optimization
Archetype B (DLRM at Scale)	AllToAll	Latency (α) & Contention	Topology-aware routing; token load-balancing
Archetype C (Federated MobileNet)	P2P/Async	Connectivity & Latency	Aggressive quantization; Error Feedback

The key insight is that the archetypes face different communication bottlenecks even when they all train neural networks. Archetype A (GPT-4/Llama-3) is bandwidth-bound and benefits from hierarchical AllReduce combined with communication-computation overlap. Archetype B (DLRM at Scale) is latency-bound and benefits from low-latency switches and topology-aware AllToAll routing. Archetype C (Federated MobileNet) is constrained by intermittent connectivity and small devices, so aggressive quantization and error feedback matter more than data-center topology. Applying the wrong optimization to the wrong archetype wastes engineering effort without improving performance.

The compression and error-feedback mechanisms developed in this chapter also matter outside data centers: for Archetype C and similar intermittent or bandwidth-poor settings, the dominant cost may be the ability to send any useful update at all rather than saturating a high-speed fabric.

The communication patterns established in this chapter reveal that distributed training is fundamentally a network engineering problem disguised as a machine learning problem. The α - β model provides the analytical framework for reasoning about this problem: every communication design decision, from algorithm selection to compression to overlap, can be evaluated in terms

of its effect on the latency and bandwidth terms. Understanding these models and techniques transforms practitioners from users of distributed frameworks into engineers who can diagnose bottlenecks, optimize topology configurations, and achieve the scaling efficiency that determines whether trillion-parameter training runs complete in weeks or months.

Key Takeaways: Every byte has a travel cost

- **The α - β model reveals the bottleneck:** The critical message size $n^* = \alpha \cdot \beta$ determines whether to optimize software latency (small messages) or hardware bandwidth (large payloads). In practice, NCCL's effective α is 5–10 $\times$ higher than wire-level latency.
- **Algorithm choice is scale-dependent:** Ring AllReduce is bandwidth-optimal but pays $\mathcal{O}(N)$ latency; Tree AllReduce is latency-optimal ($\mathcal{O}(\log N)$) but bandwidth-inefficient. Use the log-aware crossover estimate $M_{\text{crossover}} \approx N\alpha\beta / \log_2 N$ to reason about the switch point, and treat $N\alpha\beta$ only as a coarse upper-scale heuristic.
- **Hierarchical algorithms multiply bandwidth:** By performing local reductions over fast NVLink before crossing the slow InfiniBand bridge, hierarchical collectives effectively multiply inter-node bandwidth by the number of GPUs per node.
- **AllToAll is the contention king:** Unlike AllReduce, AllToAll creates $\mathcal{O}(N^2)$ logical connections. This makes Expert Parallelism (MoE) and Recommendation Systems fundamentally harder to scale than dense LLMs.
- **Error feedback makes lossy compression safe:** Sparsification can discard 99 percent of gradients, provided the “error” is accumulated locally and added to the next step. This turns biased estimators into unbiased ones over time.
- **Overlap is the final multiplier:** Communication-computation pipelining through gradient hooks and bucket fusion can hide 90–95 percent of communication time behind backward pass computation for deep models.
- **Topology discovery is not optional:** High-performance libraries like NCCL dynamically map logical rings to physical wires to avoid “hot spots” and maximize bisection bandwidth. Misaligned rank-to-GPU mapping can degrade performance by 2–4 $\times$.

If parallelism decides what must be communicated, this chapter is about what that communication actually costs. Every collective (AllReduce, AllGather, AllToAll) is an instruction in the fleet's real instruction set, and its price is set by the α - β model: a fixed latency to begin and a per-byte bandwidth to finish. The engineering is in lowering both, choosing a ring where bandwidth binds and a tree where latency does, collapsing the slow inter-node hop into a fast local one, and above all overlapping the transfer with computation so the fleet pays for it in time it would have spent anyway. Communication is the penalty compute pays to act as one machine, and this chapter is how that penalty is kept small enough to be worth paying.

What's Next: From logic to resilience

The fleet now has its *logic* (Parallelism) and its *traffic patterns* (Communication). The map is drawn and the vehicles are built. In production, however, hardware fails as a statistical certainty: GPUs overheat, networks drop packets, and nodes fail mid-calculation. In fault tolerance (Chapter 7), we examine how to maintain the illusion of a perfect supercomputer on imperfect hardware. We move from the logic of movement to the mechanics of survival, exploring checkpointing, recovery, and elastic training.

 Research Questions: For further inquiry

- How should measured α - β or LogP parameters determine the choice among ring, tree, butterfly, double-tree, and hierarchical collectives?
- How do data, tensor, pipeline, and expert parallelism impose different collective patterns and scaling ceilings?
- When does topology-aware communication outperform a theoretically optimal flat algorithm?
- When is gradient compression justified, and what convergence evidence is sufficient to trust it?

Purpose

Why does scale transform hardware failure from rare exception to routine condition that systems must absorb continuously?

A single accelerator can run for years between hardware failures. A thousand accelerators turn that same component risk into failures every couple of days. A ten-thousand-device cluster sees failures every few hours once host, power, and network domains are included. This arithmetic is inescapable: individual component reliability does not change, but aggregate system reliability degrades multiplicatively as components are added. At large fleet scale, the question is not whether failures occur during a training run but how many, and systems that cannot absorb failures without losing progress cannot operate at all. The same logic applies to serving: a globally distributed inference system experiences regional outages, network partitions, and capacity fluctuations as continuous background conditions rather than exceptional events. Fault tolerance at scale is not about preventing failures, because prevention is impossible. It is about designing systems where failures are expected, detected, isolated, and recovered from automatically, allowing useful work to continue despite the constant churn of components entering and leaving operational status. In C³ terms, fault tolerance spends compute and communication on coordination: preserving state and recovering work because at fleet scale component failure is a statistical certainty, not an anomaly.

Learning Objectives

- Calculate fleet-level MTBF from component failure rates and estimate failure frequency for large training clusters
- Classify hardware, software, and silent-data-corruption failures by detectability, blast radius, and recovery path
- Derive checkpoint intervals that balance write overhead, lost work, and cluster failure rates
- Design distributed checkpointing and elastic recovery plans for multi-terabyte model state across GPU fleets
- Evaluate fault injection and observability evidence to validate detection, isolation, and recovery behavior
- Implement serving redundancy, failover, and state replication under millisecond latency and partial-failure constraints
- Select graceful degradation strategies that preserve useful service when models, features, regions, or capacity fail

7.1 Failure Analysis at Scale

IMAGINE a 10,000-GPU cluster midway through a three-month training run for a new foundation model. The communication layer has done its job: thousands of devices exchange gradients through AllReduce, AllGather, and AllToAll as if they were one machine. Then the arithmetic of scale catches up. A GPU fails every few hours, and if the system cannot absorb that ordinary physical event, synchronized training halts and millions of dollars of compute sit idle. **Fault tolerance** is the system property that lets distributed execution continue making useful progress when components fail, degrade, or disappear. In the fleet stack shown in figure 1.13, fault tolerance acts as the resilience layer for distributed execution. The challenges span the full failure spectrum, from transient bit flips through intermittent aging-related errors to permanent component failures, as figure 7.1 illustrates. The per-category failure rates and the mean time between failures (MTBF) scaling, $MTBF_{\text{system}} = MTBF_{\text{component}}/N$, annotated in that figure are previews; later analysis derives the inverse scaling and tabulates the cluster rates. Gray failures and silent data corruption (SDC) add a second axis of difficulty: low detection rate, high blast radius.

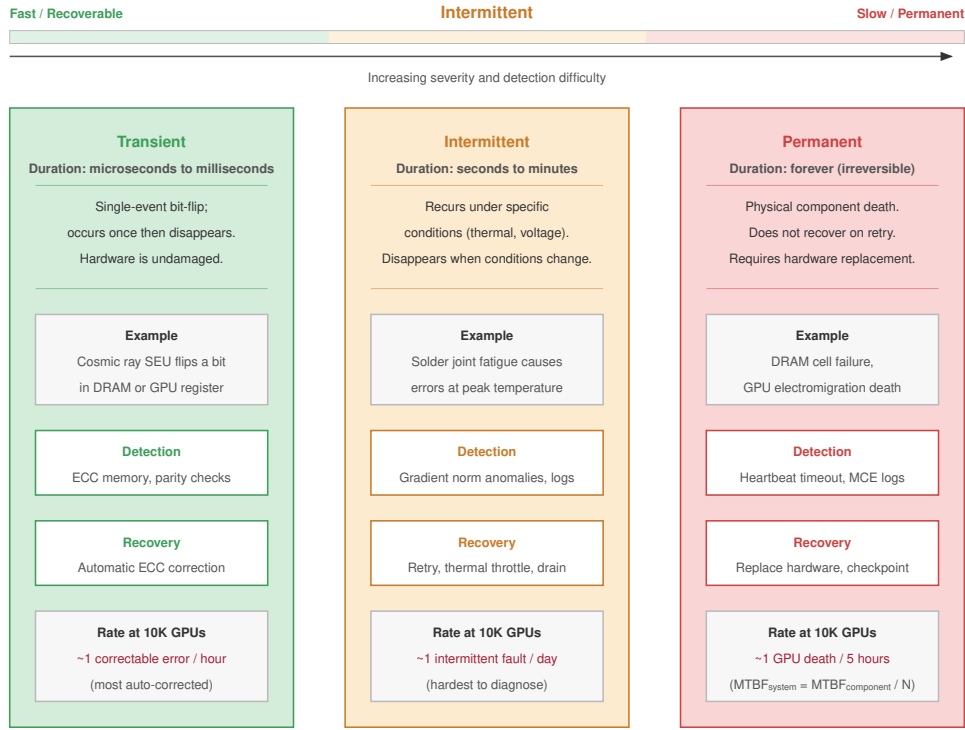

That fragility is the direct consequence of successful synchronization. Distributed training systems achieve massive throughput by coordinating thousands of devices, and collective communication keeps that coordination synchronized through rigid exchanges. The same synchronization means one stalled device can stall the fleet. Fault-tolerant ML systems preserve progress by detecting failure, checkpointing recoverable state, restarting or elastically reshaping jobs, and treating hardware churn as normal execution rather than an exceptional path.

The transition from small-scale experimentation to large-scale production changes the relationship between systems and failures. A researcher training a model on a single GPU can go years without a hardware failure. That same workload on a 1,000-GPU cluster sees GPU-only failures every couple of days, and a production cluster fails more often once PCIe, power, storage, and network domains enter the failure budget. This shift from *rare exception* to *routine occurrence* demands different engineering approaches. The mathematical analysis that follows makes this transition precise and quantitative.

Because failures *cannot* be eliminated at this scale, the engineering challenge is not to prevent them but to keep making progress despite them: fault-tolerant systems verify completion rather than assume it, treat failure as a normal code path, exercise recovery continuously rather than occasionally, and account for partial failures that leave the system in states naive error handling never anticipates. The techniques that achieve this draw on decades of distributed systems research, but ML workloads change the economics. Training exhibits properties that enable fault tolerance strategies unavailable to general distributed systems: the mathematical properties of stochastic gradient descent tolerate certain errors that would corrupt other computations, checkpoint sizes are large but predictable, and recovery targets need only be *approximate* rather than *exact*. Exploiting

System MTBF collapses as the fleet grows: 50,000 h to 5 h.

Failure taxonomy from fast/recoverable (left) to slow/permanent (right)

Figure 7.1: The ML Failure Spectrum: Reliability challenges at scale span a temporal taxonomy from transient errors (bit flips, single-event upsets) through intermittent errors (aging, marginal components) to permanent errors (stuck-at faults, dead components). Each category demands different detection latency and recovery strategy, and fault tolerance engineering must address all three to maintain fleet-scale throughput.

these properties makes ML-specific fault tolerance cheaper than the general-purpose approaches it descends from.

7.1.1 The mathematics of inevitable failure

System reliability engineering provides the foundational framework for understanding failure at scale (Birolini 2017). Individual components exhibit failure rates characterized by the failure rate parameter λ ,¹ measured in failures per unit time. For a single component with constant failure rate λ , the probability of surviving without failure until time t follows an exponential distribution,² as in equation 7.1:

$$R_{\text{single}}(t) = e^{-\lambda t} \quad (7.1)$$

MTBF for this component equals $1/\lambda$. By the book's convention, mean time to failure (MTTF) names a single component's expected time to its first failure while MTBF names the repairable system's expected time between successive failures; under the constant-rate exponential model used here the two coincide numerically, and the fault-tolerance model uses MTTF for per-component constants and MTBF for composed system rates. Data center GPUs often use planning MTBF values in the tens of thousands of hours, with field behavior depending on operating conditions, cooling effectiveness, manufacturing variation, and workload stress.³ section E.1.1 catalogs the canonical per-component MTTF values (H100, A100, TPU, PCIe, power, network) that anchor these λ and FIT figures, so a reader can substitute the constant for any device and reproduce the rates used throughout the fault-tolerance analysis.

¹ | **Failure Rate (λ):** Expressed in FITs (Failures In Time), where 1 FIT equals one failure per billion device-hours. A data center GPU with 50000 hours MTBF has FIT = 20,000, corresponding to $\lambda_{\text{hour}} = 2.0 \times 10^{-5}$ failures/hour. That seems negligible for one device but becomes dominant at fleet scale: a cluster with 10,000 GPUs accumulates 200,000,000 FITs from GPUs alone, translating to an expected GPU failure every 5 hours.

2 | Poisson Process: A statistical model for events occurring independently at a constant average rate. Reliability models assume hardware failures follow a Poisson distribution, leading to the exponential survival function $R(t) = e^{-\lambda t}$. This assumption simplifies fleet planning: the probability of at least one failure in a 10,000-component cluster is $1 - e^{-N\lambda t}$, making failure risk scale linearly with N but exponentially with t .

3 | GPU MTBF Variation: This chapter uses 50,000 hours as an A100-class planning constant, not as a guarantee for every deployed GPU. Published fleet studies from Google TPUv4 pods and Meta GPU clusters report that field reliability depends on topology, cooling, workload, and operational practice (Zu et al. 2024; Kokolis et al. 2025; Dubey et al. 2024). The planning constant therefore anchors the arithmetic, while operators should substitute measured fleet rates when they have them.

When multiple independent components operate in a system where any single failure causes system failure, equation 7.2 formalizes how system reliability becomes the product of individual component reliabilities:

$$R_{\text{system}}(t) = \prod_{i=1}^N R_i(t) = \prod_{i=1}^N e^{-\lambda_i t} \quad (7.2)$$

For N identical components with individual failure rate λ , equation 7.3 gives the identical-component simplification:

$$R_{\text{system}}(t) = e^{-N\lambda t} \quad (7.3)$$

The system failure rate becomes $N\lambda$, and equation 7.4 expresses how the system MTBF scales inversely with component count. This inverse scaling reveals the counterintuitive reality of the 9s of reliability at cluster scale:

$$\text{MTBF}_{\text{system}} = \frac{1}{N\lambda} = \frac{\text{MTBF}_{\text{component}}}{N} \quad (7.4)$$

Figure 7.2 visualizes the fundamental tension: as clusters grow, the expected time between failures shrinks below common training durations, making fault tolerance necessary for long-running fleet jobs.

Figure 7.2: The Reliability Gap: As GPU count increases, cluster MTBF drops below common training durations. A 10,000-GPU cluster experiences a failure roughly every 5 hours, making a 3-month training run impossible without fault tolerance mechanisms.

4 | Young-Daly Formula: J. W. Young derived the first-order optimal checkpoint interval in a 1974 *Communications of the ACM* paper; John Daly independently refined it in 2006 with tighter second-order bounds (Young 1974; Daly 2006). The formula's square-root relationship ($\tau_{\text{opt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$)

means that halving system MTBF only increases optimal checkpoint frequency by $\sqrt{2} \approx 1.4\times$, explaining why doubling cluster size does not demand doubling checkpoint I/O bandwidth.

7.1.2 The Young-Daly law: Optimal checkpointing

When failure is inevitable, the key engineering decision is how often to save progress. Checkpointing too frequently wastes time on I/O; checkpointing too rarely wastes time re-computing work after a failure. The **Young-Daly formula**⁴ (principle 12) resolves that tension with a single square-root law:

$$\tau_{\text{opt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$$

T_{write} in distributed ML training is not the time to flush a small process state—it is the time required to transfer hundreds of gigabytes of FP32 optimizer state (momentum and variance tensors for every trainable parameter) plus model weights to durable storage. For a 70B-parameter model with full Adam state, a single checkpoint can reach several hundred gigabytes; for the later 175B-parameter running example, that figure exceeds a terabyte. Compressing T_{write} therefore requires purpose-built high-bandwidth storage, and T_{write} itself is the central constraint that determines how tightly the checkpoint interval can be set before I/O overhead displaces productive training compute.

The optimal interval balances the cost of writing checkpoints against the expected cost of reworking lost progress, the U-shaped trade-off figure 7.3 plots. Its scaling consequence is the one to carry forward: as clusters grow, system MTBF drops, so the optimal interval shrinks, demanding higher-bandwidth storage (Chapter 4) to keep T_{write} small before the “checkpoint tax” consumes the cluster’s compute capacity. Because the relationship is a square root, halving MTBF tightens the interval by only $\sqrt{2} \approx 1.4\times$, so doubling cluster size does not demand doubling checkpoint I/O bandwidth. Section E.2.1 carries out the full derivation and the tighter second-order bounds; the later Checkpointing section (section 7.6.1) applies the formula to the local cluster once its system MTBF is in hand.

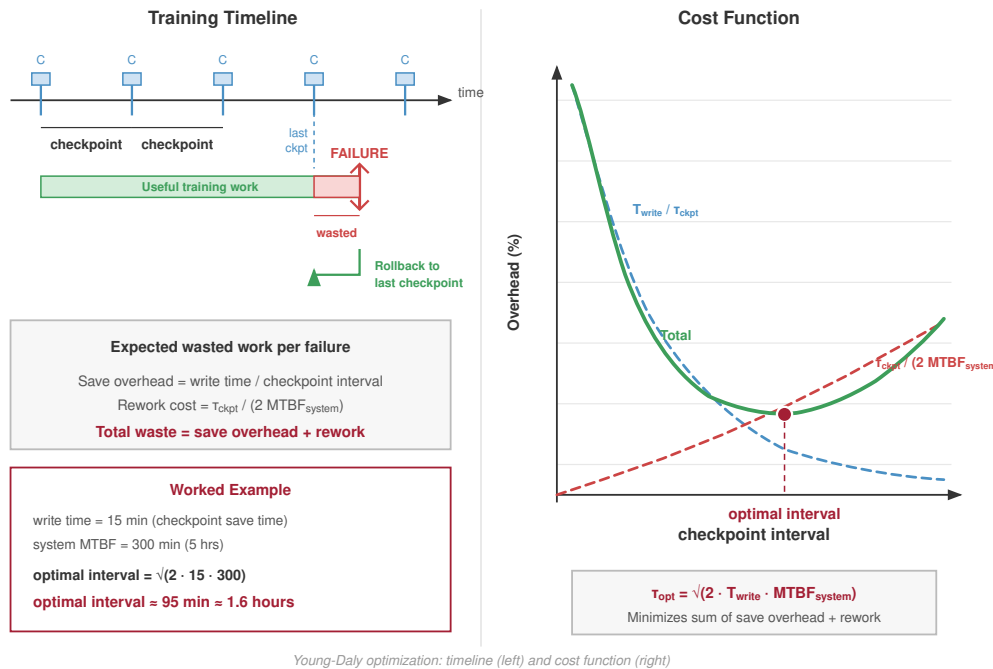

Figure 7.3: The Young-Daly Optimal Checkpoint: Total wasted work is the sum of *checkpointing overhead* (which decreases with interval τ_{ckpt}) and *rework cost* (which increases with τ_{ckpt}). The minimum point defines the optimal interval

$\tau_{\text{opt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$. For an illustrative cluster with a five-hour system MTBF and 15-minute write time, the optimal interval is approximately 1.6 hours.

A quick availability calculation shows the same scaling pressure from another angle.

Napkin Math 7.1: The 9s of reliability

Problem: A cluster of 10,000 GPUs runs with each GPU at 99.99 percent availability (only 52.6 minutes of downtime per year). What is the probability that the *entire* cluster is up at the same instant?

Math:

1. **Single GPU availability probability** (R_{GPU}): A GPU with 99.99 percent availability has an all-up probability $R_{\text{GPU}} = 0.9999$ at a randomly chosen instant.
2. **Cluster availability probability** (R_{cluster}): $R_{\text{cluster}} = (R_{\text{GPU}})^N$.
3. **Result**: $(R_{\text{GPU}})^N \approx 0.37$.

Systems insight: Even with 99.99 percent reliable hardware, a 10,000-GPU cluster has only a 37 percent chance that every GPU is simultaneously available. Hardware reliability alone is insufficient; software must handle failures automatically.

The linear relationship between component count and failure rate has a direct implication: adding GPUs turns rare component failures into a continuous system condition.

🔍 Systems Perspective 7.1: Scale transforms failure

A single GPU with an MTBF of 50,000 hours (5.7 years) absorbs the occasional failure with manual intervention, but a 10,000-GPU cluster with that same per-GPU reliability has a GPU-only system MTBF of just 5 hours: failures arrive multiple times per day. Systems must be designed expecting failure, not hoping to avoid it.

7.1.3 Quantitative reliability analysis

The GPU-only calculation in the opening reliability example supplies the scale intuition; a real training system then composes GPUs, HBM, links, power supplies, storage paths, and redundancy into one failure budget. With MTBF and the FIT rate already defined ($\text{FIT} = 10^9/\text{MTBF}$, so a 50,000-hour GPU contributes 20,000 FIT), the new question is how component rates *compose*. The composition rule depends on the redundancy structure. For **series systems** (for example, a node where all 8 GPUs must work), failure of any component fails the whole, so reliabilities multiply and rates add:

$$R_{\text{system}}(t) = \prod_{i=1}^N R_i(t), \quad \text{MTBF}_{\text{system}} = \frac{1}{\sum \lambda_i}$$

which is why adding components reduces system MTBF linearly. For **parallel systems** providing redundancy (for example, active-active model replicas), failure occurs only when all redundant components fail simultaneously:

$$R_{\text{system}}(t) = 1 - \prod_{i=1}^N (1 - R_i(t))$$

Composition also exposes which subsystem dominates the budget, and memory is the consequential case. Consider training an Archetype A (GPT-4/Llama-3) 70B model (section 1.6.1) on 1,024 A100 GPUs. Unprotected HBM is the binding term: at roughly 250 FIT per megabit, the cluster's $1,024 \times 80$ GB of memory accumulates so many failure sites that uncorrected corruption would strike roughly every 20 seconds, making large-scale training impossible. Error-correcting-code (ECC) memory protection is therefore not optional. ECC detects and corrects common single-bit errors, cutting the effective soft-error rate by roughly two orders of magnitude and pushing memory back below the logic and interconnect terms in the budget, though residual multi-bit or escaped corruptions remain as the silent-data-corruption problem.

These per-component FIT figures describe the silicon's intrinsic soft-error budget, which is why they differ from the 50,000-hour whole-device MTTf used in the worked cascade that follows: the device MTTf folds in every field failure mode (thermal stress, power events, mechanical wear), not just the logic and memory soft-error rates isolated here. The cascade composes those whole-device rates into the cluster figure that actually sets the checkpoint interval; this estimate only establishes why memory protection is the precondition for everything that follows.

7.1.4 Worked example: Cluster MTBF calculation

Consider a training cluster designed for large language model development with the following specifications:

- 10,000 NVIDIA H100 GPUs
- Individual GPU MTBF: 50,000 hours
- Each GPU connected to host via PCIe (MTBF: 200,000 hours)
- Each node contains 8 GPUs with shared power supply (MTBF: 100,000 hours)
- Network infrastructure per node (NIC, cables): MTBF 150,000 hours

Together, these components define the failure domain used in the rate calculation below.

Step 1: Calculate failure rate per GPU subsystem

Each GPU operates within a failure domain that includes the GPU itself, its PCIe connection, and proportional shares of the power supply and network infrastructure.

$$\lambda_{\text{GPU}} = \frac{1}{50,000} = 2.0 \times 10^{-5} \text{ failures/hour}$$

$$\lambda_{\text{PCIe}} = \frac{1}{200,000} = 0.5 \times 10^{-5} \text{ failures/hour}$$

$$\lambda_{\text{power/GPU}} = \frac{1}{8} \times \frac{1}{100,000} = 0.125 \times 10^{-5} \text{ failures/hour}$$

$$\lambda_{\text{network/GPU}} = \frac{1}{8} \times \frac{1}{150,000} = 0.083 \times 10^{-5} \text{ failures/hour}$$

Step 2: Calculate total per-GPU failure rate

$$\lambda_{\text{total/GPU}} = (2.0 + 0.5 + 0.125 + 0.083) \times 10^{-5} = 2.708 \times 10^{-5} \text{ failures/hour}$$

Step 3: Calculate system failure rate and MTBF

$$\lambda_{\text{system}} = 10,000 \times 2.708 \times 10^{-5} = 0.2708 \text{ failures/hour}$$

$$\text{MTBF}_{\text{system}} = \frac{1}{0.2708} = 3.69 \text{ hours}$$

This result means the cluster experiences a failure approximately every 3.7 hours on average. The expected failure cadence is 6.5 failures/day; a training run lasting one week will experience approximately 45 failures. Any training system operating at this scale must treat failure as a continuous condition, not an exceptional event. Section E.1.2 works this same cascade through step by step, composing per-component rates into a fleet-wide system MTBF, so a reader can rerun the calculation for a different node design or cluster size.

The cluster MTBF scaling in table 7.1 isolates the GPU-only baseline across cluster sizes. The full-system calculation is lower once PCIe, power, and network failure domains are included.

Table 7.1: Cluster MTBF Scaling: GPU-only mean time between failures decreases linearly with cluster size, transforming failures from rare events to continuous operating conditions at scale. Additional host, power, storage, and network failure domains reduce system-level MTBF further.

Cluster Size (GPUs)	Individual GPU MTBF	Cluster MTBF	Expected Failures per Day
8	50,000 hours	6250 hours (260 days)	0.004
64	50,000 hours	781.2 hours (33 days)	0.03
512	50,000 hours	97.7 hours (4 days)	0.25
1,000	50,000 hours	50 hours (2 days)	0.48
4,000	50,000 hours	12.5 hours	1.9

Cluster Size (GPUs)	Individual GPU MTBF	Cluster MTBF	Expected Failures per Day
10,000	50,000 hours	5 hours	4.8
25,000	50,000 hours	2 hours	12

The theoretical $1/N$ scaling in table 7.1 is not merely a textbook exercise. Figure 7.4 overlays published measurements and fitted projections from Meta’s production clusters against the theoretical curve. The Kokolis et al. (2025) study of Meta’s Research SuperCluster reported measured MTTF values for observed RSC job sizes and projected a 1.8-hour MTTF for 16,384-GPU jobs; Meta’s Llama 3 training report independently documented 419 failures across 54 days on 16,384 H100 GPUs, an observed MTTF of about 3.1 hours. Together, the measured Llama run and Kokolis projection put 16,384-GPU training on a 2-to-3-hour failure cadence. This evidence transforms the theoretical argument from an abstract scaling law into an engineering constraint that determines checkpoint frequency, recovery architecture, and infrastructure investment.

Figure 7.4: Published Failure Rates from Production Clusters: Measured MTTF values and fitted projections from Meta’s RSC clusters (Kokolis et al. 2025) plotted with Llama 3 training measurements (Dubey et al. 2024) against the theoretical $1/N$ curve. At 16,384 GPUs, the Kokolis projection and Llama 3 empirical measurement both fall in the 2-to-3-hour failure range, confirming that fault tolerance is a mathematical necessity, not an edge case. Data sources: Kokolis et al., arXiv:2410.21680; Meta, arXiv:2407.21783.

7.1.5 Failure taxonomy

The MTBF calculations in the reliability analysis quantify *how often* failures occur, which is critical for setting checkpoint intervals and sizing recovery infrastructure. Designing effective fault tolerance also requires understanding *what kind* of failures occur. Use the vocabulary carefully: a fault is the underlying defect or event, an error is the corrupted state it produces, and a failure is the externally visible behavior the training system must handle (Avizienis et al. 2004). A network partition that resolves in seconds demands different handling than a permanent GPU failure. A silent memory corruption that produces incorrect gradients requires different detection mechanisms than a node crash that stops responding entirely. Failure characteristics guide the selection of

appropriate recovery mechanisms. The taxonomy presented here classifies failures along two primary dimensions: temporal behavior (transient vs. persistent) and failure manifestation (fail-stop vs. Byzantine) (Constantinescu 2008; Lamport et al. 1982).

7.1.5.1 Transient failures

Transient failures occur temporarily and resolve without intervention, so the recovery question is whether the system can retry or validate the affected work before corrupted state propagates. Four common transient patterns matter for ML systems:

- **Network packet loss:** Drops packets while retransmission succeeds.
- **Memory bit flips:** Corrupt individual bits through cosmic ray induced single-event upsets.⁵
- **Thermal throttling:** Temporarily reduces performance during temperature spikes.
- **Software timeouts:** Arise from temporary resource contention.

Transient failures are particularly insidious in ML training because they may not trigger explicit errors. A transient memory bit flip during gradient computation produces incorrect gradients that propagate through subsequent training steps. The model continues training but produces subtly degraded results. Large-scale SDC studies show escaped corruption, while DRAM field studies show memory errors are common enough that fleet-level monitoring matters (Dixit et al. 2021; Sridharan et al. 2015; Schroeder et al. 2009). In ML training, that same undetected-corruption pattern can surface as degraded gradients, anomalous loss curves, or rollback-worthy checkpoints rather than an explicit crash⁶.

The appropriate response to transient failures depends on detection capability. Errors that trigger explicit exceptions can be handled through retry logic. Silent corruption requires validation mechanisms such as gradient checksums, periodic model evaluation, and statistical monitoring of training dynamics.

7.1.5.2 Fail-stop failures

Fail-stop failures cause components to cease operation entirely and detectably. The failed component stops responding to requests and can be identified through timeout mechanisms:

- **GPU hardware failure:** Makes a device unresponsive.
- **Node crash:** Terminates all processes on a machine.
- **Network partition:** Isolates the node from the cluster.
- **Storage failure:** Prevents checkpoint reads or writes.

In synchronous distributed training, fail-stop failures carry a particularly severe consequence: they stall the entire job. AllReduce collectives require every participating rank to contribute its gradient shard before the reduction can complete. A single GPU that goes silent—whether from a hardware fault, a process crash, or a network partition—blocks every other GPU in the ring until the timeout expires. On a 10,000-GPU job, that means 9,999 accelerators sitting idle, accumulating billable hours against a run that has made zero forward progress, until the coordinator finally declares the missing rank failed and triggers recovery.

Fail-stop failures are the easiest class to handle because detection is straightforward: the component stops responding. Recovery involves replacing the failed component and restoring state from the most recent checkpoint. The primary challenge is minimizing detection time and recovery latency.

Detection time T_{detect} typically involves heartbeat mechanisms where each GPU rank periodically signals liveness to a coordinator. If no heartbeat arrives within the timeout period T_{timeout} , the coordinator declares failure. Setting T_{timeout} requires balancing false positive rate against detection latency. False positives declare healthy workers failed due to transient delays, while slow detection wastes compute during the detection window—a cost that scales linearly with the number of GPUs blocked in the collective.

For a heartbeat interval of H seconds and network-delay standard deviation σ_d in seconds, equation 7.5 defines the timeout heuristic:

$$T_{\text{timeout}} = H + k\sigma_d \quad (7.5)$$

⁵ | **Single-Event Upset (SEU):**

From particle physics, where “upset” denotes a nondestructive state change. Cosmic rays and alpha particles from chip packaging can flip bits in memory and logic; the observed rate depends on altitude, process technology, packaging materials, shielding, and workload (Ziegler et al. 1996; Baumann 2005). ECC memory corrects single-bit errors but cannot handle every multi-bit upset in the same word, leaving a residual silent-corruption risk that compounds across the terabytes of state in large-scale ML training.

⁶ | **Silent Data Corruption (SDC):**

At fleet scale, SDC can bypass normal exception paths: infrastructure studies have documented defective hardware producing valid-looking but wrong results, while DRAM field studies show memory errors are common enough that fleet-level monitoring matters. For ML training, the practical debugging consequence is that the absence of an error message does not imply correct computation; systems need statistical checks on loss, gradients, and model state.

Here, k is a dimensionless safety multiplier that typically ranges from three to five to achieve low false positive rates while maintaining reasonable detection speed. ML training clusters built on dedicated high-bandwidth fabrics (InfiniBand, NVLink) exhibit very low baseline jitter, so σ_d is functionally small under normal conditions. The practical difficulty is distinguishing a genuinely dead rank from one that is temporarily slow—for example, a GPU lagging because it is writing a large checkpoint to attached storage while the collective is already waiting. Tuning T_{timeout} too tightly causes checkpoint writes to trigger false failure declarations; tuning it too loosely extends the window during which every other rank in the AllReduce collective is blocked idle.

7.1.5.3 Byzantine failures

Where a fail-stop component simply goes silent and is detected and replaced, a far more insidious class keeps running but produces incorrect results. A GPU that returns wrong gradients without throwing errors, a network that delivers corrupted packets that pass CRC checks, or a worker that computes different results for identical inputs all exemplify **Byzantine failures**, the most challenging class in distributed systems (Lamport et al. 1982). In ML systems, this category includes silent data corruption, numerical instability, determinism violations, and adversarial corruption; the common property is that the worker still participates while the value it contributes can poison shared state.

The physics of silent corruption At the nanometer scale of advanced transistors, hardware is not *deterministic*; it is *probabilistic*. Silent data corruption (SDC) is driven by two primary mechanisms. **Single-event upsets (SEUs)** occur when high-energy particles (cosmic rays at sea level, alpha particles from packaging materials) strike memory cells or logic gates, flipping a bit from 0 to 1; at 10,000+ GPUs, this is a statistical certainty. **Manufacturing variances** appear when “marginal” chips that pass initial QA exhibit bit flips only under specific voltage/temperature conditions, such as the intense di/dt swings of a backward pass.

Facebook documented a pervasive SDC issue where a hardware fault caused a valid file to be reported as “size zero” during decompression (Dixit et al. 2021). As figure 7.5 illustrates, the system “worked” (no crash), but data was silently deleted. In ML, this manifests as valid-looking but numerically corrupted gradients.

Real-world evidence of SDC in production systems confirms these risks. Figure 7.6 shows corrupted data blocks accumulating in a shuffle and merge database at Google, where even a small fraction of corrupted blocks can cascade into significant data quality degradation.

Google reported that SDC in TPU pods can manifest as sudden, inexplicable spikes in gradient norm (figure 7.7) (Dean 2024). A single bit flip in an exponent can turn a small gradient into a numerically enormous value, corrupting the training trajectory if the anomaly is not detected.

Google addresses this class of failure with system-level mitigation, including spare capacity and sanity checks that can drain suspect chips when loss or gradient monitors flag anomalies (figure 7.8) (Dean 2024). This moves reliability from the component, which we cannot trust, to the system, which verifies the result.

The hot spare pattern in figure 7.8 illustrates one approach to SDC mitigation, but recognizing silent corruption in the first place requires understanding what distinguishes it from benign training noise.

Checkpoint 7.1: Detecting silent corruption

Verify your understanding of Byzantine failures and SDC:

- ☐ **SDC danger:** Explain why silent data corruption (SDC) is more dangerous for ML training than a simple node crash.
- ☐ **Hot spare vs. restart:** Compare a **hot spare** redundancy strategy with traditional **checkpoint-restart** in terms of recovery latency.
- ☐ **Sanity checker:** Identify the metric used as a “sanity checker” to identify potential hardware faults: GPU temperature or gradient norm.
- ☐ **Byzantine scope:** Assess the True or False claim that Byzantine failures only occur when a malicious actor intentionally sabotages the training cluster.

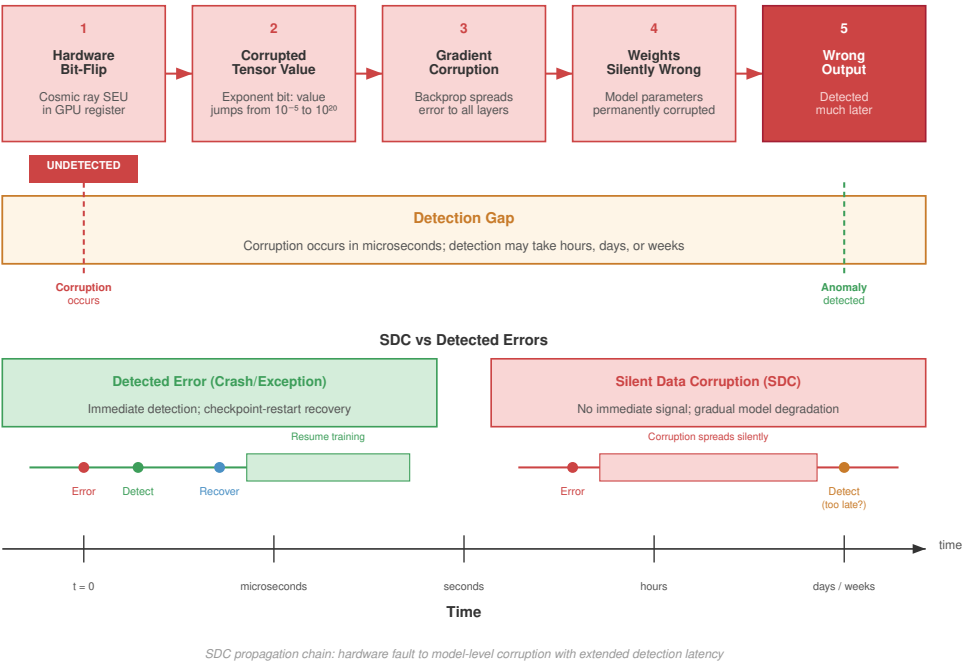

Figure 7.5: Silent Data Corruption Propagation: Unexpected faults can return incorrect file sizes, leading to data loss during decompression and propagating errors through distributed querying systems. This example from Facebook emphasizes how silent errors bypass standard exception handlers. Source: (Dixit et al. 2021).

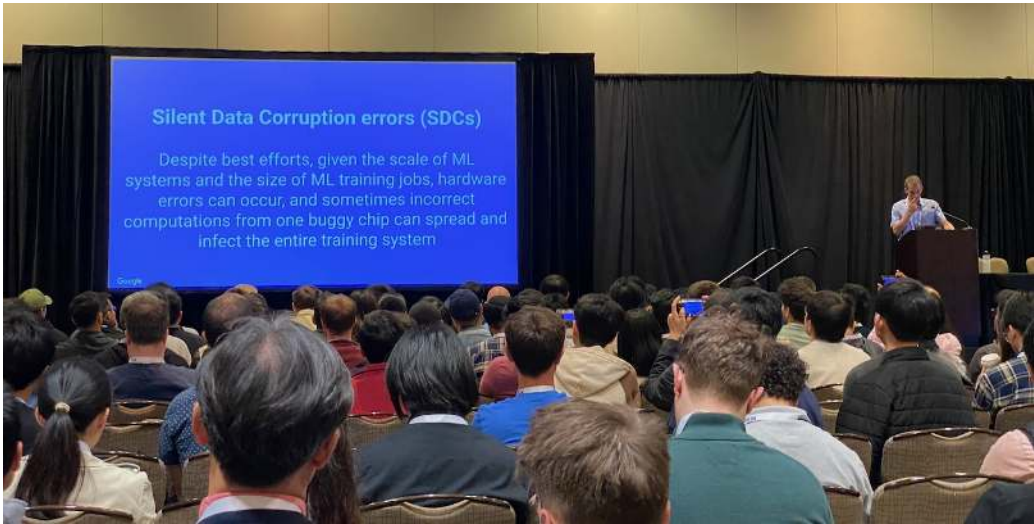

Figure 7.6: Silent Data Corruption in Spark: AI systems that use large-scale data processing frameworks such as Spark are vulnerable to silent data corruption (SDC) accumulating during data transfer and storage. SDC manifests in a shuffle and merge database, highlighting corrupted data blocks (red) amidst healthy data (blue/gray). Source: (Dean 2024).

Silent-corruption detection is the first defense, but the same logic extends to any Byzantine worker whose output remains syntactically valid. These failures are particularly dangerous in distributed training because the standard assumption that workers compute identical gradients for identical data no longer holds. A single Byzantine worker can corrupt the averaged gradient, potentially

Figure 7.7: Gradient Norm Deviation: Transient hardware faults, such as silent data corruption (SDC), can disrupt optimization by causing abrupt changes in gradient norms. Google’s production examples show SDC anomalies surfacing as visible gradient-norm spikes. Source: (Dean 2024).

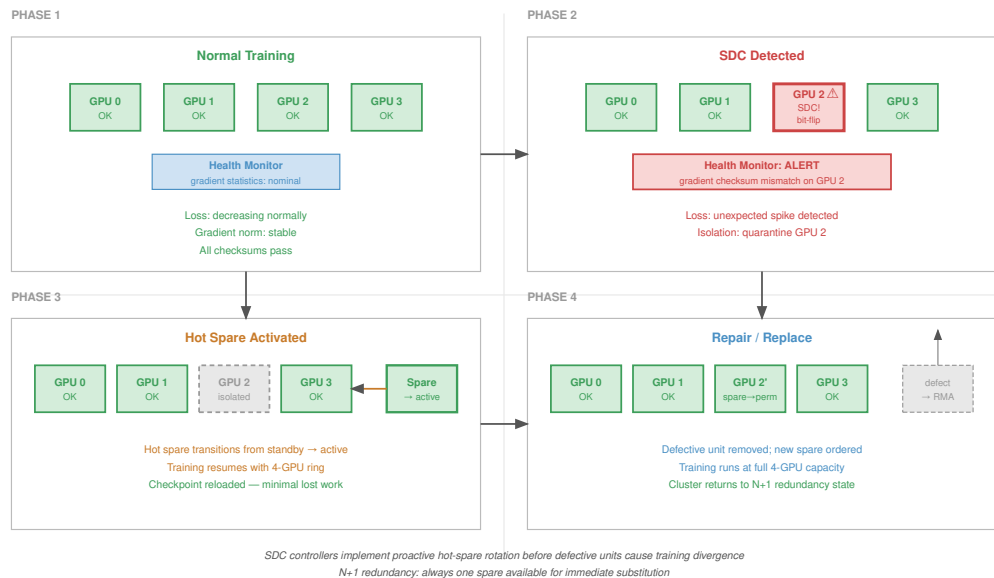

Figure 7.8: Hot Spare Redundancy: Google’s data-center examples use spare capacity and sanity checking to keep ML training moving despite hardware faults, transitioning work away from suspect resources when monitors flag anomalies. This approach contrasts with parallel redundancy techniques such as dual modular redundancy and triple modular redundancy by providing a reactive fault-tolerance mechanism. Source: (Dean 2024).

causing training to diverge or converge to a poor solution. Figure 7.9 contrasts the straightforward detection of fail-stop failures with the insidious nature of Byzantine corruption.

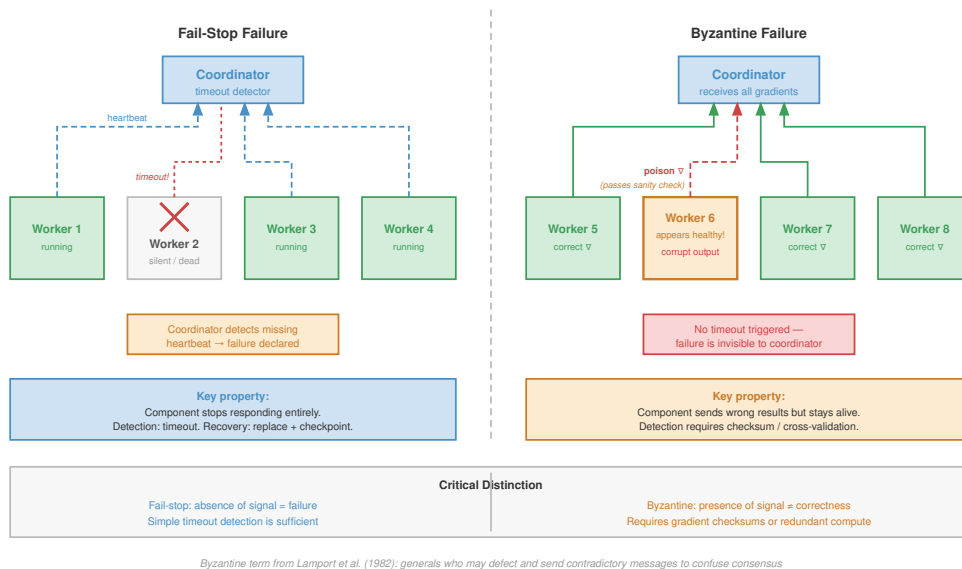

Figure 7.9: Fail-Stop vs. Byzantine Failures: In the fail-stop model (left), a failed worker simply ceases to send messages, which is easily detected by timeouts. In the Byzantine model (right), a failed worker continues to participate but sends incorrect data (for example, corrupted gradients reported as valid), which can poison the global model state if not detected by redundant validation.

Detection of Byzantine failures requires redundant computation. Multiple workers computing gradients for the same data enable comparison of results. Statistical outlier detection can identify workers consistently producing anomalous gradients. These detection mechanisms add computational overhead and may not catch subtle corruption.

Byzantine-resilient distributed training algorithms exist but impose significant overhead. Algorithms such as Krum (Blanchard et al. 2017) and coordinate-wise trimmed mean (Yin et al. 2018) compute aggregates that are robust to a bounded number of Byzantine workers, but they require more communication and computation than simple averaging. The systems consequence is visible here: corrupted gradients can push the optimizer toward an unreliable model state while the training job appears healthy. Reliability therefore has to protect semantic correctness, not only process liveness.⁷

7.1.5.4 Correlated failures

The reliability calculations in section 7.1.1 assume independent failures. Real systems exhibit correlated failures when shared dependencies fail many components at once:

- **Power supply failure:** Takes down every GPU in a node.
- **Network switch failure:** Isolates all attached nodes.
- **Cooling system failure:** Forces thermal shutdown across racks.
- **Software bug:** Crashes every process using a faulty CUDA driver version.
- **Operator error:** Misconfigures an entire cluster.

Correlated failures violate the independence assumption underlying equation 7.3. When failures are correlated, the actual system reliability is lower than the formula predicts. Correlated failures can also defeat redundancy strategies. Three replicas of a model provide no availability benefit if all three run on the same power domain and a power failure takes out all three simultaneously.

Defending against correlated failures requires understanding failure domains and ensuring redundancy spans independent failure domains. Table 7.2 catalogs common failure domains in ML infrastructure, from single GPUs to entire data center regions, each requiring distinct mitigation

⁷ **Byzantine-Resilient ML:** Named after Lamport’s 1982 “Byzantine Generals Problem,” these algorithms (Krum, trimmed mean, signSGD) tolerate a bounded fraction of corrupted workers, with the exact bound depending on the algorithm and assumptions. The trade-off is concrete: for N workers, Krum requires pairwise distance computations over worker gradients, so overhead grows quadratically with worker count and directly competes with the throughput gains of data parallelism (Blanchard et al. 2017).

strategies. Figure 7.10 illustrates how these domains nest hierarchically, with failures propagating downward through the containment structure.

Table 7.2: Failure Domains in ML Infrastructure: Understanding failure domain boundaries enables placement of redundant components across independent domains, preventing correlated failures from defeating redundancy strategies.

Failure Domain	Impact Scope	Typical Recovery Time	Mitigation Strategy
Single GPU	1 GPU	Seconds (spare)	Hot spare, elastic training
Node (power/OS)	8 GPUs	Minutes	Checkpoint, node replacement
Rack (ToR switch)	32–64 GPUs	Minutes to hours	Cross-rack redundancy
Power domain	100–500 GPUs	Hours	Multiple power feeds
Data Center region	All GPUs	Hours to days	Geographic distribution
Software version	All GPUs running version	Minutes (rollback)	Staged rollouts

The nesting of failure domains in table 7.2 has direct consequences for redundancy placement: placing replicas within the same domain provides zero protection against that domain’s failure mode.

Figure 7.10: Hierarchy of Failure Domains: Failure domains are often nested or overlapping. A GPU failure affects one device. A node failure affects 8 GPUs. A rack switch failure affects 32-64 GPUs. A power distribution unit (PDU) failure may affect multiple racks. Effective fault tolerance requires placing replicas across independent domains (for example, different racks or rows) to survive correlated failures.

The key insight from figure 7.10 is that redundancy is effective only when replicas span independent failure domains: placing three model replicas on the same rack provides no protection against the rack switch or PDU that all three share.

 Checkpoint 7.2: Mapping failure domains

Verify your understanding of how failure domains nest and their operational impact:

- ☐ **Blast radius:** Calculate how many 8-GPU nodes a rack switch failure typically affects in a standard data center configuration.
- ☐ **Zone correlation:** Explain why placing all 3 model replicas in the same Zone (for example, us-east-1a) fails to provide protection against a regional power outage.

- ❑ **Staged rollouts:** Identify the failure domain addressed by **Staged Rollouts** rather than hardware redundancy.
- ❑ **Nested domains:** Explain **Hierarchical Containment** and decide whether the corresponding Rack failure domain still matters when a Zone fails.

📖 War Story 7.1: The supercomputer that rerouted around faults (2024)

Context: Google’s TPUv4 machine-learning supercomputer used 4,096 TPU chips connected by a custom 3D torus Inter-Chip Interconnect (ICI) fabric, and Google engineers published their operating experience with automatic fault resiliency and hardware recovery (Zu et al. 2024).

Failure mode: At that scale, a failed machine, chip, ICI cable, or optical circuit switch was not merely a lost component. It could disrupt the topology that synchronous training jobs relied on for collective communication.

Consequence: Google built a control plane that detected faults, reconfigured the ICI fabric, and routed jobs around failures or onto spare healthy cubes. The paper reports 99.98 percent system availability while gracefully handling hardware outages experienced by about 1 percent of training jobs.

Systems lesson: Fault tolerance is a topology-management problem. In tightly coupled accelerator fleets, recovery must preserve the communication graph, not merely replace an individual component; otherwise one local hardware fault can become a cluster-wide training interruption.

7.1.6 The bathtub curve and hardware lifecycle

The failure taxonomy classifies failure types and domains, answering what kind of failures occur. Equally important for designing fault tolerance is understanding when in a component’s lifetime failures are most likely to occur. Hardware failure rates are not constant over component lifetime. Figure 7.11 illustrates the bathtub curve, a well-established model in reliability engineering that describes how failure rates vary across three distinct phases:

The first phase, infant mortality, exhibits elevated failure rates from manufacturing defects, improper installation, and early-life wear-out of marginal components. This phase typically lasts days to weeks for electronic components. Burn-in testing⁸ operates components under stress conditions before deployment to precipitate infant mortality failures before production use.

After surviving infant mortality, components enter the useful life phase, where they exhibit relatively constant failure rates under the standard reliability-engineering model (Birolini 2017; Klutke et al. 2003). This phase represents the longest portion of component lifetime and is the period where the exponential reliability model in equation 7.1 applies most accurately. For data center GPUs, the useful-life window is an operational planning concept shaped by refresh cycles, cooling, utilization, and observed fleet health rather than a fixed physical duration.

As components age, they enter the wear-out phase, where failure rates increase due to accumulated wear. For GPUs, wear mechanisms include electromigration⁹ in circuits, thermal cycling stress on solder joints, and degradation of thermal interface materials. The onset of wear-out depends heavily on operating conditions; components operated at high temperatures or with frequent thermal cycling enter wear-out earlier.

The practical implication for ML systems is that fleet-wide failure rates depend on age distribution. A cluster populated entirely with new GPUs will experience elevated failure rates during the first few weeks, followed by a stable period, then increasing failures as the fleet ages. Mixed-age fleets exhibit more consistent aggregate failure rates because different cohorts are in different lifecycle phases.

The three phases in figure 7.11 have direct operational consequences: burn-in testing filters infant mortality before deployment, while predictive analytics using GPU telemetry (temperature trends, error counts, performance degradation) targets the wear-out phase, enabling scheduled component

⁸ | **Burn-in Testing:** Components operate at elevated temperature (85–125 degrees C) and voltage for 24–168 hours to precipitate infant mortality failures before production. Large operators may burn in accelerators before deployment, reducing the infant-mortality failures that fresh bare-metal hardware can otherwise expose to early jobs.

⁹ | **Electromigration:** Gradual displacement of metal atoms in conductors by electron momentum transfer, first characterized in early electromigration studies and later modeled in Black’s reliability equation (Black 1969). Mean time to failure decreases with higher current density and higher temperature, so sustained high-power accelerator workloads make thermal management a direct determinant of fleet lifespan.

Figure 7.11: The Bathtub Curve: Hardware failure rates $\lambda(t)$ vary over time. (1) Infant Mortality: high failure rate initially due to manufacturing defects. (2) Useful Life: constant, low failure rate where random failures dominate. (3) Wear-Out: increasing failure rate as components age. Burn-in testing aims to filter out infant mortality failures before deployment.

replacement during maintenance windows rather than unplanned outages during training runs. ML infrastructure teams apply this model directly to cluster scheduling and fleet admission. Rather than treating fresh accelerator pods as immediately equivalent to proven production nodes, operators often run stress workloads before assigning the hardware to high-value training. Sustained matrix-multiply loops, memory tests, and communication tests expose marginal devices before they touch a multi-week pretraining run. Operators repair or replace an accelerator that fails during this screening phase before it ever touches a high-value training run; an accelerator that survives enters the useful-life period where the constant-rate exponential model applies. This discipline matters because the cost asymmetry is stark: catching an infant-mortality failure during screening costs a few hours of idle accelerator time, while the same failure during a multi-week foundation model pretraining run can invalidate days of gradient accumulation and force a checkpoint rollback. Scheduling policy reflects this asymmetry: cluster operators typically assign fresh or recently repaired nodes to short exploratory jobs or inference serving first, not to months-long pretraining jobs, until they have accumulated enough operating hours to leave the infant-mortality risk window.

7.1.7 Model-type diversity in failure impact

While the mathematics of failure rates apply universally, the failure impact by model type differs dramatically. The impact of losing an hour of training depends on what that training costs, how much state must be recovered, and how long recovery takes. Table 7.3 quantifies these factors across model architectures, revealing orders-of-magnitude variation from LLMs incurring millions of dollars in wasted compute to vision models losing modest amounts of progress.

Table 7.3: Failure Impact by Model Type: The cost of training failures varies dramatically by model type, driven by training duration, checkpoint overhead, and the value of accumulated training state. These differences demand model-specific fault tolerance strategies.

Model Type	Typical Training Duration	Checkpoint Size	State Sensitivity	Failure Cost
Archetype A (70B-class dense LLM)	2–4 weeks	350–700 GB	High (position in curriculum)	\$2–5M compute per 24hr loss
Vision (ViT-Large)	1–3 days	1–2 GB	Medium (augmentation state)	\$10–50K per day loss
Archetype B (DLRM at Scale)	Continuous	2–4 TB (embeddings)	Very High (embedding freshness)	Revenue impact per hour
Speech (Whisper-scale)	3–7 days	5–10 GB	Medium	\$50–200K per day loss
Scientific (AlphaFold)	Days to weeks	10–50 GB	High (exploration state)	Research delay

Large Language Models experience the highest absolute failure costs due to their extended training durations and the computational expense of each training hour. For example, a large training run consuming 25,000 GPUs at approximately \$2 per GPU-hour incurs \$1.2M in compute costs per day. A failure that loses 24 hours of training progress costs \$1.2M in wasted compute plus schedule delay. The checkpoint overhead spans a wide range: 70B-class dense LLM checkpoints can reach hundreds of gigabytes, and the 175B-parameter running example reaches 3.7 TB once FP32 Adam optimizer state is included.

Recommendation Systems present unique challenges because their training is often continuous rather than episodic. The value of a RecSys model derives partly from its freshness. Embeddings that capture recent user behavior outperform stale embeddings. A failure that loses hours of embedding updates may degrade recommendation quality in ways that directly impact revenue. Meta has documented that recommendation model freshness directly correlates with engagement metrics, making recovery time a business-critical metric.¹⁰

Vision Models occupy a middle ground with moderate training durations and manageable checkpoint sizes. The relatively small checkpoints enable frequent checkpointing with minimal overhead. A ViT-Large checkpoint in the 1–2 GB range imposes little overhead compared with large language or embedding-heavy recommendation workloads. Data augmentation state represents the primary state beyond model weights that must be preserved for reproducible recovery. The augmentation parameters and data shuffling seed must be captured.

Scientific Models such as those used in protein structure prediction or climate simulation often have unique state requirements beyond model parameters. AlphaFold-style training may maintain exploration state tracking which protein families have been sampled, preventing repetition during recovery. Drug discovery models may track which molecular configurations have been evaluated. This domain-specific state complicates checkpoint and recovery design.

7.1.8 Economic framework for fault tolerance investment

Fault tolerance mechanisms consume resources: storage for checkpoints, bandwidth for checkpoint writes, compute cycles for redundant calculations, and engineering time for implementation and maintenance. Rational investment in fault tolerance requires quantifying both the cost of failures and the cost of prevention.

Failure costs include wasted compute, schedule delay, opportunity cost, and engineering time. Wasted compute measures GPU-hours expended on training steps that must be repeated. Schedule delay captures how extended time to a trained model impacts business timelines. Opportunity cost recognizes that compute consumed by recovery cannot be used for other training. Engineering cost accounts for time spent debugging failures and manually recovering.

Prevention costs include storage, throughput overhead, recovery infrastructure, and complexity. Storage cost scales with model size and checkpoint frequency. Checkpoint writes consume memory bandwidth and may stall training. Recovery infrastructure requires spare capacity and automated recovery systems. Fault tolerant systems are harder to develop and debug.

¹⁰ | **RecSys Freshness:** Meta's DLRM infrastructure documents that embedding staleness measured in hours produces measurable degradation in recommendation relevance and engagement metrics. This inverts the typical fault tolerance priority: for recommendation systems, minimizing recovery time matters more than minimizing checkpoint overhead, because stale embeddings directly reduce revenue.

Optimal investment in fault tolerance balances these costs. For small-scale training on a few GPUs where failures are rare, minimal fault tolerance may be cost-optimal. Infrequent checkpoints and manual recovery suffice. For large-scale training on thousands of GPUs where failures occur multiple times daily, extensive fault tolerance provides positive return on investment. Frequent checkpoints, automatic recovery, and elastic training become essential. Figure 7.3 visualizes how the trade-off between checkpoint overhead and recovery cost reaches an optimum that depends on both system MTBF and checkpoint write time.

Equation 7.6 presents a simplified economic model for expected cost per training run:

$$C_{\text{total}} = C_{\text{compute}} + E[N_{\text{failures}}] \times C_{\text{per-failure}} + C_{\text{ft}} \quad (7.6)$$

where C_{compute} is the base compute cost, $E[N_{\text{failures}}]$ is the expected number of failures during training, $C_{\text{per-failure}}$ is the cost per failure, and C_{ft} is the cost of fault tolerance mechanisms. The cost per failure includes wasted compute plus overhead.

Equation 7.7 formalizes when fault tolerance investment is justified:

$$\frac{\partial C_{\text{ft}}}{\partial x} < \frac{\partial (E[N_{\text{failures}}] \times C_{\text{per-failure}})}{\partial x} \quad (7.7)$$

where x represents investment in fault tolerance mechanisms. In practice, this means investing in fault tolerance until the marginal cost of additional protection exceeds the marginal reduction in failure costs.

Three foundational principles guide every design decision in this domain.

🔍 Systems Perspective 7.2: Three rules of failure at scale

1. **At scale, failures are continuous, not exceptional.** A 10,000-GPU cluster experiences failures every few hours. Systems must be designed expecting failure as normal operation.
2. **Checkpoint intervals have an optimum.** The Young-Daly formula, $\tau_{\text{opt}} = \sqrt{2 \times T_{\text{write}} \times \text{MTBF}_{\text{system}}}$, provides quantitative guidance for checkpoint frequency. This formula is derived in section 7.1.2.
3. **Training and serving have fundamentally different fault tolerance requirements.** Training tolerates minutes of recovery time; serving requires milliseconds. This difference demands entirely different approaches.

Rule 3—the training/serving divergence—sets the sequence: training recovery comes first, serving resilience later. Before either, the physical realities of what breaks must be understood, starting with the hardware faults that trigger these failures.

7.2 Hardware Fault Taxonomy

Consider what happens when a cosmic ray flips a single bit in a GPU's High Bandwidth Memory, or when thermal expansion causes a microscopic fracture in an NVLink connector. These physical events cascade into software errors that can corrupt a multi-week training run, but the recovery system does not observe "cosmic ray" or "fracture" directly. It observes symptoms: a gradient spike with no process crash, a rank that disappears from the collective, or a node that fails only when it heats under sustained load. Hardware taxonomy is useful only when it turns those symptoms into a recovery decision.

7.2.1 Hardware fault impact on ML systems

ML systems amplify the consequences of hardware faults beyond what traditional applications experience. Computational intensity creates millions of opportunities per second for faults to corrupt results. Training runs lasting days or weeks increase the probability of encountering faults. Small corruptions in model weights can cause large changes in output predictions, and distributed dependencies mean that a single-point failure can disrupt entire workflows.

A single bit-flip in a weight matrix illustrates the severity. If a critical weight in a ResNet-50 model flips from 0.5 to -0.5 due to a transient fault affecting the sign bit in the IEEE 754¹¹ floating-point representation, the sign of a feature map reverses, causing a cascade of errors through subsequent layers. Fault-injection studies show that DNN resilience depends sharply on model, layer, structure, and bit position, so a small number of faults in vulnerable locations can cause disproportionate accuracy loss (Reagen et al. 2018). Unlike traditional software where a single bit error might cause a crash, in neural networks it can silently corrupt the learned representations that determine system behavior.

Reliability remains a design pressure as accelerator devices scale. Smaller geometries and lower operating voltages can reduce the charge needed to disturb a stored value, increasing sensitivity to some soft-error mechanisms (Baumann 2005), while large ML fleets expose rare hardware faults often enough that software-level detection and recovery become part of the training system design (He et al. 2023). ML system architects must treat hardware as an **unreliable substrate**, where algorithmic fault tolerance (gradient checksums, weight replication, periodic production consistency checks) is a mandatory requirement rather than an HPC specialty.

The temporal signature of a hardware fault determines that response. A one-time corruption asks for detection and rollback, a persistent defect asks for quarantine and replacement, and a recurring load-sensitive defect asks for evidence collection before the node poisons more jobs. Figure 7.12 summarizes the three categories that matter operationally.

¹¹ | **IEEE 754:** The IEEE 754 floating-point standard defines the binary32 format with 1 sign bit, 8 exponent bits, and 23 fraction bits (IEEE Standards Association 2019). The bit layout creates an asymmetric vulnerability for ML: a sign-bit flip inverts a weight entirely ($0.5 \rightarrow -0.5$), while an exponent-bit flip can shift magnitude by orders of magnitude, so resilience mechanisms often prioritize the most sensitive bit positions rather than treating all bits as equally important.

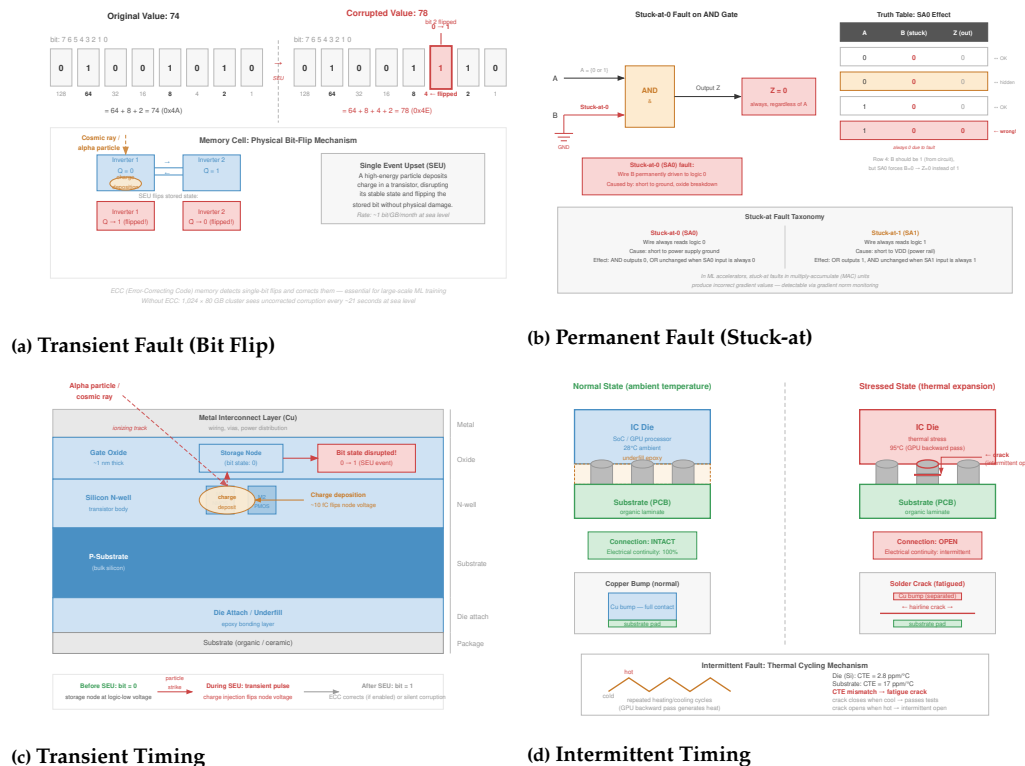

Figure 7.12: Temporal Taxonomy of Hardware Faults: Four panels show how the three temporal categories manifest in practice. Transient panels (bit flip and timing glitch) show temporary disruptions that do not cause permanent damage. The Intermittent panel shows sporadic errors driven by unstable conditions or aging. The Permanent panel (stuck-at-0/1) shows irreversible physical damage that requires replacement.

The three categories differ by what the recovery system should infer:

- Transient faults are temporary disruptions caused by external factors such as cosmic rays or electromagnetic interference (Ziegler et al. 1996). Their danger is silent corruption: a rank may keep participating while sending a wrong gradient or activation.
- Permanent faults represent irreversible damage from physical defects or component wear-out, such as stuck-at faults or device failures that require hardware replacement. Their danger is repeatability: retrying the same device reproduces the same bad computation or hard failure.
- Intermittent faults appear and disappear sporadically due to unstable conditions like loose connections, aging components, or thermal stress. Their danger is ambiguity: the job may pass validation during one run and fail under a slightly different load.

The recovery strategy changes because each category fails on a different time scale and leaves different evidence behind.

7.2.2 Transient faults

The failure taxonomy classified transients by recovery posture, asking whether the system could retry or validate the affected work. This pass asks a different question: the physical mechanism that produces them and the detection it demands. Transient faults are the most common category, and figure 7.13 illustrates the basic mechanism: a bit-flip error occurs when a single bit in memory unexpectedly changes state, potentially altering critical data or computations in ways that cascade through neural network layers.

Figure 7.13: Bit-Flip Error: Transient faults can alter individual bits in memory, corrupting data or program instructions and potentially causing system malfunctions. These single-bit errors exemplify the vulnerability of hardware to transient faults like those induced by radiation or electromagnetic interference.

Transient faults matter because they can leave no damaged component to find after the incident. A Single Event Upset from radiation, a voltage fluctuation from an unstable power path (Reddi and Gupta 2013), electromagnetic interference, electrostatic discharge, crosstalk, ground bounce, a timing violation, or a soft error in combinational logic (Mukherjee et al. 2005) can all collapse to the same ML symptom: one tensor, packet, or instruction differs from what the collective expected. The recovery design therefore emphasizes online detection, correction where possible, and rollback from a known-good state rather than manual hardware replacement.

7.2.2.1 Quantitative fault rates

Advanced semiconductor processes can increase soft-error sensitivity as node capacitance, supply voltage, and stored charge shrink (Baumann 2005). For GPUs¹², the practical risk is amplified by massive parallelism: thousands of execution lanes and high-bandwidth memories create many sites where transient faults can affect weights, activations, or gradients. Operational MTBF¹³ values are therefore workload-, component-, and environment-dependent rather than universal. For the checkpointing analysis below, the important systems rule is compounding: a cluster of 1,000 accelerators with an illustrative per-accelerator MTBF of 50,000 hours experiences an expected failure every 50 hours, necessitating robust checkpointing.

Memory subsystems are the most vulnerability-prone components, and fault tolerance mechanisms impose a direct bandwidth tax. Table 7.4 quantifies this cost across memory technologies:

The memory bandwidth protection analysis shows the throughput tax that error protection can impose on different memory technologies.

¹² | **GPU Fault Rates:** GPUs concentrate thousands of execution lanes and high-bandwidth memory stacks in a single package. ML accelerators also run sustained high-power kernels with large volumes of weight, activation, and gradient data in flight, so transient faults can affect both computation and communication state.

¹³ | **MTBF (Mean Time Between Failures):** Formalized by the U.S. military in MIL-HDBK-217 (1965), MTBF assumes exponential failure distributions during the useful-life period. For ML training, MTBF feeds directly into the Young-Daly formula: a cluster with 50,000-hour per-device MTBF and 1,000 devices has a system MTBF of 50 hours, demanding checkpoints every 1–2 hours to keep wasted compute below 1 percent of total training time.

Table 7.4: Memory Bandwidth Protection Analysis: Impact of ECC protection on effective memory bandwidth across different memory technologies used in ML accelerators. The bandwidth overhead directly affects training throughput for memory-bound workloads.

Memory Technology	Base Bandwidth	ECC Overhead	Effective Bandwidth
DDR4-3200	51.2 GB/s	12.5%	44.8 GB/s
HBM2	900 GB/s	12.5%	787.5 GB/s
HBM3	1600 GB/s	12.5%	1400 GB/s
GDDR6X	760 GB/s	Typically none	760 GB/s

The bandwidth table should not be read as a universal ranking of memory error rates. HBM, GDDR, and DDR reliability depend on device generation, operating temperature, protection scheme, and how errors are counted. The durable systems lesson is narrower: error protection consumes bandwidth and capacity, while fleet studies show that memory errors occur often enough to justify ECC, scrubbing, and monitoring in large deployments (Schroeder et al. 2009; Sridharan et al. 2015; Dixit et al. 2021). Background memory scrubbing (periodic reads and rewrites to detect accumulating soft errors) is usually engineered so that the bandwidth tax is small compared with foreground training traffic.

7.2.2.2 Transient fault impact on ML

Figure 7.14 shows the same charge-disturbance mechanism the failure taxonomy introduced (section 7.1.5.3), now at the device level: a cosmic ray strikes a memory cell or transistor and the induced charge alters stored or transmitted data. What this pass adds is the downstream effect on the model rather than the physics.

Figure 7.14: Transient Fault Mechanism: Cosmic rays and electromagnetic interference induce bit flips within hardware by altering electrical charges in memory cells and transistors, potentially corrupting data and causing system errors. Understanding these fault sources is critical for building robust AI systems that can tolerate unpredictable hardware behavior. Source: [NTT](#).

During training, transient faults in the memory storing model weights or gradients can lead to incorrect updates that compromise convergence and accuracy (He et al. 2023). During inference, a bit flip in the activation values of a neural network can alter the final classification or regression output (Mahmoud et al. 2020). In safety-critical applications, these faults can result in incorrect decisions

that compromise safety (Li et al. 2017; Jha et al. 2019; Wan et al. 2021). Resource-constrained environments amplify these vulnerabilities: Binarized Neural Networks (BNNs) (Courbariaux et al. 2016), which represent weights in single-bit precision, suffer performance degradation from 98 percent to 70 percent test accuracy when random bit-flipping soft errors are inserted with 10 percent probability (Aygün et al. 2021). In distributed training, network partitions^{14,15} can isolate ranks, and in synchronous training, even a single partitioned rank blocks the entire AllReduce collective.

7.2.3 Permanent faults

Permanent faults are irreversible hardware defects that persist until the faulty component is repaired or replaced. The operational clue is repeatability: the same accelerator, memory cell, link, or storage device fails again after retry, often at the same address, path, or workload phase. Manufacturing defects (improper etching, incorrect doping, contamination) and wear-out mechanisms (electromigration¹⁶, oxide breakdown¹⁷, thermal stress¹⁸) can all produce this signature. The most common abstract model is the stuck-at fault (Seong et al. 2010), where a signal or memory cell becomes permanently fixed at 0 or 1 regardless of input.

The most consequential permanent faults in ML accelerators are those that corrupt arithmetic silently and repeatably. A stuck-at fault in a Tensor Core’s multiply-accumulate datapath, or a defective cell in an HBM bank that stores weight shards, produces the same wrong value every time the same computation runs. In training, this means every forward pass through the affected matrix produces a deterministically biased result, and every backward pass accumulates a skewed gradient. Because the error is reproducible but numerically small, training loss may decline normally for hundreds of steps before the accumulated bias manifests as gradient divergence or unexpectedly poor validation accuracy. In inference, the same defect deterministically skews specific output logits—a safety-critical property in medical or autonomous-driving deployments, where the fault does not crash the system but systematically tilts every decision involving the affected weight tile.

The Intel Pentium FDIV bug, discovered in 1994, provides the canonical illustration of this failure mode in a general-purpose processor. An error in the lookup table used by the Pentium processor’s division unit caused incorrect results for specific operations (figure 7.15). The error was small—a mistake in the fifth digit—but it compounded across operations, corrupting precision-critical applications. The ML accelerator case differs in geometry but not in principle: where the FDIV bug corrupted scalar divisions, a stuck-at fault in a Tensor Core corrupts specific rows or columns of every matrix-multiply output that routes through the defective lane, affecting all feature maps or gradient shards that touch that partition of the computation. In safety-sensitive applications, the persistent arithmetic error becomes a safety hazard because every downstream decision inherits the biased computation.

Figure 7.16 visualizes how stuck-at faults propagate through logic gates and interconnects, causing incorrect computations or persistent data corruption that affects downstream model behavior.

For ML systems, the recovery decision is to stop trusting the component. A permanent accelerator datapath fault can keep producing bad gradients until the device is drained from the cluster (He et al. 2023; J. J. Zhang et al. 2018), while a permanent storage fault can compromise both the training dataset and the checkpoints needed for recovery. Checksum validation, replicated storage, hardware redundancy, error-correcting codes (Kim et al. 2015), and checkpoint-restart recovery¹⁹ (Egwutuoha et al. 2013) work together because each mechanism helps identify the durable copy that can still be trusted. The Young-Daly formula introduced in section 7.1.2 then gives the economic boundary. Hardware hardening increases MTBF, but the square-root relationship means reliability investment must be balanced against faster checkpointing and restart infrastructure.

7.2.4 Intermittent faults

Intermittent faults are the hardest category because they create evidence, then disappear. A node may pass a reboot test, rejoin the fleet, and fail again only when the next training job drives the package into the same thermal, voltage, or communication regime. Physical degradation (cracks in solder joints, aging ball grid arrays, residue-induced electrical connections) creates those load-dependent conditions (figure 7.17) (Constantinescu 2008; Rashid et al. 2015). Voltage-underscaling studies such as ThUnderVolt show a separate timing-error route: reduced voltage margins can make

14 | **Network Partition:** A network partition leaves one subset of workers unable to communicate with another. In synchronous training, even a single partitioned rank blocks the entire AllReduce collective. **Miniband Subnet Manager (SM):** A centralized software entity that discovers all live jobs that run long enough to encounter routing fabric or nodes and switches, assigns local identifiers, builds and calculates routing tables. In a network partition, the SM’s role is critical: it must rediscover the new topology and update routing before training can safely resume. If the SM itself is partitioned, the fabric can enter a “zombie” state where nodes are physically connected but cannot route messages, a common cause of T_{detect} delays in large training runs.

16 | **Electromigration:** Gradual displacement of metal atoms in conductors by electron momentum transfer, first characterized in early electromigration studies and later modeled in Black’s reliability equation (Black 1969). Mean time to failure decreases with higher current density and higher temperature, so sustained high-power accelerator workloads make thermal management a direct determinant of fleet lifespan.

17 | **Oxide Breakdown:** Irreversible gate oxide failure creating conductive paths through the transistor insulator. Gate oxide thickness shrank from roughly 100 nm in 1980s processes to nanometer-scale dimensions in FinFET-era devices, increasing susceptibility. Time-dependent dielectric breakdown (TDDB) constrains chip reliability projections, making oxide integrity a fleet-planning concern for ML accelerator deployments spanning 3–5 year hardware refresh cycles.

Figure 7.15: FDIV Error Regions: The downward spikes piercing the surface mark where the Pentium processor's faulty division unit produced incorrect results when calculating $4195835/3145727$. Ideally, all values should round to 1.3338, but the bug dropped affected results from 1.33384 to 1.33368, an error in the fifth digit. Source: *Byte Magazine*.

Figure 7.16: Stuck-at Fault Model: Digital circuits can experience permanent faults where a signal line becomes fixed at a logical 0 or 1, regardless of input; this figure represents a simplified depiction of a stuck-at-0 fault, where a signal is persistently low, potentially leading to incorrect computations or system failures. Source: [accendo reliability](#).

signal propagation unreliable and cause incorrect computations that are difficult to reproduce (J. Zhang et al. 2018).

Figure 7.18 reveals how residue-induced intermittent faults in DRAM chips create unreliable electrical connections that lead to sporadic failures.

For ML systems, intermittent faults should be treated as suspect until enough evidence proves otherwise. Sporadic processing or memory errors can accumulate across iterations, degrading convergence without triggering explicit failures (He et al. 2023; Rashid et al. 2015). Runtime monitoring and anomaly detection provide the first hint, environmental controls reduce thermal and voltage triggers, and adaptive resource management can drain, downclock, or avoid a suspect

Figure 7.17: Intermittent Fault Mechanism: Increased resistance from cracks between copper bumps and package solder represents a common source of intermittent faults, disrupting signal transmission and potentially causing unpredictable system behavior. Microscopic material defects like these highlight the vulnerability of hardware to latent failures that are difficult to detect during testing but can manifest during operation. Source: [constantinescu](#).

¹⁸ | **Thermal Stress:** Degradation from repeated temperature cycling that cracks solder joints and degrades thermal interface materials. ML accelerators under sustained training loads can experience thermal throttling as clock speeds drop to prevent damage. The trade-off is direct: aggressive cooling (liquid, immersion) extends component lifespan and maintains training throughput but increases data center infrastructure cost, so cooling must be evaluated against both reliability and facility cost.

component while preserving job progress (Rashid et al. 2012). The goal is not merely to keep the node alive; it is to prevent a nondeterministic component from making validation and recovery untrustworthy.

7.2.5 Hardware fault detection and mitigation

Hardware fault mitigation works only when the detection mechanism matches the fault signature. Permanent defects are best exposed before deployment, transient bit flips need online correction, and intermittent or silent errors require runtime evidence. At the hardware level, two foundational mechanisms protect against the fault classes described earlier.

Built-in self-test (BIST) (Bushnell and Agrawal 2002) incorporates additional circuitry for self-testing using scan chains²⁰ that apply predefined test patterns to internal logic during system startup. BIST catches manufacturing defects and permanent faults before they corrupt production workloads.

Error detection and correction codes²¹ (Hamming 1950) add redundant bits to detect and correct bit errors. Figure 7.19 illustrates the simplest form: parity checks append an extra bit to each data word, enabling immediate detection when a bit flip occurs. More advanced codes such as cyclic redundancy checks (CRC)²² compute checksums that detect over 99.9 percent of transmission errors, a capability critical for validating gradient payloads during the distributed AllReduce operations covered in Chapter 6.

Hardware redundancy uses component duplication and voting to detect and mask faults (Sheaffer et al. 2007). Double modular redundancy (DMR)²³ duplicates computation and compares outputs at 100 percent silicon overhead; triple modular redundancy (TMR)²⁴ performs computation three times and takes a majority vote at 200 percent overhead, enabling automatic single-fault correction (Arifeen et al. 2020). Figure 7.21 shows how a TMR voter circuit masks a single faulty unit by selecting the

Figure 7.18: DRAM Residue Fault: Intermittent failures in DRAM chips commonly arise from microscopic residue accumulation and create unreliable electrical connections. Physical defects can induce sporadic errors and highlight the need for fault-tolerant system design and hardware testing. Source: Constantinescu.

Figure 7.19: Parity Bit Error Detection: This figure provides a simple error detection scheme where an extra bit (the parity bit) ensures the total number of 1s in a data sequence is either even or odd. The second sequence includes a flipped bit, triggering the parity check and indicating a data corruption event during transmission or storage. Source: computer hope.

majority output. Tesla’s Full Self-Driving computer uses DMR across two independent system on chip (SoC) units (figure 7.20), while the Boeing 777 uses TMR in its primary flight computer for safety-critical aviation control (Yeh 1996; Bannon et al. 2019).

At the software level, the same decision tree continues, with each fault signature routed to the one evidence stream that exposes it most cheaply. Silent statistical drift appears when gradients, losses, activations, or latencies no longer match the expected distribution, and runtime monitoring plus anomaly detection (statistical outlier tests, One-Class SVM) catches it at the cheapest layer because those checks ride on metrics the training loop already emits (Francalanza et al. 2017; Chandola et al. 2009). A corrupted-but-live state or checkpoint is caught by data-consistency checks that confirm it still corresponds to trusted data (Lindholm et al. 2019). A fail-stop node is separated from a merely slow one by heartbeat mechanisms (Kawazoe Aguilera et al. 1997), and a task that stalls without crashing is caught by watchdog timers (Pont and Ong 2002) that trigger recovery on lost progress.

19 | **Checkpoint-Restart:** Originated in 1960s main-frame batch processing, where restarting multi-hour jobs from scratch was prohibitively expensive. Large distributed training jobs can checkpoint 100+ GB model states every 10–30 minutes; Google’s TPUv4 resiliency study reports coordinated checkpointing and reconfiguration that kept wasted computation from node failures below 1 percent of total training time.

Figure 7.20: Dual Modular Redundancy (DMR): Tesla's full self-driving computer employs a DMR architecture, replicating critical computations across two independent system-on-chips (SoCs). A hardware comparator unit validates that both chips produce matching outputs before allowing a control command to reach the vehicle's actuators, ensuring that a single-chip hardware failure or bit flip cannot trigger dangerous driving behavior.

20 | **Scan Chains:** Test infrastructure linking internal flip-flops into shift registers, developed in the 1970s for IC design-for-testability. The trade-off is concrete: 5–15 percent silicon area overhead buys 95 percent+ manufacturing fault coverage. For ML accelerators with billions of transistors in matrix-multiply units, scan-based testing during burn-in catches the stuck-at faults that would otherwise silently corrupt weight and gradient computations in production.

Only when none of these passive signals suffice, because the computation itself may be wrong with no statistical tell, does the system pay for software-implemented redundancy (SWIFT-style instruction duplication, N-version programming, Reed-Solomon reconstruction) (Reis et al. 2005; Avizienis et al. 2004; Plank 1997; Reed and Solomon 1960), whose duplicated or reconstructed computation is the most expensive layer and so is reserved for the highest-value state.

These mechanisms reduce the unreliable substrate risk, but they do not protect against faults introduced by the software stack itself. The next layer must reason about bugs that look like valid computation while corrupting the ML pipeline.

Checkpoint 7.3: Classifying a hardware fault

Verify your understanding of the transient, permanent, and intermittent fault categories and the fault, error, failure progression:

- ☐ **Transient fault:** Classify a GPU that produces a wrong result once after a cosmic-ray strike and then computes correctly for the rest of the run, and justify why error correction codes, not node replacement, match that fault.
- ☐ **Intermittent vs. permanent:** Distinguish an **intermittent** fault from a **permanent** one when both can produce a stuck-at value, including the diagnostic signal that separates them.
- ☐ **Fault-error-failure chain:** Trace a single bit flip through the fault, error, failure chain, identifying where error correction codes and checkpoint-restart each intervene.
- ☐ **Silent corruption:** Explain why silent corruption sits apart from the other fault manifestations even when its underlying fault is an ordinary transient bit flip.

Figure 7.21: Error Masking via Voting: In triple modular redundancy (TMR), the same computation runs on three independent units. A voter circuit takes a majority vote of the results. Even if one unit suffers a fault (for example, bit flip), the system ‘masks’ the error by selecting the matching outputs from the other two units, allowing continuous operation without interruption.

7.3 Software Faults

A team spends three months testing an LLM against complex prompt-level failure cases, only to realize that its preprocessing script accidentally truncated all inputs at 512 tokens, silently discarding the system prompt entirely. In the pursuit of complex algorithmic robustness, engineers often overlook a common source of ML failure: mundane software bugs. In ML systems, a logic error in a data loader does not crash the pipeline; it subtly degrades the gradient, making software faults uniquely damaging.

Software faults require a different recovery lens from hardware failures. Hardware faults enter from silicon, electrons, and physical wear; software faults enter through design choices, dependency versions, and pipeline glue. The fault-tolerance problem shifts from replacing a failed component to identifying which valid-looking transformation corrupted data, gradients, or predictions.

The practical challenge is that software faults interact with every other system threat. A bug in data preprocessing can create distribution shifts, an implementation error in numerical computation can corrupt model behavior while preserving valid tensor shapes, and a race condition in distributed training can make different workers update from inconsistent state. These interactions arise because AI software stacks span frameworks, libraries, runtime environments, distributed systems, and deployment infrastructure. Each layer boundary creates an opportunity for faults to emerge and propagate, making software-level mitigation essential for production-scale reliability.

7.3.1 Software fault properties and propagation

Software faults in ML frameworks range from syntactic and logical errors to memory leaks,²⁵ concurrency bugs, and integration failures. They propagate across system boundaries: an error in a tensor allocation routine can cascade to disrupt training, inference, or evaluation in seemingly unrelated modules. Some faults are intermittent, manifesting only under specific conditions such as high system load, particular hardware configurations, or rare data inputs.

²¹ | **Hamming Codes (1950):** Richard Hamming invented error-correcting codes at Bell Labs after repeated frustration with relay computer failures corrupting weekend batch jobs. His SECDED (single-error-correcting, double-error-detecting) scheme uses parity bits at power-of-2 positions to locate errors with $\mathcal{O}(\log n)$ overhead. ECC memory modules descend from this design, protecting the terabytes of model weights and optimizer state in ML training from the soft errors that would otherwise accumulate silently.

22 | **CRC (Cyclic Redundancy Check):** Polynomial checksum family introduced by Peterson and Brown (1961). CRC coverage depends on the polynomial, frame length, and error model; it is best understood as a low-cost detection layer rather than a universal guarantee. In distributed ML training, checksums or hashes can validate gradient payloads exchanged during collectives; without a verification layer, a corrupted gradient packet can silently poison the parameter update for every worker in the collective.

23 | **DMR (Double Modular Redundancy):** Duplicates computation and compares outputs to detect disagreements, at 100 percent silicon overhead vs. TMR's 200 percent. DMR detects mismatch but cannot choose the correct output by itself, so its coverage depends on the comparator, fault model, and safe fallback policy. Tesla's Full Self-Driving computer uses DMR across two independent SoCs, reflecting the design trade-off: DMR halves the hardware cost of TMR while requiring a safe fallback policy when outputs disagree (Bannon et al. 2019).

24 | **TMR (Triple Modular Redundancy):** Performs computation three times and takes a majority vote, enabling automatic single-fault correction at 200 percent hardware overhead. First applied in early fault-tolerant mainframes in the 1950s, TMR remains a longstanding pattern for radiation-exposed and safety-critical inference where single-fault correction matters more than hardware efficiency.

25 | **Memory Leak:** A programming error where allocated memory is never released. In ML systems, GPU memory leaks are uniquely destructive because accelerator memory is scarce (40–80 GB per device) and shared across the entire training pipeline. A single leaked tensor per batch—perhaps from a debugging hook left in production—can exhaust GPU memory within hours, causing silent OOM failures that kill long-running training jobs without checkpointing.

Resource mismanagement is a prominent failure class. GPU memory allocations accumulate across training iterations as intermediate activations, optimizer states, and gradient buffers are allocated but not released, until the allocator exhausts available capacity and raises an out-of-memory error mid-batch. A 70B parameter model in BF16 with AdamW optimizer states requires roughly 840 GB of GPU memory across a node, leaving virtually no headroom for unexpected buffer growth. Memory pressure builds gradually over hundreds of iterations, making root-cause attribution difficult without per-layer memory profiling.

Concurrency and synchronization errors constitute another recurring fault class. In distributed or multi-threaded environments, incorrect coordination among parallel processes leads to race conditions,²⁶ or inconsistent states.

Deadlocks²⁷ create a related synchronization failure, where workers wait indefinitely on resources or messages that never arrive. A bug in a high-level library might only manifest when paired with a specific version of a low-level numerical library such as cuDNN or MKL, requiring a holistic view of the system to identify root causes.

7.3.2 Software fault detection and prevention

Because many software faults leave the pipeline running while corrupting gradients, software fault mitigation strategies must assign each lifecycle phase a detection job. The prompt-truncation bug from the opening example should not survive until production monitoring: a unit test should catch the tokenizer boundary, an integration test should catch the batch shape and metadata path, a regression test should protect representative prompts, and runtime monitoring should detect any unexpected truncation distribution that escapes development. Table 7.5 organizes these gates by the kind of corruption they are designed to catch.

Table 7.5: **Fault Mitigation Strategies:** Software faults in ML systems require layered gates that catch different corruption modes: tokenizer boundary errors, batch-shape drift, unsafe slicing, dependency incompatibility, and runtime anomalies.

Category	Technique	Corruption caught	When to Apply
Testing and Validation	Unit testing, integration testing, regression testing	Tokenizer boundaries, batch shapes, golden-example regressions	During development
Static Analysis and Linting	Static analyzers, linters, code reviews	Unsafe slicing, implicit casts, unguarded shape assumptions	Before integration
Runtime Monitoring & Logging	Metric collection, error logging, profiling	Length-distribution shifts, NaN gradients, memory-growth anomalies	During training and deployment
Fault-Tolerant Design	Exception handling, modular architecture, checkpointing	Bad batches fail closed and recovery resumes from known-good state	Design and implementation phase
Update Management	Dependency auditing, test staging, version tracking	Tokenizer, data-collator, framework, and CUDA compatibility drift	Before system upgrades or deployment
Environment Isolation	Containerization (for example, Docker, Kubernetes), virtual environments	Environment-specific behavior and irreproducible dependency stacks	Development, testing, deployment
CI/CD and Automation	Automated test pipelines, monitoring hooks, deployment gates	Untested model, data, or preprocessing changes reaching production	Continuously throughout development

These safeguards matter only when each gate targets a concrete corruption path. A unit test that checks only whether the tokenizer runs is too weak; it must assert that system prompts, labels, masks, and sequence-length metadata survive preprocessing with the intended semantics. Integration tests then follow one batch through loading, sharding, collation, and model input construction, while regression tests preserve representative prompts and edge cases before they enter distributed execution (figure 7.22). The continuous integration/continuous deployment (CI/CD) structure in figure 7.23 is useful only when the release pipeline treats model, data, and preprocessing changes as ML artifacts that can corrupt the training objective; otherwise, it is just a generic software-delivery diagram. Automated gates make those checks release requirements instead of optional habits.

Figure 7.22: Automated Regression Testing: The recurring concerns of regression testing, spanning platform coverage, risk-based selection, parallel execution, unit and API coverage, performance impact, and continuous methodologies. For ML pipelines, these same gates must preserve tokenizer behavior, feature semantics, and batch construction across code changes. Source: [UTOR](#).

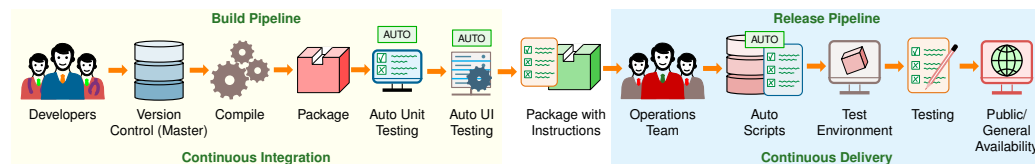

Figure 7.23: A CI/CD Pipeline: The standard software-delivery flow, from developer commit through version control, build, automated unit and UI testing, packaging, and release to general availability, grouped into a continuous-integration build pipeline and a continuous-delivery release pipeline. The accompanying text explains the additional gates, on model artifacts, data contracts, dependency versions, and preprocessing semantics, that this structure must add to become fault-tolerant for ML. Source: [geeksforgeeks](#).

These software practices catch implementation faults that surface through tests or deployment gates. Silent corruption is harder because the system may continue running while producing wrong values, so the next layer is explicit verification.

7.4 Check-and-Verify: Defending Against Silent Data Corruption

As clusters scale to 100,000+ GPUs, the probability of a “Silent Data Corruption” (SDC) event (in which an ALU or HBM bit flip occurs without triggering ECC or hardware alerts) approaches certainty during large collective operations. Standard AllReduce algorithms assume that if a node is *alive*, its data is *correct*. In the machine learning fleet, we must transition to a Byzantine fault tolerance mindset: “Trust, but verify.”

Check-and-verify methods turn that mindset into a data-path invariant. The system computes a checksum, hash, or redundant reduction over each gradient shard or reduced buffer, compares the result across ranks or against an independently computed digest, and blocks the optimizer step when the verification disagrees. A quick estimate makes the exposure concrete.

26 | **Race Condition:** A timing bug where system behavior depends on the uncontrolled sequence of concurrent events. In asynchronous distributed training, if multiple workers update the same parameter weight simultaneously without proper locking or versioning, updates can be lost or overwritten, leading to divergence or “ghost” weights that ruin convergence without triggering an error.

27 | **Deadlock:** A state where two or more processes are permanently blocked, each waiting for the other to release a resource. In pipelined training, a deadlock can occur if Stage 1 is waiting for a free buffer to send activations to Stage 2, while Stage 2 is waiting for Stage 1 to receive backward gradients, halting the entire fleet.

Silent data corruption accumulates until it becomes routine.

Napkin Math 7.2: The SDC certainty

Problem: Calculate the probability that at least one GPU in a 100,000-GPU fleet experiences a silent ALU error during a single 2 s training step.

1. **Fleet size:** 100,000 accelerators.
2. **Individual risk:** 10^{-6} per hour (a conservative estimate for SDC).
3. **The exposure:** In a 2-second window, the fleet has $100,000 \times (2/3600) \approx 56$ “GPU-hours” of exposure.
4. **The probability:** $\Pr(\text{at least one SDC}) \approx 0.0056$ percent.

Systems insight: In a 100k-GPU fleet, a silent error occurs every 18,000 steps (roughly every 10 hours). Check-and-verify methods compute a CRC or hash for each gradient shard or reduced buffer, compare the digest across ranks or against a redundant reduction, and block the optimizer step when the digest disagrees. Without checksummed collectives or hash-and-verify gradients on the AllReduce path, model parameters silently accumulate corrupted contributions and drift within half a day. Robustness moves from being a *restart* problem to a *verification* problem: the fleet must perform redundant reductions or use parity-protected gradients to catch silent parameter corruption.

The calculation makes check-and-verify mandatory, but verification only earns trust when tested against realistic failures. The next step is therefore to inject faults deliberately and confirm that the same checks catch the corruption before it reaches model state.

7.5 Fault Injection Tools and Frameworks

Verification only has value when the injected failure resembles the production failure the system must survive. A multi-node training cluster that claims to tolerate network partitions should have that connection severed in a staging environment so engineers can observe what the orchestration layer does. **Fault injection** is the engineering discipline of deliberately perturbing a system to empirically verify that robustness mechanisms work before production traffic discovers the gap. ML/tensor/GPU fault-injection tools cover bit flips, tensor faults, and accelerator-oriented failures (Z. Chen et al. 2020; Tsai et al. 2021; Gräfe et al. 2023), while network partitions, latency injection, dependency termination, and API-response faults belong to chaos and distributed-systems testing practice (Basiri et al. 2016).

7.5.1 Fault and error models

That resemblance is a modeling decision, not an implementation detail. A transient bit flip, a permanent accelerator defect, and a corrupted gradient require different detection logic, so the experiment must specify duration, location, granularity, and propagation path before it begins.

These choices define the **fault model**: how a hardware fault manifests in the system. The corresponding **error model** represents how that fault propagates and affects the system’s behavior.

The first modeling choice fixes the physical signature of the fault. Duration determines whether recovery should expect a transient event, a permanent defect, or an intermittent condition that is hard to reproduce. Location determines whether the injected fault enters through memory cells, functional units, or interconnects. Granularity determines whether the experiment studies a single bit, such as a bit flip, or a multi-bit burst error.

The error model carries that physical signature into the ML system. It describes how an initial hardware-level disturbance becomes corrupted weights, miscomputed activations, or higher-level logical errors in an ML framework. The abstraction level matters because each level exposes different propagation paths and masks different effects.

The choice of fault or error model is central to robustness evaluation. For example, a system built to study single-bit transient faults (Sangchoolie et al. 2017) will not offer meaningful insight into the effects of permanent multi-bit faults, since its design and assumptions are grounded in a different fault model entirely.

The implementation context of an error model also matters. A single-bit flip at the architectural register level, modeled using simulators like gem5 (Binkert et al. 2011), differs meaningfully from a similar bit flip in a PyTorch model’s weight tensor. While both simulate value-level perturbations, the lower-level model captures microarchitectural effects that are often abstracted away in software frameworks.

Some fault behavior patterns transfer across abstraction levels, while others do not. Studies that compare single-bit and multi-bit fault models show that impact depends on where the fault lands and how it propagates, so robustness results from one injected-fault model should not be treated as universal (Sangchoolie et al. 2017; Papadimitriou and Gizopoulos 2021). Other important behaviors like error masking (Mohanram and Touba 2003) may only be observable at lower abstraction levels. This masking phenomenon can cause faults to be filtered out before they propagate to higher levels (figure 7.24) (Ko 2021), meaning software-based tools may miss these effects entirely.

Figure 7.24: Error Masking: Microarchitectural redundancy can absorb single-bit faults before they propagate to observable system errors, highlighting a discrepancy between hardware-level and software-level fault models. This figure details how fault masking occurs within microarchitectural components, demonstrating that software-based error detection tools may underestimate the true resilience of a system to transient errors.

7.5.2 Fault injection methods

Fault injection methods trade realism against experimental scale. Hardware-based injection is the calibration point: it introduces faults into physical systems so software-level assumptions can be checked against real hardware behavior. Software-based injection is the scalable counterpart: it covers many model states quickly but must be calibrated against hardware behavior before its conclusions become production reliability claims.

7.5.2.1 Hardware-based fault injection

The method choice depends on whether the experiment needs bit-level targeting or physical radiation realism. FPGA-based fault injection uses field-programmable gate arrays (FPGAs)²⁸, reconfigurable integrated circuits that can be programmed to implement various hardware designs. By modifying the FPGA configuration, faults can be introduced at specific locations and times during the execution of an ML model.

Radiation or beam testing (Velazco et al. 2010) exposes hardware running ML models to high-energy particles like protons or neutrons. Specialized test facilities enable controlled radiation exposure to induce bitflips and other hardware-level faults, providing highly realistic fault scenarios that mirror conditions in radiation-rich environments.

28 | **FPGA (Field-Programmable Gate Array):** Reconfigurable hardware containing millions of programmable logic blocks. For fault injection, FPGAs provide bit-level targeting precision that software-based tools cannot match.

7.5.2.2 Software-based fault injection

Software-based fault injection trades physical realism for experimental scale. These tools simulate the effects of hardware faults by modifying a model’s underlying computational graph, tensor values, or intermediate computations. They integrate directly with ML development pipelines, require no specialized hardware, and allow researchers to conduct large-scale fault injection experiments quickly and cost-effectively.

PyTorchFI (Mahmoud et al. 2020), a dedicated fault injection library for PyTorch developed in collaboration with Nvidia Research, is useful when the question is how tensor-visible perturbations affect model behavior. It injects faults into weights, activations, and gradients, showing that even simple bit-level faults can cause severe visual and classification errors, including the appearance of “phantom” objects where none exist.

7.5.2.3 Bridging hardware-software gap

The abstraction choice is the central risk in software-based fault injection. These tools offer speed and flexibility, but they do not always capture the full range of effects that hardware faults can impose on a system. The **abstraction gap** arises because software-based tools operate at a higher level and may overlook low-level hardware interactions or nuanced error propagation mechanisms.

Tools like **Fidelity** (He et al. 2020) address this gap by mapping low-level hardware error behavior to software-visible effects. By studying how faults originating in hardware move through architectural registers, memory hierarchies, and numerical operations, Fidelity makes software-injected faults resemble the way faults would manifest in a physical system.

Example 7.1: Software fault injection limits

Scenario: A team validates a training system with software fault injection and concludes that a particular tensor bit flip always corrupts model output.

Mechanism: Physical beam testing can produce a different result because hardware includes **masking effects** below the software abstraction. A bit flip in a hardware register might be corrected by ECC memory or masked by logical gates before it ever reaches the variable that software tools mutate directly.

Systems lesson: Software fault injection is useful for fast coverage of model-visible states, but it can overstate vulnerability when it bypasses circuit-level defenses. Production resilience claims therefore need a hardware-calibrated fault model, not software injection alone.

7.5.3 Hardware fault summary

While hardware and software faults represent distinct failure mechanisms, they ultimately manifest as system-level events that must be managed by the reliability logic established earlier in this chapter. The fault characteristics in table 7.6 close the loop from fault model to recovery choice. The table compares transient, permanent, and intermittent faults across duration, persistence, causes, and ML system impact so the detection and mitigation strategy matches the fault category being tested.

Table 7.6: Fault Characteristics: Transient, permanent, and intermittent faults differ by duration, persistence, and recurrence, impacting system reliability and requiring distinct mitigation strategies for robust AI deployments (Constantinescu 2008). Understanding these distinctions guides the design of fault-tolerant systems capable of handling diverse hardware failures during operation.

Dimension	Transient Faults	Permanent Faults	Intermittent Faults
Duration	Short-lived, temporary	Persistent, remains until repair or replacement	Sporadic, appears and disappears intermittently
Persistence	Disappears after the fault condition passes	Consistently present until addressed	Recurrs irregularly, not always present
Causes	External factors (for example, electromagnetic interference or cosmic rays)	Hardware defects, physical damage, wear-out	Unstable hardware conditions, loose connections, aging components

Dimension	Transient Faults	Permanent Faults	Intermittent Faults
Manifestation	Bit flips, glitches, temporary data corruption	Stuck-at faults, broken components, complete device failures	Occasional bit flips, intermittent signal issues, sporadic malfunctions
Impact on ML systems	Introduces temporary errors or noise in computations	Causes consistent errors or failures, affecting reliability	Leads to sporadic and unpredictable errors, challenging to diagnose and mitigate
Detection	Error detection codes, comparison with expected values	Built-in self-tests, error detection codes, consistency checks	Monitoring for anomalies, analyzing error patterns and correlations
Mitigation	Error correction codes, redundancy, checkpoint and restart	Hardware repair or replacement, component redundancy, failover mechanisms	Robust design, environmental control, runtime monitoring, fault-tolerant techniques

7.6 Checkpointing: Preserving Progress

The practical question is how distributed training systems detect these faults and recover from them without losing days of computation. When a top-of-rack switch dies two weeks into a 175-billion parameter model training run, the cluster loses 64 GPUs instantly. The system cannot simply restart from scratch; the sunk cost is too high. The failure analysis in section 7.1 established that large-scale training systems will experience such failures frequently, requiring robust mechanisms to preserve and resume progress.

Training fault tolerance has three obligations: preserve state, detect and classify failures, and resume or resize the job. Checkpointing supplies the first obligation. The sections that follow then build the rest of the recovery model: failure detection decides what happened, recovery procedures restore a consistent process group, and elastic recovery decides whether the job can continue with a changed worker set.

Definition 7.1: Checkpointing

Checkpointing is the periodic serialization of the complete training state (parameters, optimizer state, and data loader position) to persistent storage.

1. **Significance:** It minimizes lost work after a system failure by trading checkpoint I/O against rework. Writing too often wastes accelerator time on storage traffic; writing too rarely risks replaying many completed steps after a failure. The Young-Daly formula ($\tau_{\text{opt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$) captures that local trade-off by choosing the interval that balances write cost against expected lost work.
2. **Distinction:** Unlike incremental backups, checkpointing must capture the exact execution context (including random seeds and learning rate schedules) to ensure deterministic resumption of the optimization loop.
3. **Common pitfall:** A frequent misconception is that checkpointing is “just writing to disk.” In reality, for large models, it is a storage-system stress test: the simultaneous write from thousands of GPUs can trigger a checkpoint storm that saturates the entire network fabric (BW).

A training cluster that loses power without state preservation loses millions of dollars worth of gradient updates computed over the preceding weeks. The defense is to periodically write the model state to durable storage. Checkpointing captures sufficient state to resume training from a recorded point: model parameters, optimizer state,²⁹ training progress indicators, and random state for reproducibility.

7.6.1 Checkpoint interval from failure analysis

The Young-Daly formula stated in section 7.1.2 gives the optimal checkpoint interval, $\tau_{\text{opt}} = \sqrt{2 \times T_{\text{write}} \times \text{MTBF}_{\text{system}}}$, but it cannot be applied until both inputs are known. The failure analysis

29 | **Adam Optimizer State:** Adaptive Moment Estimation (Adam) maintains per-parameter first-moment (m) and second-moment (v) estimates, tripling memory requirements compared to vanilla SGD (3×: parameters + two state vectors). For a 175B parameter model, optimizer state alone reaches 2.1 TB, which typically dominates checkpoint size and recovery time, making optimizer state the primary bottleneck in checkpoint I/O design.

Optimizer state, not weights, dominates checkpoint size.

earlier in this chapter supplies the system MTBF term, and the checkpoint payload established above supplies T_{write} . With both in hand, the formula stops being an abstract law and becomes a concrete schedule for the chapter's own cluster.

Figure 7.25 plots that trade-off for an illustrative 175B-parameter cluster: save overhead falls as intervals lengthen while expected rework rises, and the Young-Daly interval sits at the minimum of their sum. Its round inputs convey the curve's shape; the worked calculation below pins the exact interval from this chapter's own computed MTBF and write time.

Figure 7.25: The Checkpoint Trade-Off: Checkpoint save overhead decreases with longer intervals, but wasted computation from failures increases. The Young-Daly optimal interval minimizes total overhead. For an illustrative 175B-model cluster (~2.5-minute checkpoint writes, 2-hour MTBF), the optimal interval is approximately 24 minutes; the worked calculation below derives the exact interval for this chapter's 10,000-GPU cluster.

The chapter's own 10,000-GPU cluster supplies both inputs, replacing the round figures in figure 7.25 with computed values. The worked cascade (section 7.1.4) put system MTBF at 3.69 hours, and the checkpoint payload above writes in 37 s (a 3.7 TB checkpoint at 100 GB/s). Substituting these into the Young-Daly formula gives the canonical interval for this cluster.

Napkin Math 7.3: The Young-Daly optimal interval

Problem: A 10,000-GPU cluster has an MTBF of 3.69 hours. A full model checkpoint takes 37 s to write. What is the optimal checkpoint frequency?

Math: Apply the Young-Daly formula: $\tau_{\text{opt}} = \sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$

1. **Convert to common units:** $\text{MTBF}_{\text{system}} = 3.69 \text{ hours} \times 3600 \text{ s/hour} = 13284 \text{ s}$.
2. **Substitute and solve:** With $T_{\text{write}} = 37 \text{ s}$ and $\text{MTBF} = 13284 \text{ s}$, the formula gives $\tau_{\text{opt}} \approx 991.4 \text{ s}$, or about 16.5 min.

Systems insight: At this interval, the “checkpoint tax” (time spent saving + time spent re-computing) is minimized to approximately 7.5 percent. Checkpointing every hour instead would increase failure risk, wasting about 14.6 percent of the cluster's capacity. As clusters scale, the optimal interval must shrink to keep up with the falling MTBF.

This result demonstrates why failure analysis matters: without knowing the system MTBF, we cannot set checkpoint intervals rationally. With this interval, checkpoint overhead consumes approximately 7.5 percent of training time, but the estimate depends on assumptions that often fail in production.

Systems Perspective 7.3: Young-Daly formula assumptions

The Young-Daly formula provides valuable intuition but rests on assumptions that may not hold in practice:

- **Exponentially distributed failures:** Assumes a constant failure rate. Real systems exhibit “bathtub curve” behavior with higher rates during burn-in and wear-out phases.
- **Deterministic checkpoint time:** Assumes T_{write} is constant. In practice, checkpoint time varies $2\text{--}3\times$ due to storage contention, network congestion, and memory pressure.
- **Recovery time equals checkpoint time:** Assumes recovery reads the same data written during checkpoint. Often recovery takes $3\text{--}5\times$ longer due to job scheduling delays, topology reconstruction, and warmup.
- **Single failure mode:** Assumes one failure at a time. Correlated failures (power, cooling, shared switch) violate this assumption.
- **Infinite timeline:** Optimizes for long training runs. Short runs, where total time is comparable to MTBF, require different analysis.

When assumptions are violated, the optimal interval may shift significantly, but restart overhead should not be treated as if it were paid at every checkpoint. In the first-order lost-time model, restart time adds a per-failure recovery term to total expected waste; it does not replace T_{write} inside $\sqrt{2 \cdot T_{\text{write}} \cdot \text{MTBF}_{\text{system}}}$ unless a recovery-aware Daly-style model is explicitly derived and calibrated.

Figure 7.26 makes the temporal cost of failures concrete by showing the sequence of events during a training run: productive computation, periodic checkpoints, a failure event, and the recovery process with its associated wasted work.

The timeline in figure 7.26 reveals why T_{restart} matters as much as T_{write} : the total failure cost is the sum of lost work (bounded by τ_{opt}) and recovery time, which includes job scheduling, checkpoint loading, and pipeline warmup. Production systems where T_{restart} exceeds T_{write} by $3\text{--}5\times$ should include recovery time in their total-waste and SLO budgets, and should use a cited recovery-aware checkpoint model rather than folding restart time into the per-checkpoint write term.

7.6.1.1 Checkpoint overhead analysis

Beyond the time consumed by checkpoint writes, checkpointing imposes additional overhead through memory consumption and training disruption. Checkpoint serialization requires memory buffers for gathering distributed state and preparing data for write. For synchronous checkpointing, all workers must hold their checkpoint data in memory until the checkpoint completes. This potentially requires significant additional memory allocation.

Synchronous checkpointing pauses training while the checkpoint writes. Even with fast storage, the pause disrupts the training pipeline and may cause GPU idle time. Data loading and forward passes cannot proceed during checkpoint operations.

Equation 7.8 quantifies the wasted time due to checkpointing:

$$f_{\text{ckpt}} = \frac{T_{\text{write}}}{\tau_{\text{ckpt}}} + \frac{T_{\text{pause}}}{\tau_{\text{ckpt}}} \quad (7.8)$$

Here, f_{ckpt} is the dimensionless fraction of time lost to checkpointing, T_{write} is checkpoint write time, τ_{ckpt} is the checkpoint interval, and T_{pause} is any training pause beyond the checkpoint write itself. This includes memory allocation, coordination, and serialization.

Checkpoint must capture all distributed state: model weights, optimizer moments, RNG seeds, dataloader position

Figure 7.26: Checkpoint-Recovery Timeline: A training run proceeds through alternating phases of computation (green) and checkpoint writes (blue). When a failure occurs (red lightning bolt), all work since the last completed checkpoint is lost (hatched gray). Recovery involves job restart overhead, checkpoint loading, and pipeline warmup before productive training resumes. The total cost of a failure includes both the lost work and the recovery latency.

7.6.1.2 The “stop-the-world” cost

The financial impact of synchronous checkpointing at scale is severe. When a 10,000-GPU cluster pauses for the 2 minutes a multi-TB checkpoint typically takes on shared storage, it burns $10,000 \times \frac{2}{60} \approx 333$ idle GPU-hours, which at roughly \$3 per GPU-hour costs about \$1,000 in wasted compute for a single checkpoint. If checkpoints occur hourly, that idle time compounds to \$24,000 per day spent waiting for storage I/O. This economic reality drives the aggressive adoption of asynchronous checkpointing strategies that move data movement off the critical path. Table 7.7 reveals how checkpoint characteristics vary dramatically by model architecture: larger models require longer write times but also benefit from correspondingly longer optimal intervals.

The Archetype A row below uses the mixed-precision optimizer footprint (2.1 TB), not the full FP32 training-state total (3.7 TB) cited in the introduction.

Table 7.7: Checkpoint Overhead by Model Type: Checkpoint sizes use the mixed-precision optimizer footprint for large LLMs (see Archetype A note above), not the 3.7 TB full FP32 training-state total from the introduction. Larger models require longer save times but also benefit from longer optimal checkpoint intervals. The percentage column reports save-only checkpoint write tax, not total Young-Daly waste; at the optimum, expected rework adds a comparable term.

Model Type	Mixed-Precision Checkpoint Size	Write Time (100 GB/s)	Optimal Interval (5 h GPU-only MTBF)	Save Overhead
Archetype A (175B dense LLM)	2.1 TB	21 s	14.5 min	2.4%
20B dense transformer class	240 GB	2.4 s	4.9 min	0.8%

Model Type	Mixed-Precision Checkpoint Size	Write Time (100 GB/s)	Optimal Interval (5 h GPU-only MTBF)	Save Overhead
BERT-Large	1.4 GB	0.014 s	22 s	0.06%
Archetype B (DLRM at Scale)	4 TB	40 s	20 min	3.3%
ResNet-50	102.4 MB	0.001 s	6 s	0.02%
Vision transformer class	1.2 GB	0.012 s	21 s	0.06%

While the theoretical overhead of checkpointing appears manageable for individual models, writing these massive state files introduces a new bottleneck. When thousands of GPUs simultaneously attempt to write gigabytes of data to a shared file system, the resulting I/O congestion threatens to bring the entire cluster to a halt. The scale of that I/O burst is easiest to see by expanding the example from one model to thousands of simultaneous writers.

Example 7.2: The checkpoint storm

Scenario: A training job saves a distributed checkpoint from thousands of accelerators at the same instant.

Mechanism: For the 2.1 TB mixed-precision optimizer footprint in the Archetype A row above—not the 3.7 TB full FP32 total—1,000 workers would each write roughly 2.1 GB of state. The same mechanism becomes catastrophic in embedding-heavy recommendation or trillion-parameter mixture-of-experts jobs: 10,000 GPUs, each holding a 10 GB shard of model or embedding state, can flood the network fabric with 100 TB of simultaneous writes.

Systems lesson: A checkpoint storm occurs when massive parallel writes overwhelm the cluster's I/O infrastructure, causing switch buffers to overflow and storage controllers to lock up.

While table 7.7 suggests modest overhead percentages, real deployments often encounter checkpoint times far exceeding these theoretical estimates. Diagnosing such discrepancies requires examining the full system stack.

Example 7.3: Debugging checkpoint overhead

Problem: A team training a 70B parameter model observes that checkpointing takes 10 minutes per checkpoint, far exceeding their expected 2 minutes target. Training throughput has dropped 30 percent because the cluster sits idle during checkpoints. Diagnose the bottleneck and identify the recovery path.

Diagnosis: The fleet stack exposes where the checkpoint overhead comes from.

The fleet stack framework in figure 1.13 structures our investigation across three layers.

Analysis: The infrastructure layer reveals the hardware constraints.

The diagnosis begins at the bottom of the stack:

- **Model state size:** 70B parameters $\times$ 2 bytes (BF16) = 140 GB for weights, plus 560 GB for FP32 Adam optimizer states (first and second moments), totaling approximately 700 GB per checkpoint before gradients, master weights, metadata, or framework overhead
- **Storage system:** Shared NFS filer with 10 Gbps network attachment
- **Theoretical bandwidth:** 10 Gbps = 1.25 GB/s maximum throughput
- **Minimum write time:** 700 GB / 1.25 GB/s = 560 s (9.3 min)

The infrastructure layer reveals our first insight: even with perfect efficiency, the NFS bandwidth cannot achieve a 2-minute checkpoint for this model size.

Analysis: The distribution layer shifts the diagnosis from raw bandwidth to checkpoint coordination.

- **Checkpoint mode:** Synchronous, all 512 GPUs pause and wait
- **Write pattern:** All 64 nodes writing simultaneously to shared NFS
- **Observed behavior:** writes that take 10 minutes instead of the 9.3 min theoretical minimum

The Distribution Layer reveals the shared-storage bottleneck. With 64 nodes competing for 10 Gbps, each node effectively receives only 20 MB/s, the 10 Gbps link split evenly across all 64 nodes. If the checkpoint is sharded evenly, each node writes about 10.9 GB, so the write still lands near 9.3 min. The observed 10 minutes is therefore close to the bandwidth floor, not something more simultaneous NFS writers can solve.

Analysis: The governance layer connects the bottleneck to the completion target.

- **SLA requirement:** Training must complete within 2 weeks
- **Current trajectory:** 30 percent overhead extends training to 2.6 weeks
- **Budget impact:** Extended training incurs additional \$500K in compute costs

Fix: A layer-aware checkpoint path removes the critical-path storage bottleneck.

1. **Infrastructure layer:** Install local Non-Volatile Memory Express (NVMe) staging drives (3.5 GB/s per node).
2. **Distribution Layer:** Implement asynchronous checkpointing:
 - Phase 1: GPU → CPU memory copy (fast, 32 GB/s PCIe)
 - Phase 2: CPU → local NVMe (3.5 GB/s, training resumes)
 - Phase 3: Background NVMe → NFS copy (overlapped with training)
3. **Validation:** The critical-path data copy drops to approximately 0.34 s if GPU-to-CPU staging proceeds in parallel across 64 nodes (or 21.9 s if serialized through one 32 GB/s path), reducing training impact from 30 percent to under 1 percent once background NVMe and NFS copies are overlapped.

Systems lesson: Diagnosing distributed systems failures requires examining all layers. A purely algorithmic fix (Distribution Layer) would fail because the physical bandwidth was insufficient. A purely hardware fix (infrastructure layer) would be wasteful without understanding the coordination pattern. The solution required changes at multiple layers working in concert.

The interval calculation chooses *when* the system should preserve state. The next implementation question is *how* that state is written and recovered without turning the checkpoint itself into the critical path.

7.6.1.3 Synchronous vs. asynchronous checkpointing

The synchronous and asynchronous checkpointing approaches create different failure recovery trade-offs. **Synchronous checkpointing** guarantees a globally consistent state, with all workers at the same training step, simplifying recovery logic. All workers coordinate to reach a consistent state, write their portions, and resume training only after all writes complete.

Asynchronous checkpointing reduces training disruption but requires tracking which workers have completed which checkpoints, adding complexity to recovery coordination. Workers snapshot their state to CPU memory or staging storage, then continue training while a background process writes the snapshot to persistent storage.³⁰

30 | **Asynchronous Checkpointing:** Pipelines the checkpoint write behind training computation by staging GPU state to CPU memory via CUDA streams, then writing to storage on a background thread. Implementations such as DeepSpeed can approach very low checkpoint overhead when sufficient CPU staging memory is available, decoupling the checkpoint I/O latency from the training critical path at the cost of higher peak host memory consumption.

7.6.1.4 Checkpoint storage and recovery

The tiered checkpoint storage architecture described in section 4.7, with local NVMe for speed, distributed filesystem for durability, and object storage for long-term retention, provides the storage foundation on which recovery mechanisms operate. The fault-tolerance question is how recovery mechanisms use that infrastructure rather than how the storage hierarchy is designed.

For fault tolerance, the critical concern is not where checkpoints are stored but how quickly they can be read during recovery. Recovery time depends on storage tier bandwidth: local NVMe enables fastest recovery (5–10 GB/s per node), distributed filesystems provide moderate speed with durability (50–200 GB/s aggregate), while object storage offers slowest recovery but highest durability for disaster recovery scenarios.

7.6.2 Checkpoint coordination patterns

Recovery from distributed checkpoints for sharded models requires understanding the coordination protocols that ensure checkpoint consistency. When training spans multiple workers, two primary approaches exist: centralized checkpointing where a coordinator gathers all state and writes a single checkpoint, and distributed checkpointing where each worker writes its own portion of the checkpoint.

7.6.2.1 Centralized checkpointing

In centralized checkpointing, workers send their state to a coordinator process that assembles and writes the complete checkpoint. This approach simplifies checkpoint management and produces self-contained checkpoint files, but every benefit is paid for at the coordinator: all state crosses the coordinator's network links, the coordinator needs memory for the entire checkpoint, and coordinator failure loses the checkpoint operation. The pattern works acceptably for tens of workers, where the management simplicity may outweigh the bottleneck, but it becomes impractical for hundreds or thousands of workers because the coordinator becomes both the throughput limiter and the single point of failure.

The decision boundary is the size of the state and the number of writers. Centralized checkpointing is attractive when operational simplicity matters more than aggregate bandwidth, but distributed and sharded approaches become necessary once the checkpoint itself is a fleet-scale object.

7.6.2.2 Distributed checkpointing

In distributed checkpointing, each worker writes its portion of the checkpoint to a shared filesystem or object storage, as figure 7.27 contrasts with the centralized approach. A coordinator signals when to checkpoint and confirms completion, but state flows directly from workers to storage without aggregation.

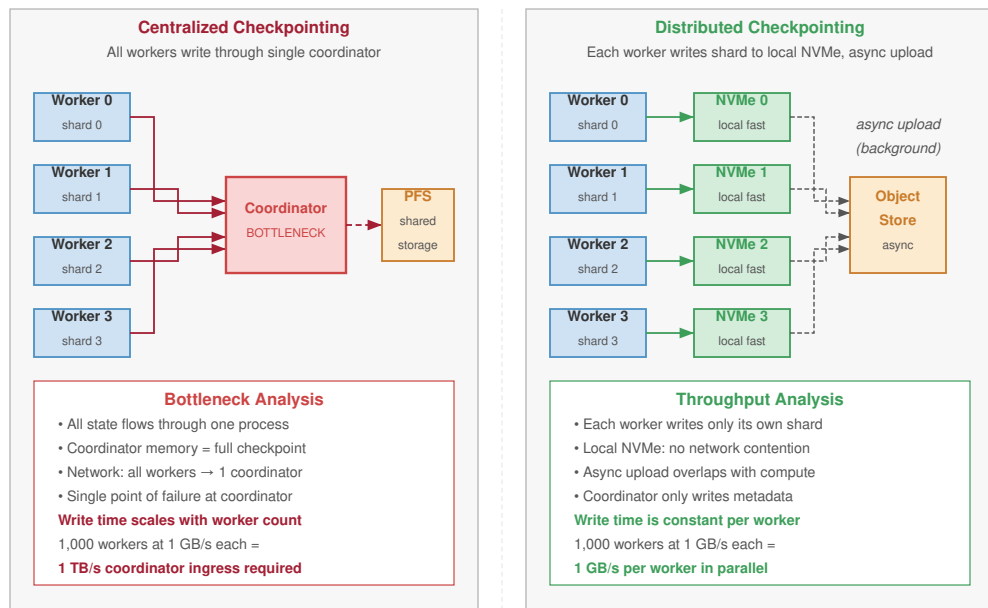

The coordination protocol proceeds in six steps:

1. Coordinator broadcasts checkpoint request with checkpoint ID
2. Each worker reaches a consistent state (barrier synchronization)
3. Each worker writes its shard to `checkpoint_{id}/worker_{rank}.pt`
4. Each worker confirms write completion to coordinator
5. Coordinator writes checkpoint metadata after all confirmations
6. Coordinator broadcasts checkpoint complete, training resumes

This protocol ensures that either all workers complete their writes or the checkpoint is incomplete. Valid checkpoints have complete metadata. Incomplete checkpoints have missing metadata and can be detected. Partial checkpoints can be garbage collected. In practice, that strictness determines whether the system can claim strict, bounded-asynchronous, or eventual consistency.

Systems Perspective 7.4: Checkpoint consistency models

The idealized protocol assumes step 2 completes quickly. At scale, this barrier synchronization becomes the dominant checkpoint cost because there is almost always at least one slow worker in a 10,000+ GPU cluster.

Centralized checkpointing (left) creates a coordinator bottleneck; distributed checkpointing (right) parallelizes I/O across all workers

Figure 7.27: Distributed Checkpoint Architecture: Comparison of centralized vs. distributed patterns. (Top) Centralized aggregation creates bottlenecks at the coordinator. (Bottom) Distributed sharding enables every worker to write directly to the Parallel File System (PFS) in parallel, aggregating bandwidth across the storage fabric and minimizing the training pause.

Strict Synchronous: All workers checkpoint at exactly the same training step. Provides strongest consistency but highest overhead from barrier synchronization.

Bounded Asynchronous: Workers may be within k steps of each other (typically $1 \leq k \leq 3$). The checkpoint manager tracks the “checkpoint wavefront” across workers. Recovery uses the earliest consistent cut across all shards. This trades perfect consistency for dramatically reduced synchronization overhead and is what production systems actually use.

Eventual Consistency: Workers checkpoint when convenient, reconcile during recovery. Lowest overhead but requires complex recovery logic to reconstruct consistent state.

The basic protocol has a subtle correctness bug: if the coordinator crashes after some workers confirm but before writing metadata, those workers believe the checkpoint succeeded while the system has no valid checkpoint. Production systems use two-phase commit³¹, a classic distributed systems protocol (Gray 1978), to make the checkpoint decision atomic:

In the prepare phase, workers write to a staging location and report success to the coordinator. In the commit phase, the coordinator atomically renames or commits all shards together, moving files from staging/ to checkpoints/, for example. If the coordinator fails between phases, workers detect the failure during the next heartbeat and roll back staged writes, so either all shards commit together or none do. Consistency remains a separate requirement: synchronous gradient updates naturally create step boundaries where all workers have applied the same updates, but asynchronous training and pipeline parallelism require more careful coordination to define a consistent cut.

7.6.2.3 Sharded checkpointing

Modern distributed training frameworks partition model state across workers using techniques like ZeRO (Zero Redundancy Optimizer) and FSDP (Fully Sharded Data Parallel). In these configurations, no single worker holds complete model state. Each worker holds only its assigned parameter shard plus corresponding optimizer state.

³¹ | **Two-Phase Commit (2PC):** Formalized by Gray (1978), 2PC ensures all participants either commit or abort atomically. The protocol’s known weakness is blocking: if the coordinator fails between prepare and commit, participants wait indefinitely. For distributed checkpointing this blocking is acceptable because a stuck checkpoint can be timed out and retried, whereas the alternative (partial checkpoint writes) would leave the system with an unrecoverable inconsistent state.

Sharded checkpointing³² (Rajbhandari et al. 2020) uses this distribution: each worker writes only its shard, dramatically reducing per-worker write volume. Recovery loads shards and redistributes state to workers based on the recovery configuration.

This approach enables efficient checkpointing even for massive models. A 175B parameter model with a 3.7 TB checkpoint distributed across 1,024 workers requires each worker to write only 3.6 GB, achievable in seconds with local NVMe storage.

When recovering with a different number of workers than the checkpoint, shard redistribution must remap state to the new worker configuration. This occurs due to elastic scaling or hardware changes. Framework support for flexible resharding enables recovery even when the worker count changes. However, possessing a valid checkpoint is not sufficient on its own. Sharded checkpointing mitigates the I/O storm, but the system must still identify the failure, trigger restoration, and coordinate the distributed shards before training can resume. The speed of detection and recovery determines the true cost of the interruption.

³² | **Sharded Checkpointing:** Each worker saves only its local partition rather than gathering state to a single writer. For ZeRO-3 or FSDP with 1,024 workers training a 175B model, each worker writes approximately 3.6 GB instead of one writer handling 3.7 TB, parallelizing I/O across all nodes. The trade-off: recovery requires all shards to be present and consistent, making the checkpoint protocol more complex and the failure of any single shard's storage fatal to the entire checkpoint.

Checkpoint 7.4: Reasoning about the checkpoint tax

Verify your understanding of how failure rate and checkpoint cost set the optimal checkpoint interval:

- ☐ **Young-Daly shift:** Use the Young-Daly formula to estimate how the optimal interval τ_{opt} shifts when a cluster doubles in size and its system MTBF halves, with T_{write} held fixed. State whether the interval lengthens or shortens and by about what factor.
- ☐ **Two-sided tax:** Explain why writing checkpoints too frequently and writing them too rarely both raise the **checkpoint tax**, including the two costs τ_{opt} balances.
- ☐ **Faster writes:** Determine how an order-of-magnitude reduction in T_{write} from sharded checkpointing changes the optimal interval and expected lost work per failure.
- ☐ **Square-root scaling:** Explain why the Young-Daly interval depends on the square root of MTBF rather than scaling linearly with it.

7.7 Failure Detection and Recovery

A GPU silently hangs, dropping its utilization to zero while its peer GPUs wait indefinitely at an AllReduce barrier. Every minute the system takes to notice this straggler and reboot the node costs thousands of dollars in idle cluster time. Checkpoints preserve state, but the recovery process itself determines how much compute a failure wastes.

Equation 7.9 decomposes recovery time into four primary components:

$$T_{\text{recovery}} = T_{\text{detect}} + T_{\text{restart}} + T_{\text{load}} + T_{\text{warmup}} \quad (7.9)$$

where:

- T_{detect} : Time between the actual hardware fault and the system classifying it as a failure
- T_{restart} : Time for the job scheduler to allocate new resources and launch replacement processes
- T_{load} : I/O time to read checkpoint state from distributed storage into GPU memory
- T_{warmup} : Time for the system to refill the data pipeline, compile just-in-time (JIT) kernels, and stabilize throughput

Each component presents distinct optimization opportunities, and the dominant term varies by cluster configuration. Understanding this decomposition enables targeted investment in the bottleneck rather than uniform improvement across all components.

7.7.1 Failure detection mechanisms

Detection is the first line of defense, governed by a fundamental trade-off between speed and false positive rate. A timeout that is *too aggressive* mistakes temporary network jitter for a node failure, triggering an unnecessary and expensive restart. A timeout that is *too conservative* allows the entire cluster to sit idle while a dead node holds up synchronization.

Detection latency climbs from seconds (crash) to hours (silent corruption).

Heartbeat monitoring is the standard mechanism: each worker periodically sends “I am alive” signals to a central coordinator or monitoring service. Missing heartbeats trigger failure classification. The heartbeat interval H and timeout T_{timeout} control the trade-off. In high-scale clusters, heartbeat arrival times often follow a heavy-tailed distribution due to network congestion, necessitating adaptive timeouts rather than static thresholds. Production systems typically use $T_{\text{timeout}} = H + k\sigma_d$ where k ranges from 3 to 5 and σ_d is the observed standard deviation of network delay.

Collective communication timeouts provide a second detection layer. During synchronous training, collective operations (AllReduce, Broadcast) are blocking: if a single rank fails silently (a frozen GPU driver, for instance) every other rank in the communicator hangs indefinitely waiting for data that will never arrive. NCCL³³ provides configurable transport and RAS timeout parameters for this purpose, while higher-level frameworks may impose process-group operation timeouts. These settings are often set conservatively to avoid crashing jobs during legitimate periods of slow communication, which unfortunately extends T_{detect} .

Container orchestration health checks provide a third layer. Kubernetes and SLURM offer liveness probes (verifying that processes are running) and readiness probes (verifying that processes are ready to handle requests). These operate independently of the training framework, catching failures that application-level heartbeats might miss—such as a process that is alive but deadlocked.

Loss spike detection catches the most insidious failure mode: silent data corruption. Hardware errors that do not crash the process but corrupt the mathematical result (bit flips in ALU logic, for instance) manifest as sudden, catastrophic spikes in the loss function. The loss jumps 10–100× or collapses to NaN instantly. Unlike gradient explosions caused by high learning rates, these spikes occur without hyperparameter changes. Robust systems instrument the training loop to pause immediately upon detecting such anomalies, pinpoint the rank with the corrupted gradient via checksums or replay, and drain that node before restarting from the last healthy checkpoint.

Training dynamics monitoring extends detection beyond explicit errors. Monitoring loss values, gradient norms, and activation statistics can detect Byzantine failures that produce incorrect results without triggering exceptions. Sudden loss spikes, gradient explosions, or statistical anomalies in per-rank gradient distributions may indicate silent corruption that would otherwise go undetected for hours.

The operational question is therefore how long detection really takes once these layers interact.

🔍 Systems Perspective 7.5: Realistic failure detection latencies

Production experience shows that failure detection takes significantly longer than theoretical heartbeat timeouts suggest. The core challenge is distinguishing failures from stragglers, as table 7.8 records. These latencies exist because aggressive timeouts cause false positives (killing healthy-but-slow workers), while conservative timeouts delay real failure detection. Production systems typically use multi-stage detection: fast initial timeout triggers investigation, slower confirmation timeout triggers recovery.

Table 7.8: Production Failure Detection Latencies: Realistic detection times for process crashes, GPU hangs, network partitions, and silent data corruption, with the dominant cause of latency for each category, showing why static heartbeat timeouts alone are insufficient.

Failure Type	Typical Detection Time	Why
Process crash	5–30 seconds	Heartbeat timeout + verification retries
GPU hang	30–120 seconds	Must distinguish from legitimately slow kernel
Network partition	60–180 seconds	Must distinguish from temporary congestion
Silent data corruption	Minutes to hours	Requires statistical anomaly detection

7.7.2 Recovery procedures

Once a failure is classified, the recovery procedure executes a rigid sequence to restore consistency:

³³ | **NCCL Timeout:** NVIDIA’s collective communication library exposes transport and RAS timeout controls such as `NCCL_IB_TIMEOUT` and `NCCL_RAS_TIMEOUT_FACTOR` (NVIDIA 2026b). Higher-level launch and distributed-training frameworks can add their own restart and operation-timeout behavior (PyTorch Contributors 2026b). Aggressive timeout settings accelerate failure detection but risk false positives during legitimate long collective operations on large models, forcing a trade-off between detection latency and training stability that has no universal optimum.

1. **Job termination:** A SIGTERM is broadcast to all surviving workers. In synchronous distributed data parallel (DDP) training, the loss of one worker invalidates the global communicator, forcing a full tear-down.
2. **Resource reclamation:** The scheduler marks the failed node as “draining” to prevent immediate rescheduling and requests a replacement from the spare pool.
3. **Job restart:** New containers are launched (from cache if available), and the training binary is re-initialized on all nodes.
4. **Checkpoint loading:** Each worker reads its state shard from the distributed filesystem. For sharded checkpoints, each worker loads only its partition.
5. **State synchronization:** Ranks handshake to establish a new communicator (for example, `ncclCommInitRank`), and workers verify they are all at the same training step.
6. **Training resumption:** The data loader fast-forwards to the correct batch index, and the training loop resumes from the checkpoint step.

Automatic recovery systems perform these steps without human intervention. Modern training frameworks integrate with cluster managers to automate parts of the sequence. DeepSpeed documents save/load routines for model and ZeRO optimizer checkpoints, which provide the durable state needed after failure (DeepSpeed Developers 2026a). PyTorch’s `torchrun` elastic launch documents failure and membership-change behavior through its rendezvous mechanism, the coordinator-backed protocol by which surviving workers agree on membership and ranks after a restart (PyTorch Contributors 2026b, 2026a).³⁴

Recovery validation is the final and often overlooked step. After loading a checkpoint, validation confirms successful recovery by verifying model parameters match expected shapes and dtypes, running a few training steps and checking that the loss is consistent with prefailure values, and confirming gradient computations produce expected statistics. If the loss diverges immediately after recovery, the checkpoint itself may be corrupted, requiring fallback to an earlier snapshot.

³⁴ | **Rendezvous:** From French “rendez-vous” (present yourselves), this coordination protocol requires all surviving workers to discover each other and agree on the new group membership before training can resume. The protocol’s cost is a synchronization barrier that blocks all workers until the slowest one arrives, creating a recovery latency proportional to cluster heterogeneity.

Napkin Math 7.4: The recovery time budget

Problem: Consider our 175B parameter model training on 1,024 GPUs. The checkpoint size is approximately 3.7 TB (weights + Adam optimizer state). Estimate the cost of a single failure event.

Setup: The recovery budget T_{recovery} has four terms.

- T_{detect} : 60 s (conservative heartbeat timeout with verification retries).
- T_{restart} : 3 min (scheduler queue time + container launch + Python import overhead + NCCL initialization).
- T_{load} : 37 s (this is the aggregate-shared-storage read of the full 3.7 TB checkpoint at 100 GB/s aggregate; with sharded local-NVMe reads at 5 GB/s, each 3.6 GB shard loads in well under one second).
- T_{warmup} : 2 min (JIT kernel compilation, data pipeline buffer fill, TCP connection re-establishment).

Total: $T_{\text{recovery}} = T_{\text{detect}} + T_{\text{restart}} + T_{\text{load}} + T_{\text{warmup}} \approx 6.6$ min per failure event.

Impact: Recovery time optimization matters more as clusters grow. With the GPU-only baseline from table 7.1, a 1,024-GPU cluster has MTBF of 49 hours and experiences about 0.49 failures/day, losing about 3 minutes daily, a modest 0.2 percent overhead. However, a 10,000-GPU cluster has GPU-only MTBF of 5 hours and experiences about 4.8 failures/day, losing about 32 minutes daily—a 2.2 percent overhead equivalent to wasting roughly 5,293 GPU-hours every day (the daily lost minutes multiplied across all 10,000 GPUs).

7.7.3 Warm restart vs. cold restart

The standard recovery procedure described earlier is a **cold restart**: every process in the cluster is killed, and the entire state is reloaded from persistent storage. Cold restart is robust and simple (it

makes no assumptions about the validity of in-memory state) but it is wasteful. When a single GPU fails in a 1,000-GPU cluster, a cold restart discards the valid memory state of 999 healthy workers, forcing them all to reload from disk.

A **warm restart** preserves the state of surviving workers. When a rank fails, surviving ranks detect the failure but do not exit. They enter a waiting state, preserving loaded model weights and optimizer states in GPU memory. The scheduler replaces only the failed node. The new node joins, loads its partition of the state from disk (or receives it via broadcast from a peer), and the communicator is rebuilt. Training resumes with minimal disruption.

Warm restarts can reduce T_{load} and T_{warmup} to near-zero for 99.9 percent of the cluster, cutting total recovery time from minutes to seconds. For the 1,024 GPUs example, a warm restart avoids reloading 3.7 TB from storage, saving the 37 s T_{load} and 2-minute T_{warmup} for all but the replacement node.

The trade-off is software complexity. Warm restarts require the application to handle dynamic membership changes without leaking CUDA memory, corrupting shared state, or deadlocking during communicator reconstruction. Frameworks like TorchElastic and DeepSpeed provide this capability, but the failure modes during warm restart itself (a crash during communicator rebuild, for instance) must be handled by falling back to cold restart. A mature deployment can use warm restart as the fast path with cold restart as the safety net. Table 7.9 contrasts the two strategies:

Table 7.9: Cold vs. Warm Restart Trade-Offs: Cold restart kills every process and reloads from disk; warm restart preserves surviving workers and replaces only the failed node. Warm restart cuts recovery from minutes to seconds for the typical single-node failure but introduces software complexity around dynamic membership management. Mature deployments can run warm restart as the fast path and cold restart as the safety net.

Aspect	Cold Restart	Warm Restart
Recovery time	4–10 minutes (full reload)	30–90 seconds (single node reload)
State guarantee	Clean: all state from checkpoint	Assumes surviving state is valid
Implementation	Simple: kill all, reload all	Complex: dynamic membership management
Failure during recovery	Retry cold restart	Fall back to cold restart
Best for	Correlated failures, SDC events	Single-node failures, GPU errors

7.7.4 Recovery automation pipeline

At the scale of 10,000+ GPUs, human intervention for every failure is impossible: failures occur multiple times per day. Recovery must be an autonomous control loop managed by the cluster’s control plane. Published large-scale systems from Meta, Google, and Microsoft illustrate multi-stage automation pipelines that classify failures and select the minimum viable remediation.

The pipeline operates in four ordered stages:

1. **Health monitoring daemon:** Continuously scrapes GPU telemetry (ECC error counters, temperature, fan speed, NVLink status) alongside application metrics like training loss and step throughput, often from a sidecar container.
2. **Failure classifier:** Determines whether a signal indicates a fatal error (for example, NVIDIA Xid error 48: double-bit ECC error), a transient stall (for example, temporary network congestion), or a performance degradation (for example, thermal throttling).
3. **Action selector:** Chooses the appropriate response. A process hang triggers a container restart (fast, local); a GPU hardware error triggers node drain and replacement (slower, requires spare capacity); a network partition triggers a pause-and-wait strategy (preserving in-memory state).
4. **Validation stage:** Runs a “canary batch” after recovery to confirm the loss matches prefailure values. If the loss diverges immediately, the checkpoint may be corrupted, triggering automatic fallback to an earlier snapshot.

This automation reduces Mean Time To Recovery (MTTR) from the 30–60 minutes typical of manual intervention to under 10 minutes for most failure types. The classification stage is critical: treating every failure as a cold restart wastes compute on transient issues, while treating a hardware failure as transient allows corrupted computation to continue.

7.7.5 Distinguishing stragglers from failures

Definition 7.2: Straggler

Straggler is a worker in a distributed training job that processes tasks significantly slower than its peers, creating a synchronization bottleneck.

1. **Significance:** In a synchronous system (BSP), cluster throughput is bounded by the speed of the slowest rank. A single 10 percent performance drop on one node can reduce the effective compute capacity of thousands of nodes by 10 percent.
2. **Distinction:** Unlike a hardware failure (where the node stops), a straggler continues to produce correct results but violates the temporal consistency required for efficient parallel execution.
3. **Common pitfall:** A frequent misconception is that stragglers are caused only by “bad hardware.” In reality, they are often caused by system jitter: background OS processes, network congestion, or thermal throttling that varies across the data center floor.

A straggler is a worker that remains functionally correct but performs significantly slower than its peers. In synchronous training, stragglers are performance poison: the speed of the entire cluster is determined by its slowest component, because AllReduce cannot complete until every rank has submitted its gradients.

For the simplified no-overlap straggler model, the step time becomes:

$$T_{\text{step, straggler}}(N) = \max(T_{\text{rank}_0}, T_{\text{rank}_1}, \dots, T_{\text{rank}_{N-1}}) + T_{\text{comm}}(N)$$

Stragglers arise from “gray failures” that do not trigger explicit errors: thermal throttling reduces clock speed, degrading interconnect cables increase communication latency, OS background processes (memory scrubbing, log rotation) consume CPU cycles, and data loading from a congested network filesystem introduces variable I/O delays. Unlike hard failures, stragglers do not trigger timeouts, allowing them to silently drag down global efficiency for hours.

The challenge is distinguishing stragglers from failures. Stragglers should trigger *mitigation* (redistribute work, replace the slow node). Failures should trigger *recovery* (checkpoint-restart). Aggressive timeouts treat stragglers as failures, causing unnecessary job restarts that waste more compute than the straggler itself. Conservative timeouts waste compute waiting for stragglers that will never speed up.

Straggler mitigation strategies span a spectrum of aggressiveness:

- **Backup workers:** Replicate work assigned to slow workers and use the first result, trading compute for latency.
- **Bounded staleness:** Allows training to proceed with stale gradients from slow workers, accepting a small convergence penalty.
- **Dynamic load balancing:** Redistributes data shards away from slow workers, reducing their per-step workload.
- **Proactive replacement:** Uses GPU telemetry trends (rising temperature, increasing ECC error counts) to detect degrading workers and replace them before they become stragglers.

A simple cost calculation shows why a severe straggler may be cheaper to replace than tolerate.

A single straggler idles every healthy accelerator.

Napkin Math 7.5: The straggler tax

Consider our 1,024-GPU cluster where a normal training iteration takes 1 second. A single GPU enters a thermally throttled state, clocking down to 50 percent speed, and now takes 2 seconds to complete its computation.

Because AllReduce cannot complete until every rank has submitted its gradients, the other 1,023 healthy GPUs sit idle waiting for the straggler.

Impact:

- **Normal step time:** 1 second
- **Straggler step time:** 2 seconds
- **Effective cluster speed:** 1 step/2s = 0.5 steps/sec

A single failing device (0.1 percent of the hardware) has reduced the throughput of the entire cluster by 50 percent. At \$3/GPU-hour, this straggler wastes \$1,536/hour in idle compute.

Systems insight: It is mathematically optimal to treat a severe straggler as a hard failure. Detecting and killing a slow node to force a restart onto healthy hardware yields higher long-term throughput than tolerating the degradation. The break-even point: if a straggler slows the cluster by more than $T_{\text{recovery}}/\text{MTBF}_{\text{system}}$ (the fraction of time spent recovering from failures), replacing it immediately is cheaper than waiting.

However, killing a slow node and restarting the job implies waiting for a replacement to maintain the original GPU count. The checkpoint-restart recovery model assumes restoring the *same* resource allocation: checkpoint, wait for a replacement, restart. Elastic recovery breaks that assumption by allowing the job to continue with *fewer* workers rather than idling the entire cluster until the original count is restored.

Checkpoint 7.5: Tuning detection and recovery

Verify your understanding of how detection latency and recovery strategy trade against one another:

- ☐ **Timeout tuning:** Given the heartbeat timeout rule $T_{\text{timeout}} = H + k\sigma_d$, explain what failure mode you trade away when you lower k from 5 to 3, and which one you make worse.
- ☐ **Warm vs. cold restart:** Choose a **warm restart** or a **cold restart** for a single GPU failure in a 1,000-GPU job with surviving state intact, and identify two conditions that push recovery back toward the cold path.
- ☐ **Hot spare cost:** Explain why a **hot spare** cuts recovery latency relative to detect-then-restart, including the standing cost the cluster pays to keep that spare available.
- ☐ **Straggler decision:** Determine what governs whether to wait out a slowed node or kill it and recover onto healthy hardware.

7.8 Elastic Recovery

Suppose a 1,024-GPU training job loses an 8-GPU node to a hardware fault, but the cluster has no spare nodes available. Under checkpoint-restart recovery, the remaining 1,016 GPUs sit idle for hours waiting for a repair. Elastic recovery instead allows the job to dynamically resize and continue with slightly less compute, breaking the rigid assumption of a fixed worker count.

Definition 7.3: Elastic training

Elastic Training is the capability of a distributed training job to dynamically adjust its worker count during execution without requiring a full restart.

1. **Significance:** It converts hard failures into throughput degradations rather than full stops. A 1,024-GPU job that loses 8 GPUs continues at 99.2 percent capacity instead of dropping to zero. It requires learning rate recalibration and gradient accumulation adjustment to maintain mathematical consistency as the global batch size changes.
2. **Distinction:** Unlike checkpoint-restart recovery (which halts the job, waits for replacement hardware, and reloads state), elastic recovery is always-live: the optimization loop never stops, it only changes its parallel width.
3. **Common pitfall:** A frequent misconception is that elasticity is “automatic.” In reality, recovery requires coordinated adaptation: the training framework, the data loader, and the orchestrator must all synchronize their state to ensure that no data samples are lost or double-counted during the resize.

Figure 7.28 traces the recovery sequence: detect the failure, pause, rescale across the surviving workers, and resume.

Figure 7.28: Elastic Training Recovery: Unlike static training which aborts on failure, elastic training adapts. When a worker fails, the job pauses, redistributes the dataset and model shards across the remaining $N - 1$ workers, and resumes training from the last consistent state. This capability transforms hard failures into temporary throughput degradations.

7.8.1 Recovery adaptation mechanisms

As figure 7.28 illustrates, elastic recovery converts what would otherwise be hard failures into graceful capacity adjustments: a lost worker reduces the active count rather than aborting the job, the running step adapts to the smaller resource allocation, and the cluster resumes productive work within seconds rather than waiting minutes to hours for replacement hardware. When a failure reduces the worker count, the surviving workers must adapt several training components before they can resume. Each adaptation addresses a specific consistency requirement that, if violated, would corrupt the model or waste computation.

Batch size adjustment is the first concern: with fewer workers, each worker must process more samples to maintain the global batch size, or the global batch size must be reduced. Reducing global batch size during recovery may require learning rate adjustment to preserve convergence properties.

The relationship between batch size and optimal learning rate determines how aggressively the job can resize without destabilizing training. Goyal et al. (2017) demonstrated that a linear scaling rule works well for large-batch ImageNet training with warmup: when scaling the batch size by factor k , scale the learning rate also by factor k . Equation 7.10 expresses an alternative square-root heuristic that provides more conservative adjustment during recovery:

$$\eta_{\text{new}} = \eta_{\text{base}} \times \sqrt{\frac{N_{\text{new}}}{N_{\text{base}}}} \quad (7.10)$$

where N represents the number of workers (and thus the global batch size). The linear rule (Goyal et al. 2017) is often preferred for large-batch training with warmup when the other optimizer assumptions match the original recipe, while square-root scaling is a conservative recovery policy rather than a paper-backed law.

Gradient accumulation offers an alternative to learning rate adjustment: to maintain the original effective batch size with fewer workers, each surviving worker can accumulate gradients over multiple micro-batches before synchronization. If worker count drops by half, doubling the accumulation steps preserves the same effective batch size and avoids any learning rate change, at the cost of doubling per-step wall time.

Data loader redistribution is a coordination requirement that recovery must handle atomically. When workers are lost, the data loader must redistribute data shard assignments to ensure all training data is still processed and no samples are duplicated or dropped. A failed redistribution silently corrupts the training distribution.

State resharding adds further complexity when using sharded model parallelism (ZeRO/FSDP), because the loss of a worker means one shard of the model state is no longer locally resident. Recovery can proceed online (migrating the orphaned shard to a surviving worker) or through checkpoint reload (resharding from the last durable checkpoint).

7.8.1.1 Spot instance preemption as a failure class

Hardware faults are not the only event that removes workers from a running job. Cloud providers often price preemptible (“spot”) instances below on-demand capacity, with the caveat that they can be reclaimed with little warning. From the training framework’s perspective, a spot reclamation is indistinguishable from a hardware failure: workers vanish, and the job must decide whether to halt or adapt.

Traditional static jobs cannot survive spot preemption because a single lost node kills the entire run. Elastic recovery handles preemption identically to hardware faults:

1. The job detects the node loss (the mechanism is the same timeout or heartbeat failure).
2. It pauses briefly to redistribute the workload among surviving nodes.
3. Training resumes at reduced scale.

This recovery capability can unlock a significant cost advantage. Organizations can train on cheaper, preemptible hardware because elastic recovery converts each preemption into a temporary throughput reduction rather than a fatal error. In a scenario where spot capacity costs \$0.60/hour instead of \$3.00/hour, the savings can outweigh the efficiency loss from occasional resizing pauses.

7.8.1.2 Framework support for elastic recovery

The framework question is which resize invariants it can enforce automatically: group membership, shard ownership, data coverage, and batch math. The recovery adaptation mechanisms above (batch size adjustment, learning rate recalibration, data loader redistribution, state resharding) must be implemented by the training framework, and frameworks differ in how much of this recovery logic they automate after a failure.

PyTorch Elastic (TorchElastic) detects worker failures through a rendezvous mechanism³⁵ that re-executes whenever the worker group changes (PyTorch Contributors 2026b, 2026a). Surviving workers re-form the communication group with new RANK and WORLD_SIZE assignments after restart. TorchElastic handles rank reassignment and communication-group reconstruction, but leaves batch size, learning rate, and checkpoint semantics to user code.

DeepSpeed (Rasley et al. 2020) provides ZeRO-based distributed training and checkpointing building blocks for large models (DeepSpeed Developers 2026a). Its recovery model is checkpoint-based: after a failure, the job reloads from the last durable checkpoint, and Universal Checkpointing addresses portability across some changes in parallelism and topology (DeepSpeed Developers 2026b). The elastic behavior still depends on the surrounding launcher and resource manager rather than being made transparent by the framework alone.

Ray Train, built on Ray’s actor model, provides a checkpoint-oriented recovery path for worker failure and node preemption. Ray can restart a worker group after a failure and resume from the latest available checkpoint, while the training function remains responsible for saving and loading sufficient state (Ray Project 2026).

Horovod Elastic builds on Horovod’s data parallel training system (Sergeev and Balso 2018) with a documented elastic state API for worker additions and removals (Horovod Developers 2026). When the worker group changes, Horovod can reset ranks and reconstruct communication, while the training script remains responsible for convergence-sensitive choices such as learning-rate or batch-size policy.

The elastic training framework support summarized in table 7.10 compares the recovery automation and state management approaches across these frameworks.

Table 7.10: Elastic Recovery Framework Comparison: Frameworks differ in how they detect worker failures and how much of the recovery sequence (group reconstruction, state redistribution, batch size adjustment) they automate.

Framework	Failure Detection	Automatic Recovery	State Resharding	Cluster Integration
PyTorch Elastic	Rendezvous timeout	Yes	Manual	Kubernetes
DeepSpeed	External	Checkpoint-based	Deployment-dependent	External schedulers
Ray Train	Actor supervision	Checkpoint retry path	Checkpoint reload	Ray Cluster
Horovod Elastic	Driver heartbeat	Yes	Manual	SLURM, Kubernetes

7.8.2 Model-specific training fault tolerance

The checkpoint and recovery strategies developed above require adaptation because workloads lose different kinds of state when they fail. The design question is therefore not simply how often to checkpoint, but which state variable would make a restart mathematically or economically wrong. For recommendation workloads, incremental checkpointing, tiered checkpointing, and embedding versioning protect freshness when full-state exactness is too expensive. Table 7.11 turns that question into a compact recovery map.

³⁵ | **Rendezvous:** From French “rendez-vous” (present yourselves), this coordination protocol requires all surviving workers to discover each other and agree on the new group membership before training can resume. The protocol’s cost is a synchronization barrier that blocks all workers until the slowest one arrives, creating a recovery latency proportional to cluster heterogeneity.

Table 7.11: Training Recovery State Invariants: Workloads require different checkpoint contents because they make different state variables quality-bearing. The correct recovery policy starts from the state that would make a restart wrong, then chooses sharding, incrementality, or domain-state capture accordingly.

Workload	State at Risk	Checkpoint Implication
LLM training	Optimizer state, curriculum position, document position, long-context schedule	Preserve the FP32 optimizer state where precision matters, shard writes with ZeRO/FSDP, move serialization off the critical path, and include the data-schedule position so the optimization trajectory resumes correctly.
Recommendation	Embedding freshness, feature-store version	Favor freshness over full-state exactness with incremental checkpointing, tiered checkpointing, and embedding versioning.
Vision	Augmentation seeds, shuffling order, batch-normalization statistics, progressive-resizing schedule	Capture the stochastic and normalization state that controls the input stream; weights alone are not enough to reproduce the training trajectory.
Scientific ML	Simulator state, search frontier, explored configurations, validation seeds	Treat the model, simulator, search process, and random state as one consistency unit so recovery does not duplicate exploration or invalidate comparisons.

The common pattern is that recovery correctness is broader than weight restoration. LLMs can reload weights but resume with the wrong curriculum position; recommendation models can reload dense parameters but serve stale embeddings; vision models can reload weights but alter augmentation or normalization state; and scientific models can reload a neural network while losing the simulator state that made the data meaningful.

Elasticity and checkpointing provide the necessary resilience for long-running batch training jobs, but the operational calculus changes completely once the model is deployed to users. The challenge shifts from protecting *weeks of batch computation* to protecting *milliseconds of real-time latency*.

7.9 Serving Fault Tolerance

When a user asks a voice assistant to turn off the lights, they will not tolerate a five-minute pause while the inference server reloads from a checkpoint. Serving models presents a fundamentally different challenge: users expect millisecond-level responsiveness even when backend GPUs crash.

Serving systems rely on replicas, routing, readiness checks, load balancing, KV cache state (cached transformer attention state), and graceful degradation as building blocks. Serving fault tolerance asks how those mechanisms behave when replicas, GPUs, or state stores fail under live latency budgets. The focus here is narrower than a complete serving architecture: each mechanism is treated as a reliability boundary for real-time inference.

7.9.1 Stateless vs. stateful serving

The first serving decision is where request state lives, because that choice determines whether failover is a retry or a state-reconstruction problem. In stateless serving, each request is independent. The serving system maintains no per-session state; all information needed to process a request is contained in the request itself plus the static model weights.

The stateless pattern appears when the input itself carries all context: an image classifier processes one image, an object detector processes one frame, a single-turn text classifier processes one snippet, and an embedding service maps one input to one vector. Fault tolerance can then focus on replica health and request routing. **Redundant replicas** serve requests in parallel, **load balancing** sends traffic only to healthy replicas, **health checks** remove failed replicas from rotation, and automatic replacement starts a new replica when capacity falls. When a replica fails, in-flight requests to that replica can be retried elsewhere, because no quality-bearing session state has been lost.

The simplicity of stateless serving makes it the simpler architecture when the application permits it. However, many ML applications inherently require state across requests. Consider a chatbot: a single-turn question-answering system can operate statelessly, processing each question independently. A conversational assistant that remembers previous exchanges, however, must maintain conversation history, transforming fault tolerance from simple retry to state preservation.

Stateful serving appears wherever the current request depends on earlier requests. LLM conversations accumulate KV cache (the cached key and value projections for all prior tokens, whose management Chapter 10 develops in full) across turns, streaming speech recognition maintains context from previous audio, recommendation sessions accumulate user context, and interactive editing maintains document state across edits. The fault-tolerance consequence is that failure loses quality-bearing state, not just serving capacity. KV cache loss requires reprocessing previous turns, session context loss forces users to repeat previous interactions, and accumulated user state loss degrades quality when context is unavailable. The mitigation choice follows the size, update rate, and quality value of that state: session affinity routes a session to the same replica, state checkpointing periodically saves session state, state replication maintains a standby copy, and graceful degradation keeps the service available at reduced quality if state cannot be recovered.

Table 7.12 contrasts stateless and stateful serving fault tolerance, showing how the fundamental difference manifests in every aspect of design, from request routing to recovery complexity.

Table 7.12: Stateless vs. Stateful Serving Fault Tolerance: Stateful serving introduces significant complexity in fault tolerance due to the need to preserve accumulated session state.

Aspect	Stateless Serving	Stateful Serving
Request routing	Any replica	Session-affine replica
Failure impact	Retry on another replica	Potential state loss
Recovery complexity	Restart and load weights	Reload state + reconstruct context
Redundancy approach	Active-active replicas	Replicated state + standby
Failover latency	Milliseconds (load balancer)	Seconds (state transfer)

7.9.2 Redundancy and replication

Redundancy buys availability only when replica placement and spare capacity match the failure domain being defended against. Multiple copies of serving capability let the system continue operating when individual replicas fail.

7.9.2.1 Availability calculations

For a single replica with availability A_{single} (probability of being operational at any given time), equation 7.11 quantifies how multiple independent replicas achieve higher system availability:

$$A_{\text{system}} = 1 - (1 - A_{\text{single}})^k$$

(7.11)

where k is the number of replicas. For a service whose single replica is available 99 percent of the time, redundancy compounds as follows.

For a single replica, $A_{\text{single}} = 99\%$ corresponds to 3.65 days of downtime per year. Adding independent replicas changes the tail of the failure distribution quickly: two replicas give $A = 1 - (0.01)^2 = 99.99\%$, or 52.6 minutes of downtime per year, and three replicas give $A = 1 - (0.01)^3 = 99.9999\%$, or 31.5 seconds. The math is powerful, but it rests on the independence assumption; shared power, shared networking, and shared software bugs reduce actual availability below these theoretical values.

7.9.2.2 Replication strategies

The availability equation says how much redundancy can help; the replication strategy determines what that redundancy costs during normal operation and failover. In **active-active replication** (figure 7.29, left), all replicas actively serve requests, so capacity is used efficiently but a failed replica immediately increases load on the survivors. In **active-passive replication** (figure 7.29, right), a primary serves traffic while standby replicas remain idle but ready, simplifying failover at the cost of unused resources during normal operation.

Geographic replication extends the same choice across regions. It protects against data-center or regional network failures, but requests routed to distant regions pay additional latency. Multi-tier designs combine several replication policies at once: edge caches replicate for latency, regional serving clusters replicate for availability, and a global primary or coordination layer preserves consistency and freshness.

Redundancy turns days of downtime into seconds.

Figure 7.29: Serving Redundancy Strategies: Comparison of Active-Active vs. Active-Passive replication. Active-Active (left) distributes load across three active replicas, each receiving roughly one-third of traffic, maximizing utilization but requiring capacity headroom to absorb failures. Active-Passive (right) keeps standby replicas idle and synchronized via heartbeat, simplifying failover logic at the cost of idle resource utilization.

7.9.2.3 Replica placement and failure domains

Effective redundancy requires placing replicas in independent failure domains. Different machines tolerate individual machine failures; different racks tolerate rack-level failures from power or top-of-rack switch issues; different availability zones tolerate data-center-section failures; and different regions tolerate entire data-center failures. The independence level should match the availability requirement and cost constraint: regional replication is expensive because it duplicates compute and network capacity, but it is necessary when regional failure must not become user-visible downtime.

Placement only creates the possibility of recovery. The serving system still needs a control loop that notices the failure, removes the affected replica from traffic, and preserves enough state that the user-visible service continues with bounded degradation.

7.9.3 Failover mechanisms

When a replica fails, traffic must be redirected to healthy replicas. The speed and reliability of this failover determines the impact of failures on users. The mechanism decomposes into three questions: how the system detects health, how the routing layer acts on that signal, and what happens to stateful sessions already attached to the failed replica.

7.9.3.1 Health checking

Health checks decide when traffic should move, so they must test not only liveness but readiness and inference correctness. Liveness checks verify that the process is running and responsive, often through a simple HTTP endpoint that returns 200 and triggers restart when it fails. Readiness checks go further: for ML serving, a replica is not ready until model weights are loaded, the GPU is initialized and responsive, warmup has completed, and dependencies such as feature stores and caches are available. Inference health checks add a correctness probe by running a known input through the model and verifying the expected output, catching silent failures where the process is healthy but the model response is wrong.

Health check parameters set the false-positive/latency trade-off. A check interval such as 5 s controls sampling frequency, a 2 s timeout controls patience, a failure threshold of 3 missed probes marks a replica unhealthy, and a success threshold of 2 clean probes returns it to service.

7.9.3.2 Load balancer integration

Load-balancer design sets how much request context the routing tier can use during failover. L4 load balancing routes based on IP and port, offering simple and fast operation. L7 load balancing routes based on HTTP and gRPC content, enabling more specific routing. Service mesh adds traffic management, observability, and security around those routing decisions.

Load-balancer failover latency depends on health check frequency and failure detection logic. Aggressive settings enable fast failover but increase false positives, marking healthy replicas as unhealthy during transient issues.

7.9.3.3 Session affinity and stateful failover

For stateful serving, session affinity routes all requests within a session to the same replica. Load balancers maintain session-to-replica mapping through sticky sessions implemented with cookies, headers, or IP hashing. State failover choices then trade recovery speed against consistency and operational complexity: state loss accepts degraded quality by regenerating state from scratch, checkpointing periodically saves session state for recovery, replication copies state to a standby replica, and distributed state stores move session state into external systems such as Redis or Memcached.

The choice depends on state size, update frequency, and the quality impact of state loss; table 7.13 summarizes the trade-offs across the four common approaches:

Table 7.13: Stateful Failover Approaches: Four strategies for handling session state when a serving replica fails. State loss is fastest and simplest but discards quality on failover; checkpointing trades recovery latency for eventual consistency; synchronous replication offers strong consistency at the cost of operational complexity; distributed state stores split state management into a separate tier with configurable consistency.

Approach	Recovery Latency	Consistency	Operational Complexity
State loss	Fast	None	Low
Checkpointing	Medium	Eventual	Medium
Synchronous replication	Fast	Strong	High
Distributed state	Fast	Configurable	Medium

7.9.4 Model-specific serving fault tolerance

Model-specific serving differences follow from what state is expensive to lose and how quickly the user needs a response. The policy question is therefore a state-loss budget: which state can be rebuilt, which state must be replicated, and which state may be degraded temporarily without violating the product contract. Table 7.14 maps that question across the three common regimes.

Table 7.14: Serving Recovery State Invariants: Serving fault tolerance starts from the state whose loss changes user-visible quality. LLMs protect live context, recommendation systems protect feature freshness, and vision services protect preprocessing and device correctness.

Serving workload	State expensive to lose	Fault-tolerance policy	Degradation path
LLM conversation	KV cache, conversation context, prefix state	Replicate or checkpoint high-value session state; regenerate only when the latency budget allows.	Rebuild from transcript, reuse cached prefixes, or ask for retry.
Recommendation	Fresh user features, item features, embeddings	Replicate feature stores, cache hot features, and monitor freshness as a reliability signal.	Serve stale or default features with measured quality loss.
Vision service	Preprocessing state, device health, edge input	Retry stateless requests on healthy replicas and fail closed on preprocessing or accelerator-health faults.	Use a smaller local model, defer prediction, or return low confidence.

The KV cache³⁶ can be substantial (gigabytes for long contexts across attention layers). Losing the KV cache requires regenerating all previous turns, which can take seconds to minutes.

LLM serving choices trade KV-cache recovery latency against memory and storage overhead. The simplest strategy is to accept regeneration cost by rebuilding KV cache from conversation history after failure, but this can turn a long conversation into a multi-second or multi-minute restart. KV-cache checkpointing saves live state periodically and bounds the amount of regeneration, while KV-cache replication keeps a standby copy for fast failover at the cost of extra memory. **Prefix caching** narrows the state that must be recovered by storing common system prompts and shared context separately, so only session-specific state requires regeneration. Productized as prompt caching services like those offered by cloud providers, this approach stores and reuses KV cache for common prefixes, reducing both cost and recovery time for failures.

Recommendation serving protects freshness rather than conversational continuity. Recommendations depend on user and item features from feature stores, so feature-store unavailability can either degrade ranking quality or block recommendations entirely. The serving decision is the staleness budget: replicated feature stores keep recent features available across zones, local caches cover hot features, fallback to stale features accepts measured quality loss, and default features let the service return a lower-quality result when lookup fails. Real-time features such as recent user actions make freshness monitoring part of fault tolerance, because a pipeline that keeps serving old features is available operationally but wrong semantically. Large embedding tables may also sit behind dedicated embedding services, which need their own replication and failover plan.

Vision serving is usually closer to the stateless end of the spectrum because each image or frame can be retried on another replica. That simplicity does not eliminate fault tolerance work; it changes where the checks belong. GPU health monitoring must remove replicas with thermal throttling or memory errors before they return corrupted results, and preprocessing must fail closed when resize, crop, color conversion, or normalization stages malfunction. For edge vision, the main failure mode may be disconnection rather than a data-center replica crash, so the system often degrades by using a smaller local model, delaying nonurgent predictions, or returning a lower-confidence result until cloud connectivity returns.

When full redundancy fails (such as when an edge device loses connectivity, or a massive traffic spike overwhelms the available data center replicas), the system cannot simply crash. Instead, it must actively trade output quality for continued availability, a strategy known as graceful degradation.

7.10 Graceful Degradation

During a major regional network outage, an e-commerce site suddenly loses access to its heavy, GPU-accelerated recommendation cluster. Rather than showing users empty pages or crashing, the

³⁶ **KV Cache:** Stores key and value projections for all previous tokens across all attention layers, scaling as $2 \times N_L \times H_{KV} \times S \times d_{\text{head}} \times \text{bytes}$. For a Llama-family 70B model with 80 layers, 8 key-value heads, 128K context, 128-dimension heads, and BF16 storage, the KV cache is about 43 GB per conversation; using 64 independent key-value heads would be about 344 GB. Losing this state on failure forces regeneration of all prior tokens, converting a sub-second failover into a minutes-long re-computation that violates serving latency SLAs.

A long conversation carries tens of GB of live state.

site instantly switches to serving precomputed, generic popular items. The serving fault tolerance mechanisms developed above aim to maintain full service, but graceful degradation dictates what happens when those defenses are overwhelmed.

 Definition 7.4: Graceful degradation

- Graceful Degradation* is a fault tolerance strategy in which a system responds to resource exhaustion or component failure by deliberately reducing service quality (falling back to a smaller model, serving cached results, or returning partial outputs) rather than failing completely, maintaining measurable availability at reduced capability.
1. **Significance:** Graceful degradation converts total outage risk into a controlled quality reduction. A recommendation system that falls back from a 7B-parameter ranker to a collaborative-filtering model on GPU failure may reduce click-through rate by 8–15 percent but maintains request availability instead of turning every affected request into an error. The engineering calculation changes from total outage duration to measured quality loss during fallback.
 2. **Distinction:** Unlike complete system failure (where the service returns errors to all requests), graceful degradation provides a managed transition through a predefined capability hierarchy—each fallback level has known accuracy, latency, and resource characteristics that allow the system to continue satisfying SLOs at reduced quality.
 3. **Common pitfall:** A frequent misconception is that degradation is automatic in well-designed systems. Graceful degradation requires explicit preengineering: fallback models must be preloaded or precomputed, switchover logic must detect the failure condition and trigger the transition without human intervention, and each degradation level must have been validated to actually satisfy its reduced SLO before it is needed in production.

7.10.1 Degradation dimensions

A degradation plan must name which service property will be sacrificed before an incident begins. Table 7.15 summarizes the main levers. The table is a pre-incident design checklist, not an outage-time brainstorming aid: each sacrificed property needs a measured quality budget, an activation condition, and a recovery path before the failure occurs.

Table 7.15: Graceful Degradation Dimensions: Degradation plans choose which service property can be reduced while still returning a useful answer. Naming the dimension in advance prevents the system from treating every failure as a binary serve-or-crash decision.

Dimension	What the System Sacrifices	Typical Fallback
Quality	Model accuracy or ranking quality	Use a simpler model, such as a collaborative-filtering fallback for a multi-tower recommender.
Latency	Response speed	Batch more requests together to preserve throughput and model quality under high load.
Coverage	Result completeness	Return top-10 search results instead of top-100.
Freshness	Recency of computed results	Serve cached or stale candidates, such as hour-old news recommendations during an outage.
Feature completeness	Input richness	Use content features when user history or real-time context is unavailable.

These dimensions are not interchangeable. A search product may sacrifice coverage by returning fewer results while keeping freshness intact; a recommender may sacrifice freshness by serving cached candidates while preserving latency; and an interactive assistant may sacrifice quality by using a smaller model while keeping the session alive. The correct fallback is therefore workload-specific: it follows the property whose temporary loss least harms the application and whose recovery path can be validated before the incident.

7.10.2 Graceful degradation strategies

The dimensions in table 7.15 become operational only when the service binds each sacrificed property to a specific fallback mechanism. The strategy ladder starts with model fallback when the primary inference path is too expensive or unavailable, then moves to feature fallback when input quality degrades, and finally to load shedding when demand exceeds capacity and the system must preserve the highest-value requests first.

7.10.2.1 Model fallback

Model fallback turns quality into an explicit availability lever by maintaining multiple model versions with different resource requirements. The primary model provides full capability at the highest resource cost, a secondary model reduces capability and resource demand, a tertiary model preserves minimal capability, and a static fallback serves precomputed defaults with no inference at all. When the primary path is unavailable or overloaded, the policy descends only as far as resource pressure requires, then returns upward after the primary path is healthy again.

An image classification cascade makes the trade-off concrete. The primary path might run a ViT-Large model with 307 million parameters and 88 percent ImageNet top-1 accuracy, fall back to EfficientNet-B4 with 19 million parameters and 83 percent accuracy under pressure, then fall back again to MobileNet-V3-Large with 5.4 million parameters and 75 percent accuracy when only minimal classification remains affordable. If even that path cannot meet the SLO, the service can return cached labels, a coarse category, or “classification unavailable” rather than blocking the request indefinitely. For that ladder to be real rather than aspirational, the production system must keep multiple models deployed, route requests to the appropriate level, monitor fallback frequency, and measure the quality impact of each level.

Recommendation and ranking systems use the same pattern when a complex deep learning model falls back to a top-n popularity list, a linear ranker, or a cached response during primary serving failures. Complex models often fight for the last mile of accuracy while simple heuristics provide the bulk of the utility, so the fallback path must be monitored as a first-class quality signal rather than treated as a silent failover. Otherwise the product appears healthy while quality is silently traded for availability.

7.10.2.2 Feature fallback

Feature fallback controls how much input quality the model may lose before the request must be blocked. When feature retrieval fails, precomputed population-level defaults can substitute for missing user or item features: a recommender might use the average user embedding, genre-level item defaults, or the most recent cached value for a real-time signal. When defaults are too weak, the system can compute approximate features from available data, such as demographic similarity for missing user history, text embeddings for missing item attributes, or time-based defaults for missing context.

The key design step is prioritizing features by their contribution to prediction quality. Table 7.16 summarizes a four-level policy in which critical features block the request, important features use defaults, useful features use cached values, and optional features can be omitted with bounded quality impact:

Table 7.16: Graceful Feature Degradation Tiers: Features classified by importance to prediction quality, with the corresponding response when each tier is unavailable. Critical features block the request entirely; lower tiers allow the system to fall back to defaults, cached values, or omission with bounded quality impact. The tiers convert a binary “feature available or not” question into a four-step degradation ladder.

Tier	Example Features	Missing Action	Quality Impact
Critical	User ID, Item ID	Block request	Cannot serve
Important	User history, Item attributes	Use defaults	5–10% quality loss
Useful	Real-time context	Use cached	2–5% quality loss
Optional	Secondary signals	Omit	< 2% quality loss

7.10.2.3 Load shedding

Load shedding protects the system by sacrificing selected requests before overload spreads to every request. Random shedding is the simplest policy: drop a fraction of incoming requests and preserve enough capacity for the rest. Its weakness is that it treats all requests as equally valuable. Priority-based shedding turns quality-of-service degradation into an explicit policy by serving premium users before free users, revenue-generating requests before analytics requests, and interactive traffic before background batch work. The system is still degrading, but it is degrading according to a predeclared service contract rather than whichever queue happens to fill first.

Admission control applies the same idea at system entry points. It rejects requests that would exceed capacity rather than accepting work that will degrade every request already in the system. Circuit breakers³⁷ protect downstream dependencies by failing fast when a model replica, feature store, or supporting service is unhealthy.

Circuit breakers operate in three states: closed (normal operation), open (failing fast to prevent resource exhaustion), and half-open (probing for recovery). Figure 7.30 shows how these state transitions both shield the system from cascading failures and automatically test whether conditions have improved.

³⁷ | **Circuit Breaker:** Named after the electrical safety device that cuts power during overload. In software (popularized by Michael Nygard’s 2007 *Release It!*), the pattern wraps service calls and “trips open” after a failure threshold, failing fast instead of waiting on a dead dependency. For ML serving, this prevents a single failing model replica or feature store from exhausting connection pools and cascading failures across the entire inference fleet.

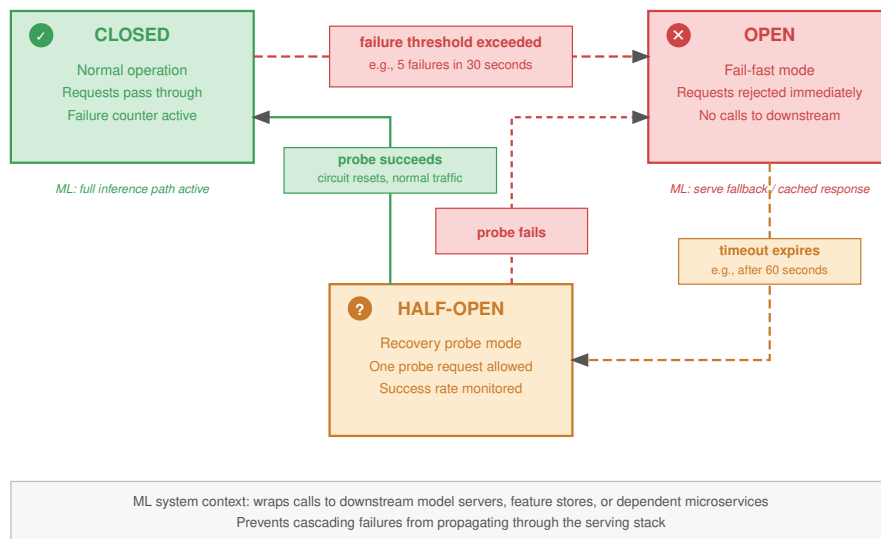

Figure 7.30: Circuit Breaker States: The circuit breaker protects the system from cascading failure. Closed: normal operation. Open: error threshold exceeded; all requests fail fast to prevent resource exhaustion. Half-Open: after a timeout, a limited number of requests are allowed through to probe the dependency’s health. Success resets to Closed; failure returns to Open.

7.10.2.4 Graceful degradation implementation

The three-state cycle prevents a single failing dependency from consuming the entire system’s connection pool: the open state fails fast, and the half-open state probes for recovery before restoring full traffic. Implementation begins by turning the degradation ladder into a control loop. Tail-latency percentiles show when users experience delay, error rates show which dependency is failing, CPU/GPU/memory utilization shows whether the system is saturated, and queue depth shows whether the service is accepting work faster than it can finish it. These health signals choose when to enter and leave each degradation level.

Degradation triggers define conditions that activate degradation. Listing 7.1 illustrates three common trigger conditions that progressively activate fallback mechanisms based on latency, error rate, and feature store health.

Listing 7.1: Progressive Degradation Triggers: Conditions that activate graceful degradation based on tail latency, error rate, and feature store health. Each trigger activates a different fallback mechanism appropriate to the detected problem.

```
# Monitor tail latency for user-facing impact
if p99_latency > threshold:
    activate_model_fallback() # Switch to faster, simpler model

# Track error rates to detect downstream failures
if error_rate > threshold:
    activate_circuit_breaker() # Fail fast, prevent cascade

# Feature store slowdowns degrade recommendation quality
if feature_store_latency > threshold:
    activate_feature_fallback() # Use cached/default features
```

Degradation should increase progressively as conditions worsen rather than switch at one cliff. The system can raise the fallback percentage gradually as load increases, then require sustained improvement before traffic returns to higher-capability paths. Hysteresis prevents oscillation between primary and fallback modes when the service hovers near a threshold.

7.10.3 Degradation monitoring and alerting

Because graceful degradation trades quality for availability, monitoring must make that trade visible rather than letting the system appear healthy while serving lower-fidelity results. The monitoring surface must expose how much service quality has been traded away. Table 7.17 turns that surface into an action map: fallback share reveals how often model quality was reduced, default-feature share reveals input-quality loss, drop rate reveals capacity protection, and the primary-vs-fallback quality gap reveals whether the degraded path remains acceptable.

Table 7.17: Degradation Monitoring Action Map: Graceful degradation is safe only when the quality trade is observable. Each signal ties a degraded serving mode to the escalation and postincident question that prevent silent quality loss.

Signal	Quality trade exposed	Escalation rule	Postincident question
Fallback-model request share	Model capability reduced to preserve serving	Sustained activation beyond 5 minutes becomes a warning.	Did the fallback preserve enough user value?
Default-feature request share	Input richness reduced because dependencies lag	Severe degradation affecting over 50% of requests becomes critical.	Which feature dependency needs replication or caching?
Load-shed request rate	Coverage reduced to protect the service	Any growth after the circuit breaker opens triggers capacity investigation.	Was admission control early enough to prevent cascade?
Primary-vs-fallback quality gap	Product quality lost during the incident	Degradation beyond 1 hour escalates even when availability metrics look healthy.	Is the fallback path still a valid product experience?

After the event, postincident analysis should identify the root cause, evaluate fallback effectiveness, measure user and business impact, and define improvements that prevent recurrence. Implementing these fallback mechanisms safely requires deep visibility into the system’s runtime state. When a complex recommendation pipeline begins degrading, operators must rapidly determine which microservice is failing, and that diagnosis depends on distributed debugging and observability.

7.11 Distributed Debugging and Observability

At 2:00 AM, latency on the flagship generative API spikes from 200 ms to 5 seconds, but CPU, memory, and network metrics all look perfectly normal. Deciding whether to shed load, restart replicas, or degrade gracefully requires knowing exactly where the request is stalling across hundreds of microservices. Distributed debugging and observability provide the diagnostic capability required to locate these invisible bottlenecks.

7.11.1 Why distributed ML systems are hard to debug

Distributed ML debugging is hard because the evidence needed for recovery is split across timing, state, scale, and model behavior. Distributed systems exhibit nondeterministic behavior³⁸ from multiple sources. Network timing variations change execution order, thread scheduling differences alter race conditions, GPU kernel execution order varies across runs, and floating-point operation ordering changes results. A bug that manifests on one execution may not reproduce on subsequent executions. These “Heisenbugs” appear to disappear when observed.

Partial failures turn that nondeterminism into a recovery problem. Unlike single-machine systems where failures are typically total, distributed systems experience partial failures where some components fail while others continue, and the interaction between working and failed components produces complex failure modes. Scale then removes manual inspection as a viable debugging method: with thousands of components, automated tools must filter massive telemetry streams and identify the few signals that explain the incident. ML systems add model behavior to the same diagnostic problem because silent accuracy degradation produces wrong results without errors, numerical issues like NaN and infinity propagate through computation, data-dependent bugs manifest only for specific inputs, and learning causes expected behavior changes that can resemble bugs.

7.11.2 Observability pillars

Observability is useful only when it connects a symptom to an action: shed load, restart a replica, roll back a checkpoint, or degrade gracefully. Suppose a recommendation service suddenly violates its latency SLO while the model replicas still report healthy GPU utilization. Metrics establish the timing and scope of the symptom, traces show which service span is consuming the request budget, and logs explain what happened inside that service at the moment the cascade began. Figure 7.31 summarizes those three evidence types, but the operating rule is correlation: no signal is sufficient unless it can be joined to the same request, model version, feature version, and deployment event.

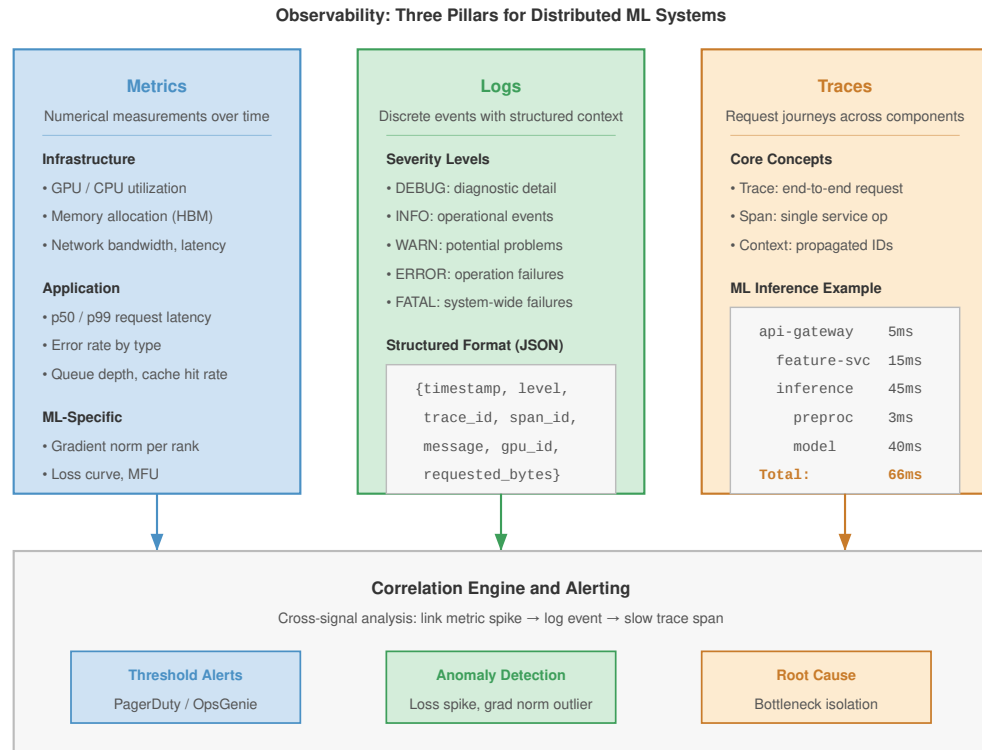

Metrics are the first evidence because they compress fleet behavior into time series that can trigger action. In ML fleets, useful metrics span infrastructure signals such as CPU and GPU utilization, memory allocation, network bandwidth, and storage I/O; application signals such as request rate, latency percentiles, error counts, queue depths, and cache hit rates; and ML-specific signals such as inference latency by model, batch utilization, feature retrieval latency, feature freshness, and prediction distributions for drift detection. A metric stream becomes fault-tolerance infrastructure only when an alert maps to a recovery decision. High p99 latency may trigger load shedding, a falling cache hit rate may trigger fallback features, and a sudden prediction-distribution shift may block a rollout before it corrupts user-facing decisions.

Logs provide the event context that a metric intentionally discards. Structured logging uses formats such as JavaScript Object Notation (JSON) with consistent fields, so incident tooling can search by service, request, model version, GPU, feature store, or trace identifier. Listing 7.2 shows a GPU memory allocation failure that records both the local failure context and the trace identifiers needed to connect the event to distributed metrics and spans.

Listing 7.2: Structured JSON Log Entry: A structured log entry for a GPU memory allocation failure, including trace and span identifiers for correlation with distributed traces and resource metrics for diagnosis.

```
{
  "timestamp": "2024-01-15T10:23:45.123Z",
  "level": "ERROR",
  "service": "inference-server",
  "trace_id": "abc123",
  "span_id": "def456",
  "message": "GPU memory allocation failed",
  "gpu_id": 3,
  "requested_bytes": 4294967296,
  "available_bytes": 2147483648
}
```

³⁸ | **Heisenbug:** Coined in hacker culture circa 1983, formalized by Jim Gray in his 1985 analysis of computer failures, as a pun on Heisenberg’s uncertainty principle. The bug disappears under observation because adding instrumentation changes timing. In distributed ML training, this is especially pernicious: inserting gradient logging alters NCCL collective timing, masking the very race condition that caused the silent corruption.

Metrics, Logs, and Traces each capture a different dimension; the correlation engine links them to isolate root causes in distributed ML failures

Figure 7.31: The Three Pillars of Observability: Diagnosis of fleet failures requires correlating three signal types. Metrics reveal *when* and *where* a problem occurs (for example, GPU utilization drops). Logs provide the *what* through event context (for example, Out-of-Memory exception). Traces provide the *why* by linking events across the distributed lifecycle (for example, identifying the specific request that triggered the memory spike).

For fault tolerance, the important logging property is consistent correlation rather than the particular backend. Log levels should map incidents to escalation consistently across components, but the recovery system depends more on whether operators can query events by the same request, trace, model version, feature version, and deployment identifiers that appear in metrics and spans. Log aggregation is therefore useful because it preserves the join between local failure context and fleet-wide symptoms.

Traces show where latency or failure propagated across distributed components. A **trace** is the end-to-end journey of a request, a **span** is one operation within that journey, and **context propagation** carries the trace identity across service boundaries. A trace through an ML inference pipeline illustrates how these spans compose:

```
Trace: user-request-12345
  Span: api-gateway (5 ms)
    Span: auth-service (2 ms)
  Span: feature-service (15 ms)
    Span: user-feature-lookup (8 ms)
    Span: item-feature-lookup (12 ms)
  Span: inference-service (45 ms)
    Span: preprocessing (3 ms)
    Span: model-inference (40 ms)
    Span: postprocessing (2 ms)
  Span: response-formatting (1 ms)
Total: 66 ms
```

OpenTelemetry provides a standard API for distributed tracing. Backend systems like Jaeger, Zipkin, or cloud tracing services store and visualize traces. The durable requirement is not the particular tracing backend; it is preserving enough context to answer whether the fault lives in request routing, feature retrieval, model execution, postprocessing, or a dependency outside the model service.

7.11.3 ML-specific debugging

Operational signals are not enough when a computation is numerically valid but wrong for the model. ML systems also require specialized debugging capabilities.

7.11.3.1 Numerical debugging

Numerical debugging targets failures where tensors remain valid objects but contain invalid values. NaN detection³⁹ is essential because NaN values propagate silently through all downstream computations. Listing 7.3 shows a minimal check that catches corruption before it reaches users.

Listing 7.3: NaN Detection: Checking model outputs for NaN values prevents silent corruption from propagating to downstream consumers. Logging the input hash enables reproducibility during diagnosis.

```
# Check tensor for NaN values
# (propagate from any corrupted computation)
if torch.isnan(output).any():
    log.error("NaN detected in output", input_hash=hash(input))
    # Log input hash for reproducibility, then fallback or fail fast
```

During training, gradient statistics make numerical faults visible before they corrupt the whole run. Gradient norm detects explosion or vanishing, gradient distribution detects anomalies, and layer-wise gradients identify problematic layers.

Mixed-precision training⁴⁰ can introduce numerical issues. Monitor for loss scale adjustments indicating underflow, gradient overflow exceeding FP16 range, and inconsistency between FP16 and FP32 results.

7.11.3.2 Data debugging and validation

Data bugs surface as valid-looking but wrong inputs, so the debugging target is not just numerical validity but semantic correctness at each pipeline boundary. Validation checks expected format, shape, value ranges, required fields, and encoding before data reaches the model, catching malformed examples while the failure is still local to the input path.

Once the input passes those static checks, the system needs evidence about behavior over time. Distribution monitors track feature drift, null-rate changes, and outliers as they emerge, while transformation instrumentation logs intermediate shapes and statistics so teams can compare each stage against known-good data. Together, these signals separate a corrupted input path from a numerical failure inside the model.

7.11.3.3 Straggler detection and analysis

Straggler diagnosis asks which component is slow enough to become a failure-equivalent bottleneck. The same request may succeed on every replica, but the slowest replica still determines tail latency and can force retries that look like failure under load. Operation-level timing instrumentation measures time for each operation, enabling latency attribution across pipeline stages. Listing 7.4 wraps operations in context managers that emit per-span timing metrics, making it straightforward to compare performance across replicas.

³⁹ | **NaN Propagation:** IEEE 754 specifies that any arithmetic operation involving NaN produces NaN, meaning a single NaN in one gradient computation silently corrupts every downstream parameter update. Common triggers in ML training include division by zero in normalization layers (batch norm with zero variance), log of nonpositive values, and FP16 overflow to infinity. Without per-step NaN detection, an entire training run can produce a model full of NaN weights before any monitoring alarm fires.

⁴⁰ | **Mixed-Precision Numerical Issues:** FP16's dynamic range spans only 6×10^{-8} to 65,504, compared to FP32's 1.2×10^{-38} to 3.4×10^{38} . Loss scaling (multiplying loss by 1,024 before backpropagation, then dividing gradients) prevents underflow, but overflow still triggers automatic step-skipping that wastes computation. BF16 mitigates this by matching FP32's exponent range at the cost of reduced mantissa precision, trading numerical resolution for training stability.

Listing 7.4: Operation-Level Timing: Context manager instrumentation attributes latency to individual pipeline stages, enabling straggler detection by comparing the same span across replicas.

```
# Wrap operations in timing context managers for latency attribution
with timer("feature_lookup"):
    features = feature_store.lookup(
        ids
    ) # Often the latency bottleneck
with timer("model_inference"):
    predictions = model(features) # GPU time, compare across replicas
```

Compare component timing across replicas using percentile analysis. p50 shows typical performance, while p99 shows tail latency. Comparing p99 across replicas identifies workers whose slow path has become a fleet-wide bottleneck.

The diagnosis must then separate the root causes that produce the same slow-worker symptom. Hardware issues include thermal throttling and memory errors, data skew means some inputs are slower to process, resource contention occurs when other processes consume resources, and network issues create slow connections to data stores.

7.11.4 Common failure patterns

The observability pillars enable detection of recurring failure patterns that experience with large-scale ML systems has identified. Figure 7.32 catalogs the most common training loss signatures, each requiring a different diagnostic and recovery response.

7.11.4.1 Training failures

A training-loss signature is useful because it maps a curve to a recovery decision. Figure 7.32 shows the curves first; table 7.18 then makes the operational mapping explicit, treating the curve as evidence for a specific recovery action.

Table 7.18: Training Failure Response Map: Training-loss curves are operational evidence only when they lead to different recovery actions. The response map ties each signature to the failure class most likely to explain it and to the first action operators should take.

Signature	Likely Interpretation	Recovery Response
Spike followed by recovery	Transient data issue or numerical instability	Continue training, but investigate the incident to rule out a systematic input problem.
Spike followed by plateau	Learning rate too high, corrupted checkpoint, or data bug	Roll back to an earlier checkpoint and validate the data path before resuming.
Gradual divergence	Silent data corruption, hardware error, or distributed-training desynchronization	Isolate the failing rank, validate checkpoint integrity, and compare telemetry across workers.
Hang without an error	Collective deadlock or crashed worker blocking synchronization	Use timeout detection and restart or reconstruct the worker group.

7.11.4.2 Serving failures

Serving failures require the same symptom-to-action mapping under much tighter latency constraints. Table 7.19 separates the common symptoms by what they reveal and what the serving system must do first.

Table 7.19: Serving Failure Response Map: Serving incidents must be classified quickly because every diagnosis competes with a user-facing latency budget. The table ties each symptom to the first operational response rather than treating all serving failures as generic errors.

Symptom	Likely Interpretation	Immediate Response
Latency spikes	Resource contention, garbage collection, cold caches, or model reloads	Check placement and capacity; repeated spikes usually mean the problem is no longer transient.

Symptom	Likely Interpretation	Immediate Response
Rising error rates	Dependency failure, data-format change, or model bug	Investigate immediately because errors compound across dependent services.
Silent quality degradation	Model drift, feature degradation, or data-pipeline fault	Use quality monitoring beyond standard operational metrics.
Cascade failure	Timeout exhaustion, resource depletion, or error propagation from one failing component	Trip circuit breakers and preserve isolation boundaries before the failure spreads.

Cascade failures are particularly insidious because the root cause is obscured by the symptoms it generates. A concrete diagnosis shows how the three observability pillars work together to trace a cascade back to its origin.

Example 7.4: Diagnosing a cascade failure

Scenario: A recommendation system experiences sudden latency spikes.

Diagnosis: The three observability pillars work together to diagnose the root cause. Metrics reveal the symptom: p99 latency jumped from 45 ms to 800 ms at 14:32, with error rate increasing from 0.1 percent to 15 percent. Traces isolate the bottleneck: the feature-service span consumes 700 ms instead of the normal 12 ms, while the model-inference span remains normal at 40 ms. Logs identify the root cause: feature-service logs show repeated connection timeouts to the user embedding cache at 14:31, followed by cache miss storms as requests bypass the failed cache and hit the embedding database directly.

Systems lesson: The cache node failure caused a cache-miss avalanche, overwhelming the embedding database and propagating latency to all requests. The fix is a circuit breaker on cache access, falling back to default embeddings when cache is unavailable.

7.12 Case Studies

Published production systems make the chapter’s scale lesson concrete: failure detection, state preservation, and observability reappear as checkpoint tax, topology reconfiguration, chaos testing, and elastic recovery. The cases below use public reports from Meta, Google, Netflix, and Microsoft to show representative engineering patterns. Treat the operational numbers as reported magnitudes that reveal the design pressure, not as universal constants. Meta’s OPT-175B training run on a 992-GPU cluster provides the first example: dozens of hardware failures had to be absorbed without aborting training.

7.12.1 Large-scale LLM training at Meta

The training of the Open Pre-trained Transformer (OPT-175B) at Meta provides a well-documented study in the physics of failure for large deep-learning jobs (Zhang et al. 2022). Using a cluster of 992 NVIDIA A100 GPUs continuously for two months, the engineering team faced a statistical certainty: hardware components would fail, and they would fail often. Over the course of the training run, the team logged approximately 90 manual restarts driven by hardware failures (ECC memory errors, NCCL/InfiniBand network issues, lost GPUs) and training-stability incidents, alongside the cycling of more than 100 hosts (Meta AI Research 2022). In a synchronous data-parallel regime, a single GPU failure halts the entire cluster, making the mean time between failures (MTBF) of the aggregate system a fraction of any individual component’s reliability. For OPT-175B, roughly two machines went down per day, dropping the effective system-wide MTBF to a fraction of a day and necessitating a fault tolerance strategy that treated interruption as the norm rather than the exception.

During the OPT run, the team monitored progress through train-log freshness checks: the public logbook records a 15-minute modified-file threshold, later relaxed to one hour, as part of restart monitoring (Meta AI Research 2022). Detection was only half the battle; the critical engineering challenge was minimizing the “restart tax”—the time lost reloading the model and optimizer states from persistent storage. Early in the project, synchronous checkpointing to a remote distributed file system consumed nearly 12 percent of the total effective training time, a prohibitive overhead

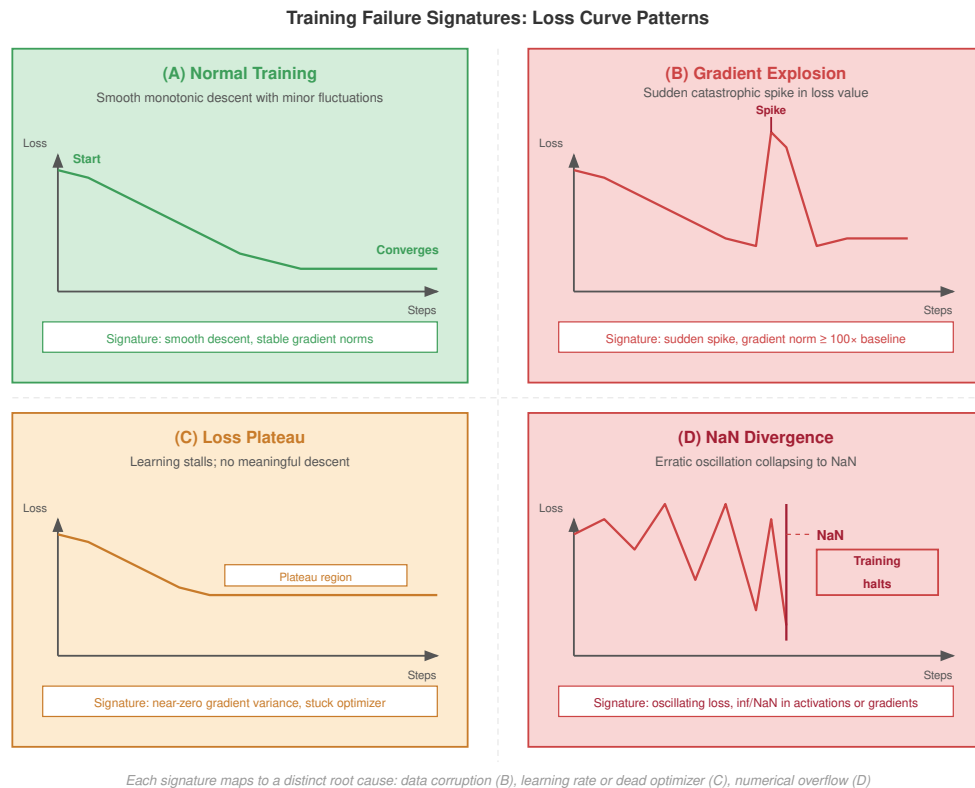

Figure 7.32: Training Failure Signatures: Common patterns of model loss over time that indicate underlying system or algorithmic failures. (A) Normal Training. (B) Gradient Explosion. (C) Loss Plateau. (D) NaN Divergence. Identifying these signatures automatically is essential for rapid recovery in autonomous training pipelines.

that extended the project timeline by weeks. To combat this, the team implemented asynchronous checkpointing, offloading the serialization of the 350 GB model state to CPU memory first, then streaming it to disk in the background while computation for the next batch resumed immediately. This optimization reduced checkpoint overhead to less than 3 percent, reclaiming hundreds of GPU-hours.

Recovery procedures also had to account for nonhardware failures, specifically “loss spikes” caused by numerical instabilities. Unlike a hardware crash where the last checkpoint is valid, a loss spike implies the model weight trajectory has become corrupted. The recovery strategy combined a “last good checkpoint” rollback with intervention in the optimizer: when gradient overflows or loss-scale floors were observed, the team reverted to an earlier checkpoint and resumed training with a lowered learning rate (ultimately running at roughly two-thirds of the rate OpenAI used for GPT-3) to stabilize the trajectory (Meta AI Research 2022). This dual-layer resilience—handling both physical silicon failures and mathematical divergence—allowed Meta to sustain approximately 147 TFLOP/s per A100 (near 50 percent of FP16 peak) despite daily interruptions (Zhang et al. 2022). The enduring lesson from OPT-175B is that at scale, the trade-off between checkpoint frequency and training throughput is a central variable in determining the feasibility of a model; checkpointing too often wastes compute, while checkpointing too rarely risks losing days of progress to a single bit flip.

7.12.2 Google TPU pod resilience

Google’s TPUv4 supercomputer takes a fundamentally different architectural approach to fault tolerance, driven by a custom Inter-Chip Interconnect (ICI) fabric and a network of Optical Circuit

Switches (OCS) that dynamically reconfigure the topology. A TPUv4 pod contains 4,096 chips organized as 64 “cubes” of 64 chips each, with each cube arranged in a $4 \times 4 \times 4$ 3D mesh (Zu et al. 2024). In this architecture, the network effectively is the computer: a single chip or optical link failure does not merely reduce capacity by $1/4096$ th—it creates a hole in the communication topology that would deadlock the synchronous mesh required for collective operations such as AllReduce.

Consequently, Google’s strategy focuses on slice abstraction rather than in-place repair. The OCS network combines multiple healthy cubes into logical “slices” sized to the training job’s needs. When a fault is detected—via two software components, `libtpunet` and `healthd`, that monitor link integrity and machine health—the orchestration system does not attempt to route around the failure within the active slice. Instead, the control plane preempts the job and reconfigures the OCS fabric to attach the workload to spare healthy cubes elsewhere in the pod. This treats hardware as immutable infrastructure during a job’s execution: rather than repairing the running topology, the system reconstitutes one with identical shape from surviving healthy components.

The quantitative success of this approach is measured in system availability. Across Google’s production TPUv4 fleet, the dynamic reconfiguration strategy achieves 99.98 percent system availability while gracefully handling hardware outages experienced by approximately 1 percent of training jobs (Zu et al. 2024). Daily component failure rates are low in relative terms—0.08 percent of TPU machines, 0.005 percent of ICI cables, and 0.04 percent of OCS units—but at fleet scale they aggregate to a steady stream of reconfiguration events that the control plane must absorb without disrupting training throughput. The key lesson from the TPU experience is that for tightly coupled, high-bandwidth systems, attempting to repair a running topology is often futile; it is more efficient to treat the cube as the atomic unit of failure and reconfigure the optical fabric to assemble a fresh slice around the surviving healthy components.

7.12.3 Netflix chaos engineering for serving dependencies

While training resilience focuses on long-running batch jobs, Netflix’s published work on Chaos Engineering (Basiri et al. 2016) provides the serving-side contrast. The premise is simple but operationally demanding: because production systems have many interacting dependencies, teams should validate steady-state behavior by deliberately injecting failures instead of waiting for real incidents to discover whether fallbacks work.

For ML serving, the same discipline applies to feature stores, model-serving dependencies, caches, and fallback paths. A model endpoint can be healthy while a feature service is slow, stale, or unavailable; if the system lacks a tested fallback, a local dependency problem can become user-visible latency or degraded recommendations. Chaos tests make those assumptions executable by injecting latency, terminating dependencies, or forcing fallback paths in controlled conditions.

The recovery procedure for these injected faults centers on fallback hierarchies. If the primary deep learning model fails or times out, the serving system can switch to a lighter model, cached response, or simple popularity-based default. The systems lesson is that resilience in ML serving is not a static property but a continuous practice of active verification: a fallback path that is never exercised is just documentation, not fault tolerance.

7.12.4 Microsoft DeepSpeed fault tolerance

Microsoft’s DeepSpeed library illustrates a narrower framework-level lesson: large-model fault tolerance has to coordinate checkpointing, sharded optimizer state, and resource management instead of relying on a monolithic restart script. DeepSpeed provides ZeRO-based distributed training and checkpointing building blocks for models with more than 100 billion parameters (Rasley et al. 2020; DeepSpeed Developers 2026a). With the Zero Redundancy Optimizer (ZeRO), the model parameters, gradients, and optimizer states are sharded across all available GPUs rather than replicated (Rajbhandari et al. 2020). A single node failure can therefore strand the state shard it held, so recovery depends on durable checkpoints and orchestration that knows how to restore or redistribute those shards.

Rather than implying in-memory repair after every node loss, the supported recovery model is checkpoint-centered. Each rank writes its state shard as part of a distributed checkpoint, and after a failure the job reloads the last durable checkpoint under the worker topology chosen by the launcher and resource manager. Universal Checkpointing extends that model by making checkpoints more

portable across selected parallelism and topology changes, but it still relies on explicit save/load discipline (DeepSpeed Developers 2026b). If replacement capacity exists, the job can resume at the original scale; if the surrounding elastic launcher resumes with fewer workers, the training script must still preserve data coverage and batch-size or learning-rate invariants.

The systems lesson is therefore not that DeepSpeed alone makes worker loss transparent. It is that sharded training frameworks must expose checkpointing and state-management primitives that schedulers can compose into elastic recovery policies. Building those primitives into the framework layer reduces bespoke recovery engineering, but the end-to-end guarantee still comes from the combination of framework support, checkpoint discipline, and scheduler integration.

These case studies reveal three universal principles:

- **Detection speed determines recovery cost:** Meta’s log-freshness monitoring, Google’s automated ICI reconfiguration, and Netflix’s chaos experiments all demonstrate that faster detection means less state lost.
- **The atomic unit of failure matters:** Google reroutes the communication fabric, DeepSpeed restores shards through checkpoints, and Netflix validates service-level fallbacks. Each organization chose the granularity that matches its architecture’s coupling.
- **Fault tolerance is a spectrum, not a binary:** From Meta’s checkpoint-rollback to Netflix’s graceful degradation hierarchy, systems implement multiple layers of defense, each trading fidelity for speed.

Despite these patterns, engineering teams frequently stumble over common misconceptions when designing resilient ML systems.

7.13 Fallacies and Pitfalls

An infrastructure team might spend weeks hardening their storage layer against disk failures, only to have their entire training run destroyed by a subtle software bug in their PyTorch distributed backend. Fault tolerance for distributed ML systems involves counterintuitive mathematics and subtle trade-offs where conventional data center wisdom often fails.

Fallacy: *Hardware failures are the main concern.*

This intuition comes from traditional systems where disk failures, power outages, and network partitions dominate. In ML systems, hardware failures are only one part of a broader incident mix.

Industry experience from large-scale ML systems points to a broader failure mix because ML jobs are long-lived, stateful, and sensitive to small control-plane mistakes. Hardware failures still matter, but software bugs, configuration errors, resource exhaustion, and cross-layer causes often dominate the incident count: a malformed checkpoint path can make recovery impossible, a mismatched collective library can hang all ranks, an undersized shared-memory limit can crash data loaders, and a stale feature schema can silently corrupt training. These failures are not less serious because they are “software”; they can destroy the same multi-day job that hardware redundancy was meant to protect.

Investing heavily in hardware redundancy while neglecting software robustness (input validation, gradual rollouts, configuration management) leaves many important failure modes unaddressed. The most reliable ML systems treat software bugs as inevitable and design defensively.

Pitfall: *Setting checkpoint interval by intuition.*

Organizations commonly set checkpoint intervals based on “feels right”: “every hour seems reasonable” or “every 1000 steps.” The Young-Daly formula reveals these intuitions are often wrong. For a 1000-GPU cluster with MTBF of 4 hours and checkpoint time of 5 minutes:

$$\tau_{\text{opt}} = \sqrt{2 \times 5 \times 240} = \sqrt{2400} \approx 49 \text{ minutes}$$

The intuitive “every hour” is close but suboptimal. If checkpoint time increases to 15 minutes (larger model, slower storage), the optimal interval becomes 85 minutes, not the “every 15 minutes” that some teams adopt to “stay safe.” Too-frequent checkpointing wastes more compute than it saves. The quantitative approach reveals that intuition-based intervals often deviate 2–3× from optimal in either direction.

Fallacy: *If each GPU is 99.99 percent reliable, a 10,000-GPU cluster is also 99.99 percent reliable.*

Reliability does not compose by averaging—it compounds by multiplication. For N serial components each with availability A , and assuming their failures are independent, the aggregate availability is A^N . With $A = 0.9999$ and $N = 10,000$, the cluster availability is $0.9999^{10,000} \approx 0.37$: the cluster is down 63 percent of the time. Individual component reliability is necessary but nowhere near sufficient at fleet scale. System-level fault tolerance (checkpointing, elastic recovery, redundancy across failure domains) must be designed explicitly, not assumed to emerge from per-component MTTF.

Pitfall: *Using MTBF calculations as if failures were independent.*

The reliability equation $\text{MTBF}_{\text{system}} = \text{MTBF}_{\text{component}}/N$ assumes component failures are statistically independent. In production, failures correlate:

- **Shared power domain:** UPS failure takes down an entire rack.
- **Shared switch:** Top-of-rack switch failure partitions all connected GPUs.
- **Shared software:** A bug triggered by specific input fails all replicas simultaneously.
- **Thermal correlation:** Cooling failure causes clustered GPU throttling.

Correlated failures change two quantities that the simple MTBF equation hides: incident frequency and blast radius. A cluster with 1000 independent GPUs each with 50,000-hour MTBF has a first-GPU-failure MTBF of 50 hours. If a shared power, cooling, or software hazard adds an incident rate 10 times larger than that independent first-failure rate, the effective incident MTBF drops to about 5 hours. Separately, a correlated incident may take out 10 GPUs at once, increasing recovery cost even if the independent GPU failure rate itself has not changed. Reliability engineering must identify and mitigate correlation through diversity: different power feeds, different network paths, different software versions in canary deployments.

Fallacy: *Component MTTF values predict individual failure timing.*

Engineers read a GPU MTTF of 50000 hours and plan around a five-year replacement cadence per device. MTTF is a statistical property of a population, not a prediction for any single component. A GPU with MTTF 50000 hours might fail at 200 hours or last 100,000 hours; the distribution is broad. What MTTF reliably predicts is the aggregate failure rate: in a fleet of 10,000 GPUs, the steady-state failure rate is approximately $10,000/50,000 = 0.2$ failures per hour, or roughly one failure every 5 hours. Fleet-scale reliability engineering relies on this statistical regularity to size automated recovery, spare-pool depth, and on-call rotations. Trying to predict which individual GPU will fail next is a category error and a waste of monitoring effort.

Pitfall: *Ignoring restart overhead in checkpoint planning.*

The Young-Daly formula accounts for checkpoint save time, but practitioners often forget restart overhead:

- **Job scheduling delay:** Acquiring replacement GPUs takes minutes in shared clusters.
- **Checkpoint loading:** Reading distributed checkpoint from storage.
- **Warmup time:** Learning rate warmup, batch normalization statistics recalculation.
- **Communication re-establishment:** NCCL ring topology reconstruction.

Total restart time can be $3\text{--}5\times$ checkpoint save time. A 5-minute checkpoint save followed by a 20-minute restart means each failure costs 25 minutes before accounting for lost work since the last checkpoint. That recovery term should be included in the expected waste and recovery-SLO budget; it should not be added to T_{write} as though it were paid at every checkpoint unless a specific recovery-aware checkpoint model derives that dependency.

Fallacy: *Every failure should be handled as a full restart.*

Engineers often treat all failures as “node crashed, restart from checkpoint,” but different failure modes require different responses. Transient failures (network congestion, thermal throttling) should trigger retry/pause, not restart, since state remains in memory. Permanent failures (GPU death, node crash) require checkpoint-restart with migration to new hardware. Silent corruption (bit flips, ECC errors) demands rollback to a previous checkpoint, not just the latest one, requiring checkpoint history retention. Resource exhaustion (OOM, memory fragmentation) needs reconfiguration before restart; otherwise the job crashes again immediately. As section 7.1.5 details, misdiagnosing failure type wastes compute: treating transient network blips as permanent failures wastes hours re-initializing, while ignoring silent corruption poisons model weights undetected.

Pitfall: *Assuming checkpoints are consistent without validating state.*

Modern frameworks checkpoint transparently, creating the illusion of automatic consistency. In practice, distributed checkpoints require coordination that can fail subtly:

- **Rank desynchronization:** If rank 0 checkpoints iteration 1000 while rank 1 checkpoints iteration 1001, the checkpoint is inconsistent.
- **Partial writes:** Storage failure mid-checkpoint leaves incomplete shards.
- **Optimizer state lag:** Sharded optimizer state may not match model weights if captured at different times.
- **In-flight gradients:** AllReduce in progress during checkpoint may or may not be included.

Production systems must implement checkpoint validation: verify all shards exist, verify iteration numbers match, verify optimizer state matches model state. Organizations that discover corrupted checkpoints during recovery from a failure have no recourse except restarting from an earlier (potentially much earlier) checkpoint.

Fallacy: *Fault tolerance can be tested only when failures happen.*

Fault tolerance mechanisms are code paths that execute rarely in normal operation. Like backup systems never tested until disaster strikes, fault tolerance code paths accumulate bugs:

- Checkpoint restoration logic untested because training never crashed
- Fallback model never loaded because primary never failed
- Circuit breaker thresholds tuned for old traffic patterns

Chaos engineering (intentionally injecting failures) transforms fault tolerance from “we think it works” to “we know it works.” Organizations that regularly kill random GPUs during training, inject network partitions, and fail primary models discover bugs before they matter. The cost of regular fault injection (some failed experiments, some minor outages) is far less than the cost of discovering broken fault tolerance during an actual failure.

Pitfall: *Using elastic training as a substitute for checkpointing.*

Elastic training adjusts parallelism degree when workers fail, continuing with reduced capacity, which appears to eliminate checkpoint-restart overhead. However, state consistency challenges remain: reducing the active worker count requires redistributing model shards, optimizer states, and data assignments consistently. Below some minimum viable size, training becomes infeasible (model does not fit, batch size too small), requiring checkpoint-restart regardless. Each removed worker reduces throughput; accumulated failures progressively degrade training speed until checkpoint-restart becomes preferable to continued degradation. If a failure was caused by a software bug triggered by specific data, the bug persists in remaining workers. Elastic training is complementary to checkpointing, not a replacement; the reduced checkpoint frequency still requires occasional checkpoints for catastrophic failures and training completion.

Fallacy: *Overhead budgets are fixed fractions of training time.*

Reference tables that show “pipeline bubble: 10 percent, checkpoint overhead: 5 percent, failure recovery: 3 percent” are easy to read as physical laws and pass through as line items in capacity plans. They are engineering targets, not constants. Pipeline bubble overhead depends on the number of microbatches and the interleaved schedule; failure-recovery overhead drops dramatically with elastic training that avoids full restarts; checkpoint overhead is a function of model size, storage bandwidth, and whether checkpointing is synchronous or asynchronous. Treating these numbers as fixed percentages leads to passive acceptance of avoidable inefficiency. The Young-Daly formula already shows that checkpoint cadence is a decision; the same is true of every other overhead listed in the reference tables.

Pitfall: *Adding GPUs without accounting for communication and recovery overhead.*

Capacity plans typically account for Amdahl’s Law and AllReduce overhead but treat reliability as a fixed background condition. At extreme scale, each additional GPU increases the aggregate failure rate, which inflates the expected recovery and replay time per job. There exists a cluster size beyond which the time lost to failures and recovery exceeds the time saved by additional parallelism, and wall-clock training time increases rather than decreasing with N . This is the reliability version of diminishing returns and it applies on top of the Amdahl ceiling. The two effects

must be modeled together: useful goodput equals $\text{MFU} \times \text{scaling efficiency} \times (1 - \text{failure overhead})$, and the failure-overhead term grows with N .

Fallacy: *Silent data corruption is negligible because hardware has ECC.*

GPUs and memory systems include extensive error correction (ECC, CRC, parity), creating the intuition that silent data corruption is negligible. Large-scale CPU SDC and memory-error studies reveal otherwise: silent corruptions and memory faults still occur at fleet scale and can escape ordinary error reporting (Dixit et al. 2021; Sridharan et al. 2015). For a 10,000-GPU cluster, even rare per-device corruption events become operationally relevant because the system continuously executes enormous volumes of memory and arithmetic operations. Silent corruption causes mysterious training anomalies: loss spikes attributed to “bad batches” may be hardware errors, gradient NaNs blamed on learning rates may be bit flips, and models failing to converge despite correct hyperparameters may have corrupted weights. Detection strategies include redundant computation (computing batches on multiple workers and comparing), gradient checksums (verifying AllReduce consistency), and statistical monitoring of gradient/activation distributions. Unlike detectable failures, silent corruption does not trigger errors; training “succeeds” but produces subtly broken models, requiring detection mechanisms as discussed in section 7.11.3.

Pitfall: *Relying only on hardware ECC instead of end-to-end validation.*

ECC is a necessary layer, but it is not an end-to-end correctness proof for a training run. The pipeline also needs checksums on data shards, validation of checkpoint shards, gradient and activation anomaly detection, and replayable tests that can distinguish a bad batch from corrupted state. End-to-end validation makes the silent-corruption problem observable at the ML-system boundary, where the damage would otherwise appear only as unexplained training behavior.

Recognizing these fallacies prevents engineers from optimizing for the wrong failure modes. The core principles required to build resilient machine learning fleets follow from the quantitative reasoning developed throughout this chapter.

7.14 Summary

Fault tolerance transforms the statistical certainty of hardware failure from a project-ending catastrophe into a manageable operational routine. The mathematics are unforgiving: individual component reliability compounds multiplicatively across thousands of devices, driving system-level MTBF from years down to hours. At large fleet scale, failure is not an exceptional event to be debugged but a continuous background condition that systems must absorb without losing forward progress. The engineering challenge, therefore, is not to prevent failures but to build systems where recovery is automatic, fast, and invisible to the training or serving workload.

Checkpointing provides the foundational mechanism for preserving training progress across failures. Synchronous checkpointing offers simplicity but imposes I/O overhead that scales with model size, while asynchronous approaches overlap checkpoint writes with computation at the cost of additional consistency complexity. The Young-Daly formula, $\tau_{\text{opt}} = \sqrt{2 \times T_{\text{write}} \times \text{MTBF}_{\text{system}}}$, gives engineers a principled way to balance checkpoint frequency against overhead; depending on checkpoint size and cluster MTBF, the optimum can range from seconds for small models to tens of minutes for large jobs. Beyond basic checkpointing, elastic training breaks the rigid assumption that worker count must remain fixed: when nodes fail, the system redistributes data and model shards across the surviving workers, adjusts batch size and learning rate, and resumes training with reduced throughput rather than halting entirely.

Serving fault tolerance presents a fundamentally different challenge from training. Training tolerates minutes of recovery latency and benefits from SGD’s mathematical tolerance of approximate restarts, while serving demands millisecond-level responsiveness and must preserve per-session state such as KV caches and conversation histories. Stateless serving achieves fault tolerance through straightforward replica redundancy and load balancing, but stateful serving for LLMs requires active state replication, session-affine routing, and graceful degradation hierarchies that fall back to lighter models when primary systems are unavailable. The case studies examined in this chapter, from Meta’s OPT-175B training through roughly 90 restarts driven by hardware failures and training-stability incidents to Netflix’s chaos engineering for ML serving, demonstrate that these principles are not theoretical but operational necessities at production scale.

Engineers who internalize these principles gain a diagnostic framework for reasoning about resilience at any scale. When a training run stalls, they can immediately assess whether the bottleneck is checkpoint I/O overhead, insufficient detection speed, or a failure mode that elastic training cannot absorb. When a serving system drops requests, they can trace the fault through the redundancy hierarchy to determine whether the root cause is replica health, state replication lag, or an inadequate fallback strategy. This systematic reasoning distinguishes organizations that treat fault tolerance as an afterthought from those that engineer it as a first-class system property. As ML systems scale, the cost of unplanned downtime grows proportionally: a 10,000-GPU cluster idled for an hour represents tens of thousands of dollars in wasted compute, making the techniques developed in this chapter economic necessities rather than optional refinements.

Key Takeaways: Failure is normal operation

- **Scale makes failure routine:** A 10,000-GPU cluster encounters hardware failures every few hours under the chapter's component-rate assumptions; software must treat failure as a normal state.
- **Checkpointing is the baseline:** Synchronous checkpointing is simple but incurs high overhead; asynchronous approaches hide I/O latency at the cost of consistency complexity.
- **The Young-Daly formula governs checkpoint intervals:** The optimal checkpoint interval $\tau_{\text{opt}} = \sqrt{2 \times T_{\text{write}} \times \text{MTBF}_{\text{system}}}$ balances the cost of saving state against the cost of lost work, often landing in the tens-of-minutes range for large training jobs while remaining much shorter for small checkpoints.
- **Elasticity enables persistence:** Designing training jobs to be “elastic” (reconfiguring around lost nodes, as figure 7.28 illustrates) can reduce idle time and lost work when the training script preserves the necessary data, batch-size, learning-rate, and checkpoint invariants.
- **Stateful serving exposes the serving-side state problem:** For LLMs, the KV cache represents a massive serving state that must be replicated or migrated to prevent high-latency session restarts, with strategy trade-offs summarized in table 7.13.
- **Training and serving require different strategies:** Training fault tolerance is checkpoint-centric and tolerates minutes of recovery, while serving fault tolerance is state-migration-centric and demands sub-second failover.
- **Production scale validates the theory:** The chapter's training and serving case studies show that large systems only stay reliable when fault tolerance is continuously exercised rather than assumed.

If failure cannot be prevented, the only move left is to make it cheap, and that is what turns resilience from a wish into a calculation. Checkpointing spends compute and communication on nothing a user ever asked for, copies of state held only against the day a node dies, and the Young-Daly interval is the arithmetic of how much to spend: not how to avoid losing work, but how much work is affordable to lose between saves. Set it well and a dead node costs minutes, not days. The failures still arrive exactly as often; what changes is that they stop deciding the outcome. This is the coordination tax made explicit, paid on purpose so that at fleet scale, where component failure is a statistical certainty, the certainty stops mattering.

What's Next: From resilience to resource management

Keeping the fleet running despite inevitable hardware failures requires three layers: checkpointing preserves progress, elasticity absorbs node losses, and redundancy protects stateful serving sessions. A fault-tolerant cluster still needs orchestration, however, to decide which jobs run where, when to preempt, and how to share resources fairly among competing workloads.

Chapter 8 examines the orchestration layer, from Slurm and Kubernetes scheduling to gang scheduling, multi-tenancy, and capacity planning, that transforms a collection of fault-tolerant nodes into a managed production system.

 Research Questions: For further inquiry

- How should checkpoint cadence account for MTBF, checkpoint write time, restart overhead, and validation cost together?
- How do parallelism and collective choices change the blast radius of a single node, link, or rank failure?
- When is elastic recovery preferable to full restart, and which training invariants must it preserve?
- What end-to-end evidence can detect silent data corruption before it appears as degraded model behavior?

Purpose

Why does resource allocation become the primary bottleneck when hardware is plentiful?

A thousand accelerators sitting idle waiting for scheduling decisions cost the same as a thousand accelerators computing useful work. At scale, the limiting factor shifts from having enough hardware to using it efficiently: jobs waiting in queues while resources sit idle, fragmentation leaving gaps too small for any pending job, deadlocks where multiple jobs each hold partial resources while waiting for more. Orchestration is the discipline of extracting useful work from shared infrastructure, deciding which jobs run on which nodes, when preemption serves the greater good, how to balance fairness across teams against raw utilization, and how to prevent the coordination mechanisms themselves from becoming bottlenecks. Poor orchestration transforms expensive hardware into expensive waste; effective orchestration transforms a collection of machines into a coherent computing resource where capacity translates reliably into completed work. In C^3 terms, orchestration is the coordination tax paid on purpose: theoretical peak utilization is traded away so that the fleet's shared resources do not deadlock or fragment under load.

Learning Objectives

- Analyze scheduling objectives, fragmentation, and deadlock risks for distributed training jobs under shared fleet constraints
- Compare HPC, cloud-native, and hybrid orchestration paradigms for batch training and self-healing serving workloads
- Apply gang, bin-packing, and topology-aware placement policies across NVLink domains and switch hierarchies
- Design elastic training and preemption policies that trade throughput, recovery overhead, and spot-instance savings
- Evaluate ML-specific schedulers using job duration, iteration progress, fairness, and adaptive resource-allocation signals
- Design inference autoscaling, isolation, and routing policies using queue depth, tail latency, and GPU memory pressure
- Diagnose utilization losses from quota hoarding, noisy neighbors, fragmentation, topology mismatch, and data starvation

8.1 The Scheduling Problem

IMAGINE two research teams sharing a 1,000-GPU cluster: Team A submits a 512-GPU job that will run for a month, while Team B submits hundreds of 8-GPU experiments that each run for an hour. If the scheduler simply processes jobs as they arrive, Team B's tiny experiments might indefinitely block Team A's massive training run. The scheduling problem is the challenge of navigating this multi-dimensional conflict between throughput, fairness, and cluster utilization.

Partitioning computation, synchronizing it efficiently, and recovering from hardware failures solve the problem of running a single job across many machines. Orchestration solves the next problem: deciding which jobs run, where they run, and how resources are shared among competing demands.

In the fleet stack shown in figure 1.13, orchestration operates at the Distribution Layer, but its decisions are fundamentally constrained by the Infrastructure Layer. The scheduler must reason about physical realities: GPU heterogeneity, NVLink topology, rack power limits, and network bisection bandwidth. When scheduling goes wrong, debugging requires examining all four layers to identify whether the root cause is infrastructure (hardware constraints), distribution (algorithm limitations), serving (workload mismatch), or governance (policy misconfiguration). Orchestration is where physical infrastructure meets the demands of distributed algorithms, translating resource requests into placement decisions that respect both hardware topology and organizational policy.

To make the scheduling problem concrete, consider a research organization operating a 10,000-GPU cluster. Brown et al. (2020) report that training GPT-3 175B used 3.14×10^{23} floating-point operations on a V100 GPU cluster. Imagine 100 large-scale training jobs of that class queued, alongside thousands of smaller experiments and inference workloads all competing for the same resources. The system must decide which jobs run, when they run, and where they run. A naive first-come-first-served policy would let the first few large jobs monopolize the cluster for weeks, starving smaller experiments that researchers need to iterate quickly. A strict fair-share policy would fragment GPUs across many small allocations, preventing any large job from assembling the contiguous allocation it needs. Neither extreme works. The scheduler must navigate a multi-dimensional trade-off space where every decision affects throughput, fairness, cost, and researcher productivity simultaneously.

The economic stakes make these decisions consequential at every scale. A 10,000-GPU cluster at \$2/GPU-hour costs \$480,000 per day to operate, whether the GPUs are computing useful work or sitting idle in a queue. If scheduling inefficiencies leave 30 percent of GPUs idle, that translates to \$144,000 per day in wasted capacity, or about \$52.6M annually. Conversely, improving utilization from 50 percent to 80 percent adds 3,000 fully utilized GPU-equivalents of productive capacity without purchasing additional hardware. That gain is equivalent to buying 6,000 raw GPUs if they ran at the old 50 percent utilization. At this scale, a 1 percentage-point improvement in utilization is

worth more annually than the salary of the engineer who achieves it. *Scheduling is not operational overhead; it is one of the highest-leverage engineering investments in ML infrastructure.*

ML workloads present scheduling challenges that distinguish them from ordinary cloud service placement and from HPC workloads that can tolerate flexible resource counts. Gang scheduling¹ represents the most critical difference for synchronous distributed training: a job requiring 1,024 GPUs *cannot* make useful iteration progress with only 512. Many HPC jobs also need co-scheduled ranks, but synchronous data parallel training exposes the cost at every AllReduce. Every worker must participate in every collective, and a missing worker blocks all others. Section D.2.1 develops the ring and tree AllReduce cost model that makes this constraint physical: the collective stalls until the last worker arrives, so allocating N GPUs but landing $N - 1$ leaves the missing rank's peers burning fully idle on the synchronization barrier. A scheduler that partially allocates resources creates deadlocks where multiple jobs each hold some GPUs while waiting for more, with none able to proceed. This all-or-nothing requirement means the scheduler cannot simply “pack jobs tightly” as a traditional bin packer would; it must reason about atomic, multi-resource allocations across the entire cluster.

If gang scheduling is the first hard constraint, topology awareness via **placement groups**² is the second: to support tensor parallelism, the scheduler must ensure GPUs are placed within the same high-bandwidth NVLink domain rather than scattered across the data center.

GPU heterogeneity is the third dimension. Many clusters contain mixtures of A100 and H100 accelerators with different compute throughput, comparable HBM capacity (80 GB on A100 versus 80 GB on H100), and different interconnect bandwidth. An H100 provides roughly twice the training throughput of an A100 for transformer workloads but costs proportionally more. Some models fit in A100 memory with appropriate parallelism strategies; others require the larger H100 memory to avoid excessive model sharding. The scheduler must match workloads to appropriate hardware based on actual requirements, not user preferences, while maintaining high utilization across heterogeneous pools. When users request specific GPU types out of habit rather than necessity, the mismatch between requested and required resources can leave entire hardware pools idle while queues overflow on preferred hardware.

Job duration unpredictability compounds these challenges further. A training run may converge early and complete in days rather than weeks. Hardware failures may abort jobs unexpectedly, returning resources at unpredictable times. Hyperparameter searches may reveal early that certain configurations will not succeed, leading to voluntary termination. Traditional scientific computing workloads, such as weather simulations or molecular dynamics, have more predictable runtimes that enable better scheduling decisions: the scheduler can project when resources will become available and plan accordingly. ML workloads deny this luxury, forcing schedulers to operate with deep uncertainty about when current jobs will release resources.

The interaction between these challenges creates combinatorial complexity. A scheduler must simultaneously handle gang scheduling constraints (atomic allocation), heterogeneous resources (capability matching), topology requirements (NVLink locality for tensor parallelism), priority and fairness policies (organizational equity), preemption decisions (which running jobs to interrupt), and cost optimization (spot vs. on-demand placement). Each dimension constrains the others: a topology-optimal placement may violate fairness policies, a cost-optimal spot placement may violate reliability requirements, and a fairness-driven allocation may fragment resources in ways that prevent gang scheduling.

These constraints define the central problem of orchestration: the scheduler is not merely packing jobs onto GPUs, but maintaining a consistent, economically useful view of a failing, heterogeneous fleet. The first step is to see why cluster scheduling is fundamentally harder than single-machine process scheduling. At fleet scale, placement stops being only an optimization challenge and becomes a distributed systems problem of keeping state coherent across thousands of machines.

8.1.1 Distributed scheduling complexity

A single-machine scheduler enjoys luxuries that a cluster scheduler cannot: it has instantaneous, consistent visibility into all resource states; it can make atomic decisions that take effect immediately; and failures are binary (the machine is up or it is down). Cluster scheduling surrenders all three of these properties, and several fundamental distributed systems problems emerge as a result.

¹ | **Gang Scheduling:** Formalized by Ousterhout (1982) for parallel systems, where the “Ousterhout matrix” co-schedules related threads across processors in synchronized time slices. In ML clusters, the constraint is stricter: synchronous AllReduce requires all workers simultaneously, so partial allocation wastes 100 percent of held resources rather than merely degrading throughput. Under the chapter’s cloud-equivalent \$2/GPU-hour scenario, a 1,024-GPU job holding 900 idle GPUs while waiting for 124 more burns approximately \$1,800/hour.

² | **Placement Group:** A cloud-native abstraction (AWS, GCP) that requests instances be placed within a single high-bandwidth, low-latency network domain. For the ML Fleet, placement groups act as the topology contract that guarantees the bisection bandwidth ($BW_{\text{bisection}}$) required for AllReduce, preventing the “topology lottery” where nodes are scattered across different data center racks.

Partial failures pose the first challenge. A node can fail between allocation and job start, creating a gap between the scheduler’s decision and its effect. The scheduler may successfully allocate 32 GPUs across 4 nodes, only to have one node fail before the job launches. The remaining 24 GPUs sit idle while the scheduler detects the failure, updates its state, and re-plans the allocation. Meanwhile, other jobs that could have used those 24 GPUs have already been placed elsewhere, potentially on suboptimal hardware. The fault tolerance mechanisms from Chapter 7 handle failures during *execution*; the scheduler must handle failures during *placement*, a fundamentally different problem because the job has not yet established any state to recover from.

Network partitions create a second problem that is unique to distributed scheduling. The scheduler may lose connectivity to a subset of nodes while those nodes continue operating normally. From the scheduler’s perspective, the nodes appear failed and their GPUs appear unavailable. From the nodes’ perspective, jobs may still be running and producing useful work. This ambiguity creates a dilemma with no universally correct resolution. Reallocating the GPUs to new jobs risks double-allocation if the partition heals; waiting for reconnection wastes capacity that may be perfectly functional. The duration of the partition is unknowable in advance, so any fixed timeout represents a guess about network behavior that may prove wrong.

State inconsistency emerges as a third challenge that compounds the first two. Resource state may differ between the scheduler’s view and reality on individual nodes. A GPU the scheduler believes is free may still be cleaning up from a previous job: flushing caches, deallocating device memory, running a zombie process from a failed container, or completing a CUDA driver reset after an error. Conversely, a GPU marked as “in use” may have been freed by a job that terminated between heartbeat intervals. This inconsistency means the scheduler operates on a model of cluster state that is always slightly stale, and the degree of staleness varies across nodes depending on heartbeat frequency, network latency, and the complexity of cleanup operations.

Ordering without global time presents the fourth fundamental issue. Without a global clock, determining whether allocation A happened before allocation B across different nodes requires careful protocol design using logical clocks or consensus algorithms. Two jobs may both believe they “own” the same GPU if the system does not enforce ordering through consensus protocols or centralized coordination. This scenario is not theoretical: during recovery from a network partition, allocation messages from before and after the partition may arrive in the wrong order at different nodes, creating conflicting resource assignments that must be detected and resolved.

These four challenges echo the consistency, availability, partition-tolerance trade-off described by the CAP theorem³. CAP is a theorem about distributed data systems, not a literal proof about every scheduler, but the analogy is useful: a control plane must choose how much stale or uncertain state it is willing to tolerate before making allocation decisions. Slurm-style centralized batch control emphasizes an authoritative allocation view before jobs start. Kubernetes-style reconciliation emphasizes continuously driving the actual cluster toward declared desired state. Custom ML schedulers often accept bounded inconsistency in exchange for scheduling throughput, using optimistic concurrency where conflicts are detected and resolved after the fact rather than prevented through locking.

The control-plane tension becomes concrete when the scheduler interacts with the ML framework’s own distributed coordination plane during a partition. A scheduler may decide that a subset of nodes is unavailable while workers on those nodes are still blocked inside a collective operation. That creates a brief window of conflicting intent: the scheduler wants to recover the allocation, but the training job has not yet converged on a new membership view. Elastic launch and rendezvous mechanisms such as TorchElastic reduce this ambiguity by using heartbeats and re-rendezvous so the framework can either reform a viable worker group or terminate cleanly, giving the scheduler a clearer recovery signal than an opaque collective timeout (PyTorch Contributors 2026b, 2026a). This layered coordination—scheduler-level policy for coarse allocation, framework-level membership for workers—is the characteristic architecture of production distributed training clusters.

8.1.2 Failure rates at scale

At scale, failure is normal operation, not exceptional. This principle, established in the reliability analysis of Chapter 7, has direct consequences for scheduling: the scheduler must not merely tolerate failure but actively plan for it in every allocation decision. Component reliability does not change

³ | **CAP Theorem:** Conjectured by Brewer (2000) and proven by Gilbert and Lynch (2002), CAP establishes that no distributed data system can simultaneously guarantee Consistency, Availability, and Partition tolerance. For ML schedulers, use CAP as a design analogy rather than a product claim: the concrete policy question is how much uncertainty the control plane accepts before it allocates, reclaims, or reschedules expensive accelerators.

with cluster size, but aggregate system reliability degrades multiplicatively. Counting GPU hardware faults alone understates the rate; with 99.9 percent annual GPU reliability (typical for data center hardware), the hardware-only expectation for a 4,096-GPU cluster is modest:

$$\text{Expected failures per day} = 4096 \times \frac{0.001}{365} \approx 0.01 \text{ GPU failures/day}$$

This calculation captures only GPU hardware failures. Including software failures (driver crashes, CUDA context corruption), thermal events (throttling, emergency shutdowns), network interface failures, host OS issues, and container runtime errors, large clusters can see 1 to 4 failures per day per 1,000 GPUs. A 10,000-GPU cluster would then experience 10 to 40 component failures daily. A multi-week training run on 4,096 GPUs is therefore very likely to encounter multiple failures. Section E.1.1 tabulates the FIT rates and MTTF figures behind the 99.9 percent annual reliability assumption, letting an operator substitute measured hardware rates and confirm whether the empirical 1-to-4 failures-per-day band still holds.

The scheduling implications are profound and shape nearly every design decision in the scheduler. The scheduler cannot treat the cluster as a static resource pool where resources, once allocated, remain available until voluntarily released. Instead, it must anticipate that allocated resources will disappear during job execution, maintain spare capacity or implement rapid rescheduling to keep jobs running through the constant churn of hardware entering and leaving operational status, and distinguish between transient failures (which may self-resolve within minutes and should not trigger expensive reallocation) and permanent failures (which require new resource allocation and checkpoint recovery) (Tiwari et al. 2015).

Consider the scheduler’s decision when a node heartbeat is missed. The scheduler has three options:

- **Wait for recovery:** The scheduler waits to see if the heartbeat resumes, risking wasted GPU time if the node is truly dead.
- **Reallocate immediately:** The scheduler assigns the node’s resources to other jobs, risking conflict if the node recovers and its original jobs are still running.
- **Mark suspect:** The scheduler marks the node as suspect and begins repositioning replacement resources while waiting for confirmation, consuming spare capacity that could be used for other work.

Each option trades off between responsiveness and correctness, and the effective choice depends on the failure mode distribution for the specific hardware in the cluster, information the scheduler must learn from historical failure data. Section E.3.1 decomposes recovery time into its detect, reschedule, reload, and replay phases, which bound how long the scheduler can afford to wait on a missed heartbeat before committing to reallocation rather than betting on a transient self-resolution.

These requirements connect the scheduler directly to the checkpoint and recovery infrastructure from Chapter 7: scheduling decisions about spare capacity, preemption policies, and elastic training support determine how quickly the system recovers from statistically expected failures. A scheduler that reserves spare capacity or supports elastic recovery can restore throughput much faster than one that requires every failed job to wait for a full fresh allocation and reload, but the correct reserve fraction and recovery time are workload- and fleet-specific parameters rather than universal constants.

8.1.3 Scheduling objectives and their conflicts

Every scheduling decision represents a trade-off between four fundamental and often contradictory objectives:

- **Throughput:** The total useful work completed per unit time naturally favors large, long-running jobs that saturate hardware and minimize context-switching and data-movement overhead.
- **Fairness:** The equitable distribution of resources across users or teams prevents a single large team from monopolizing the fleet. Dominant resource fairness (Ghodsi et al. 2011) equalizes each user’s largest normalized share across resources such as GPUs, CPU, and memory.

failure cadence

Normal component failure rates make fleet failures routine.

- **Latency:** Rapid completion of short jobs maintains researcher velocity, but aggressive preemption can starve large training jobs.
- **Cost efficiency:** Interruptible spot instances, off-peak scheduling, and tight packing reduce budget burn, but often increase failure rates or completion time.

The objectives conflict because each one rewards a different scheduling behavior. A throughput-maximal policy fills the cluster with massive training runs, achieving near-perfect utilization but forcing every other user to wait weeks for a slot. Fairness-driven allocation fragments resources, leaving small gaps that cannot be filled by large jobs and sacrificing aggregate throughput for social harmony. A latency-optimal scheduler, similar to Shortest Job First, aggressively preempts long-running training jobs to service interactive debugging sessions or small experiments. Cost optimization often means accepting higher failure rates and longer completion times, trading researcher productivity for budget preservation.

Optimizing all four simultaneously is impossible; every scheduling policy represents a specific point in this four-dimensional trade-off space. The most direct conflict exists between throughput and latency, a tension analogous to the throughput-latency trade-off in computer architecture. A throughput-optimal scheduler prioritizes the largest, most parallelizable jobs because they use the hardware most efficiently. However, this policy is latency-catastrophic for small jobs: a researcher submitting a 10-minute debugging task might wait days for the large job to finish. Conversely, a latency-optimal scheduler minimizes average wait time but potentially starves large jobs indefinitely, reducing aggregate cluster throughput by leaving large blocks of resources idle while waiting for “just one more” small job to finish.

Consider a 64-GPU fine-tuning run for our 175B model, a scheduling-demo workload distinct from the full 1,024-GPU pretraining run that recurs elsewhere in the fleet discussion. From a throughput perspective, this is an ideal job: it runs for days with high utilization and zero scheduling overhead once started. From a latency perspective, it is a boulder in the stream. To schedule it, the system might need to drain 64 GPUs of all other work, forcing hundreds of smaller jobs to wait. Once running, it occupies those resources immovably. If the scheduler prioritizes this run (throughput), the P99 latency for small jobs explodes. If it prioritizes small jobs (latency) by allowing them to preempt or fragmentation-fill the cluster, the 64-GPU job may never assemble the contiguous block it needs to start. This zero-sum game forces organizations to make explicit policy choices. In scheduler terminology, those choices often appear as Quality of Service classes: job-priority tiers that decide which objective wins when throughput, latency, fairness, and cost collide.

Past about 70 percent utilization, queue wait time explodes.

Napkin Math 8.1: The queuing theory of GPU clusters

A GPU cluster can be modeled as an M/G/1 queue, where jobs arrive according to a Poisson process (λ_{job}) and service times follow a general distribution (G) with mean $1/\mu$ and standard deviation σ . The Pollaczek-Khinchine formula defines the expected waiting time in the queue (W_q):

$$\frac{W_q}{1/\mu} = \frac{\rho}{1-\rho} \cdot \frac{1+C_s^2}{2}$$

Here, $\rho = \lambda_{\text{job}}/\mu$ represents cluster utilization, $1/\mu$ is the average job duration, and $C_s = \sigma\mu$ is the **coefficient of variation** of job duration. The right-hand side is therefore the waiting time expressed as a multiple of the average job duration.

In standard web serving, request service times are often approximated by an exponential distribution, yielding $C_s \approx 1$. In ML clusters, job durations follow a heavy-tailed distribution: a vast number of short debugging jobs (minutes) mixed with a few massive training runs (weeks). The representative $C_s = 3$ calculation in this callout captures that variance without claiming a universal fleet constant. The impact on wait times is multiplicative. For the scheduling argument here, the single-server multiplier is sufficient; section F.1.1 generalizes the result to the M/G/c/K queue and validates it against Little’s Law for readers sizing a scheduler’s admission queue under heavy-tailed arrivals.

At 80 percent utilization ($\rho = 0.8$): with an exponential workload ($C_s = 1$), $W_q = 4 \times$ the average job duration. With a typical ML workload ($C_s = 3$), $W_q = 20 \times$ the average job duration. This explains the “utilization wall” in ML infrastructure. A web server cluster feels responsive at 80 percent load, but an ML cluster at the same utilization feels broken, with jobs languishing in the queue for days. The heavy tail of the service distribution acts as a latency multiplier, forcing operators to run ML clusters at lower utilization (often 60 to 70 percent) to maintain acceptable responsiveness for interactive users.

8.1.4 Bin packing

The most fundamental scheduling algorithm is **bin packing**⁴: fitting jobs of varying sizes into fixed-capacity nodes. This problem is NP-hard in its general form, meaning no known algorithm finds optimal solutions in polynomial time. Fortunately, practical heuristics such as first-fit decreasing and best-fit decreasing achieve near-optimal results for the workload distributions typical of ML clusters, where job sizes follow a heavy-tailed distribution (many small jobs, few large ones).

Consider a 64-node cluster with 8 GPUs per node, totaling 512 GPUs. If jobs request 6 GPUs each, each job occupies one full node but wastes 2 GPUs per node, reducing effective capacity to 75 percent. The remaining 2 GPUs per node cannot be combined across nodes because GPU workloads require local memory access. This **fragmentation** grows worse with heterogeneous job sizes: a mix of 1-GPU, 3-GPU, and 7-GPU jobs creates irregular gaps distributed across many nodes, where no single pending job can fit into any individual gap, yet the total free capacity would be sufficient if the gaps were contiguous.

ML workloads make bin packing multi-dimensional in ways that traditional scheduling rarely encounters. Each job requires GPUs together with CPU cores for data preprocessing, host memory for data loading and augmentation pipelines, local SSD storage for dataset caching, and network bandwidth for gradient synchronization. A job requesting 4 GPUs, 32 CPU cores, and 256 GB of RAM may not fit on a node that has 4 free GPUs but only 16 free CPU cores because other jobs have consumed the host CPU for preprocessing. The scheduler must simultaneously satisfy all resource dimensions, and the job fits only if every dimension has sufficient capacity on the selected node. This multi-dimensional constraint dramatically reduces the solution space compared to single-dimensional packing, because a bottleneck in any single resource dimension can strand capacity in all others.

Locality constraints further restrict placement beyond simple resource availability. A training job using tensor parallelism requires GPUs connected via NVLink within the same node, since cross-node communication over InfiniBand is an order of magnitude slower (450 GB/s per direction intra-node vs. 50 GB/s per port inter-node). A job requesting “4 GPUs with NVLink connectivity” cannot use 2 GPUs from node A and 2 from node B, even if all 4 GPUs are individually available and the total capacity is sufficient. These topology constraints transform a packing problem into a placement problem where which specific resources matter as much as how many resources are available. The placement problem is strictly harder than the packing problem because it adds spatial constraints to the existing capacity constraints.

Schedulers address fragmentation through several complementary strategies, each targeting a different aspect of the problem. Backfill scheduling allows smaller jobs to fill gaps while larger jobs wait for contiguous resources, improving utilization without violating priority ordering. The insight is that small jobs can execute and complete in the gaps, freeing those resources before the large job’s target start time. Backfill scheduling requires estimating when current jobs will complete (to determine whether a backfill candidate will finish before the large job can start), which is why accurate runtime estimates are so important.

Periodic **defragmentation** migrates or preempts low-priority jobs to consolidate free resources into contiguous blocks, analogous to memory compaction in operating systems. The scheduler identifies nodes where partial allocations leave stranded resources, preempts the jobs occupying those resources, and re-schedules them on nodes where they can be packed more efficiently. The cost of defragmentation (preempting running work, which wastes compute between the last checkpoint and the preemption event) must be weighed against the benefit (enabling large jobs to start sooner,

⁴ | **Bin Packing:** The one-dimensional version is NP-hard; ML scheduling adds four to five dimensions (GPU, CPU, memory, network, topology), making exact solutions intractable for clusters above a few hundred nodes. First-fit-decreasing heuristics achieve within 11/9 of optimal for typical workloads, but the real cost in ML clusters is not *suboptimality* in packing but *fragmentation*: stranded GPUs that individually satisfy no pending job yet collectively represent millions of dollars in idle capacity.

improving overall throughput). Operators often schedule defragmentation during low-demand periods when the impact of preemption is lower.

A third strategy, **over-subscription**, allows more jobs to be admitted than strictly fit, relying on statistical multiplexing to avoid simultaneous peak usage across all resource dimensions. If each job's GPU utilization averages 70 percent (alternating between compute-intensive and data-loading phases), the cluster can support approximately $1.4\times$ as many jobs as the strict GPU count would allow. Over-subscription works well when resource utilization is genuinely bursty and jobs' peak usage periods are uncorrelated, but can cause severe performance degradation (thrashing, memory pressure, network congestion) when multiple jobs peak simultaneously. The key to safe over-subscription is monitoring actual utilization in real time and throttling admission when contention is detected. Figure 8.1 shows the combined effect: although 19 GPUs (roughly 30 percent of the cluster) sit idle, no single node has a contiguous block of eight, so a full-node job cannot be placed.

Figure 8.1: The Fragmentation Problem: The heatmap shows a snapshot of an 8-node cluster (rows) with 8 GPUs each (columns). Different colors represent distinct active jobs, while gray slots represent free GPUs. Although 19 GPUs (~30 percent of capacity) are available globally, they are fragmented across nodes. A new job requiring 8 contiguous GPUs (a full node) cannot be scheduled because no single row is completely empty, illustrating how bin-packing inefficiencies reduce effective cluster capacity.

8.1.5 Gang scheduling

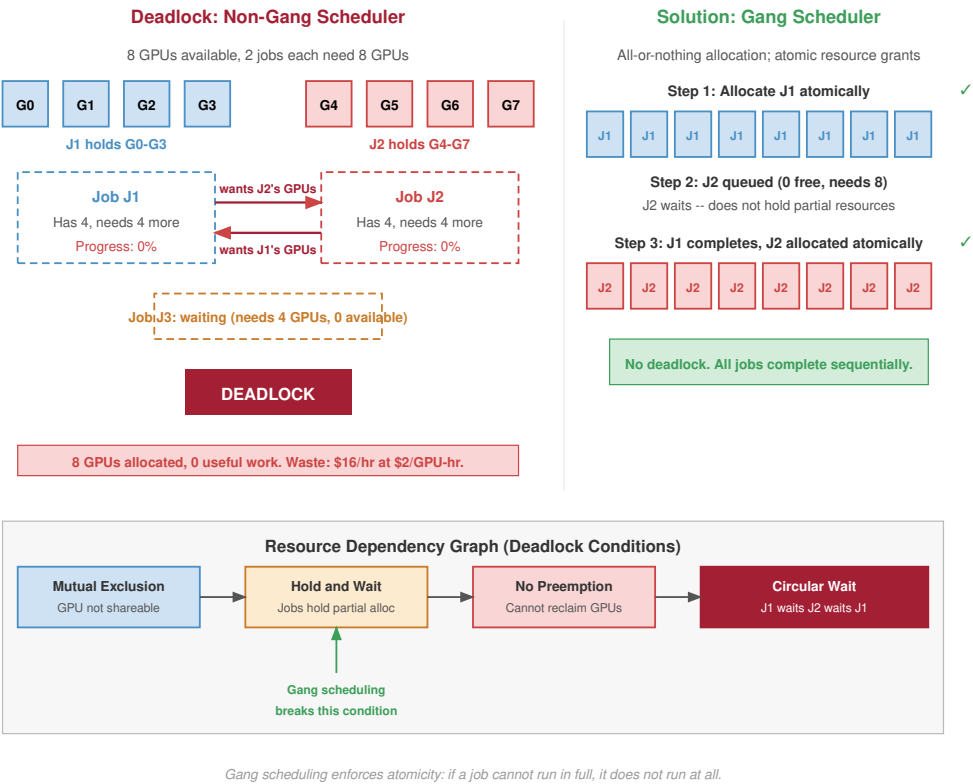

Partial allocation of multi-GPU jobs creates a failure mode unique to ML clusters: two jobs can each hold half the resources they need, blocking each other indefinitely while every allocated GPU sits idle. Figure 8.2 contrasts this deadlock scenario with the atomic allocation approach that eliminates it.

Definition 8.1: Gang scheduling

Gang Scheduling is the ML cluster scheduling policy that allocates all of a job's accelerators atomically (all-or-nothing) because synchronous distributed training makes the marginal value of a partial allocation zero: every worker must reach every collective, so a job cannot trade fewer GPUs for proportionally slower progress.

1. **Significance:** A 1,024-GPU synchronous job holding 512 GPUs completes zero training steps, not half as many: each AllReduce stalls until every rank arrives, so the held GPUs burn power and capital at 0 percent useful output. Without atomic allocation, two such jobs can each acquire half the cluster and deadlock, both at zero progress while consuming the full cluster's operating cost.

2. **Team B status:** Holds 512 GPUs, Needs 1024 GPUs. Progress = 0 percent.
3. **Cluster status:** 1024 GPUs allocated, 0 samples processed.
4. **Waste:** \$2048 per hour in idle electricity and capital.

Systems insight: This is a circular dependency: Team A is waiting for Team B's GPUs, and Team B is waiting for Team A's. Without gang scheduling (all-or-nothing allocation), cluster efficiency drops to zero. In a large fleet, even a 5-minute deadlock can cost thousands of dollars. Batch schedulers and Kubernetes batch extensions address this by enforcing a job-level admission boundary: if the full gang cannot start, the job should remain queued rather than hold a partial allocation.

5 | **Hold-and-Wait Deadlock:**

One of the four classical conditions jointly sufficient for deadlock in resource-allocation systems. In GPU clusters, this condition is uniquely expensive: two jobs each holding 500 GPUs while waiting for 200 more strand 1,000 GPUs indefinitely, burning approximately \$2,000/hour. Gang scheduling eliminates hold-and-wait by construction, requiring atomic all-or-nothing allocation at the cost of reduced packing flexibility.

The partial-allocation pattern in figure 8.2 is a **hold-and-wait deadlock**⁵ in which two jobs each hold half the cluster and neither can proceed. The implementation guarantee is straightforward: for a job J requesting N GPUs, the scheduler must guarantee that either all N GPUs are allocated atomically, or the job remains in the queue without holding any resources. This binary outcome eliminates deadlock by construction, since a job that holds no resources cannot block other jobs. Implementing this guarantee efficiently, however, is the challenge that defines much of cluster scheduling algorithm design.

Naive gang scheduling is wasteful in predictable ways. If the cluster has 900 free GPUs and a job requests 1,024, the 900 GPUs sit idle until 124 more become available, potentially wasting thousands of GPU-hours. **Backfill scheduling** addresses this by identifying jobs in the queue that can fit within the 900 available GPUs without delaying the large job's expected start time, an idea popularized in the ANL/IBM SP scheduling system (Lifka 1995). A 128-GPU job with estimated runtime of 2 hours can safely backfill if the 124 additional GPUs needed by the large job will become available within 2 hours anyway (from other completing jobs). The backfilled job uses resources that would otherwise be idle, improving utilization without violating the large job's scheduling guarantee.

The accuracy of runtime estimates determines backfill effectiveness, and this creates a game-theoretic challenge. If users consistently overestimate runtimes, backfill slots are artificially narrow and fewer jobs fit, reducing utilization. If users underestimate, backfilled jobs may still be running when the large job's resources become available, forcing preemption that wastes the backfilled job's progress. In practice, users have strong incentives to overestimate (to avoid being killed before completion) and weak incentives to estimate accurately, leading to systematic inflation that degrades backfill performance. Research schedulers like Tiresias (Gu et al. 2019) address this fundamental problem by eliminating the requirement for runtime estimates entirely, instead using observed resource consumption to dynamically adjust priority. This approach, discussed in detail in section 8.6.1, turns the runtime estimation problem from a user-facing burden into a system-level observation.

A quick cost estimate shows why even modest improvements in this balance justify engineering effort.

Systems Perspective 8.1: The economics of idle GPUs

The cluster economics introduced in section 8.1 set the stake; the gang-scheduling decision is where a scheduler first earns or burns it. Taking the same 10,000-GPU cluster:

- **Operating cost:** \$480,000/day (\$175.2M/year)
- **Lower utilization** (60 percent): 6,000 productive, 4,000 idle = \$192,000/day wasted
- **Higher utilization** (80 percent): 8,000 productive, 2,000 idle = \$96,000/day wasted
- **Improvement value:** Moving from 60 percent to 80 percent saves \$96,000/day, or about \$35.0M/year

The increment gang scheduling owns is the deadlock it prevents: a single hold-and-wait deadlock can strand the whole cluster, erasing more than a full day of this utilization gain in one event.

Gang scheduling removes the hold-and-wait deadlock from the utilization example, but another wait-for pattern remains: priority inversion can still strand reserved GPUs behind jobs that cannot finish their own exit path.

8.1.6 Deadlock prevention and detection

Gang scheduling eliminates the hold-and-wait condition, one of the four formal Coffman conditions for deadlock, but it does not immunize the cluster against all forms of resource contention. Deadlocks can still emerge from the interaction of priority rules, preemption policies, and auxiliary resource dependencies. In a cluster with thousands of GPUs and petabytes of state, these edge cases transition from theoretical curiosities to daily operational incidents.

The most pernicious of these is priority inversion, a scenario borrowed from real-time systems where a high-priority job is indefinitely blocked by a low-priority job. Consider a 175B parameter training run (high priority) requesting a gang of 64 GPUs. The scheduler has reserved 60 available GPUs, but the remaining 4 are held by a low-priority data processing job. Normally, the scheduler would preempt the low-priority job to satisfy the high-priority request. However, if a stream of medium-priority development jobs saturates the cluster's CPU or network bandwidth, starving the low-priority job of the resources it needs to checkpoint and exit, the low-priority job stalls. It cannot release the GPUs because it cannot complete its exit sequence. The high-priority job waits for the low-priority job, which is effectively blocked by the medium-priority jobs. The result is a 60-GPU idle block that persists until an operator manually intervenes.

Priority inversion is a wait-for chain, not a root-failure tree.

Definition 8.2: Priority inversion

Priority Inversion is an ML cluster scheduling pathology in which a high-priority task is forced to wait for a lower-priority task to release a shared resource.

1. **Significance:** It reduces the progress rate of the entire fleet to that of the lowest-priority job. In ML clusters, this typically occurs when a low-priority job holding GPUs is starved of auxiliary resources (for example, BW for checkpointing), preventing it from finishing and releasing the accelerators needed by high-priority workloads.
2. **Distinction:** Unlike Standard Queuing (where tasks wait their turn), Priority Inversion involves an Active Blockage: the high-priority task is ready to run but is transitively dependent on a task that the scheduler does not prioritize.
3. **Common pitfall:** A frequent misconception is that strict priority levels solve this. In reality, without Holistic Preemption (reserving all resources needed for a task to exit), increasing priority levels can actually increase the likelihood of inversion by creating more complex dependency chains.

Solving this requires a choice between prevention and detection. Prevention mechanisms, like strict gang scheduling and aggressive timeouts, eliminate deadlock states by construction but often sacrifice utilization. Detection mechanisms allow the system to enter potentially unsafe states to maximize throughput, relying on monitoring to identify and resolve deadlocks when they occur.

For large-scale fleets, exact deadlock detection is computationally nontrivial. A cluster with 10,000 GPUs and 500 pending jobs has a state space exceeding 10^{15} possible allocations, so constructing and traversing a global wait-for graph in real time is often intractable. Large-scale schedulers therefore approximate liveness rather than prove it. A **lease-based resource** gives every allocation a time-to-live (TTL), allowing the scheduler to reclaim GPUs when a job stops renewing its claim. **Progress monitoring** then checks whether the job is actually advancing, using signals such as GPU utilization, step counters, or heartbeat timestamps to identify zombie allocations. When the scheduler must preempt a lower-priority job, **holistic preemption** reserves the CPU, network, and storage bandwidth needed for that job to checkpoint and exit cleanly; otherwise, the victim can be too starved to release the accelerators. These strategies accept a nonzero rate of false positives to preserve cluster liveness.

8.1.7 Heterogeneous gang scheduling

The traditional gang scheduling model assumes a homogeneous Bulk Synchronous Parallel (BSP) workload: N identical workers executing the exact same compute graph. Some training workflows break this assumption because one logical job contains several roles with different resource profiles. In preference-training pipelines such as reinforcement learning from human feedback (RLHF), for example, one component may update the policy while another scores outputs or supplies reference behavior. The scheduler still sees one job, but the gang contains trainers, evaluators, and inference-style workers that need different GPU counts, memory footprints, and lifetimes.

🔍 Systems Perspective 8.2: Routing over synchrony

Heterogeneous gang scheduling reframes this allocation. The scheduler must atomically allocate a diverse constellation of resources: high-HBM nodes optimized for memory-bound inference generation, alongside high-compute nodes for compute-bound backpropagation. The orchestration challenge shifts from static topological bin-packing to dynamic data routing. Activations and gradients are no longer just reduced within a homogeneous ring; instead, data must stream continuously between inference nodes generating rollouts and training nodes computing policy updates. If the heterogeneous gang allocation is not perfectly balanced across these distinct workload profiles, the entire cluster falls out of sync, leaving expensive accelerators starved for data.

Heterogeneous RLHF gangs are the exception; for common homogeneous training jobs, the recurring tension is gang scheduling's safety against backfill's utilization. Gang scheduling prevents deadlock but wastes resources; backfill improves utilization but requires runtime estimates that users cannot accurately provide. Two common orchestration paradigms resolve this tension through fundamentally different architectural philosophies.

8.2 Orchestration Paradigms

The gang-scheduling/backfill tension does not have a tool-neutral answer: the orchestration paradigm determines which guarantee the platform protects first. Slurm, shaped by HPC batch systems, favors explicit resource requests and predictable allocation. Kubernetes, shaped by cloud-native service management, favors declared desired state and continuous reconciliation. The choice is therefore not Slurm vs. Kubernetes as products; it is which control model best matches the workload mix, failure behavior, and operational culture of the fleet.

The fundamental distinction is between *imperative* and *declarative* resource management. In an imperative system, users specify exactly what resources they need and the system allocates them directly. In a declarative system, users specify what they want running and the system converges toward that state. This distinction, familiar from programming language design, determines how ML workloads are scheduled, monitored, and recovered from failure.

8.2.1 Slurm: The HPC heritage

Slurm Workload Manager⁶ originated at Lawrence Livermore National Laboratory as a scalable, fault-tolerant resource manager for Linux clusters (Yoo et al. 2003). Its batch-oriented design fits the distinctive requirements of scientific computing: long-running jobs, expensive shared hardware, and users who can specify resource needs in advance. In ML infrastructure, the same model maps to GPU training through partitions for heterogeneous accelerator pools and predictable allocations for long-running distributed jobs.

Slurm uses an **imperative scheduling model**: users submit job scripts specifying exact resource requirements, and the scheduler places jobs into partitions based on priority, fairness, and resource availability. This directness makes reasoning about allocation guarantees straightforward. When a user submits `sbatch --gres=gpu:8 --nodes=4`, Slurm guarantees that if the job starts, it will have exactly 32 GPUs across 4 nodes. The user knows precisely what they are getting, and the scheduler knows precisely what it must provide. The cost of this directness is that users must understand their resource needs precisely; requesting more than needed wastes resources, while requesting less causes out-of-memory errors or reduced performance.

⁶ | **Slurm Workload Manager**: Originally “SLURM,” an acronym for Simple Linux Utility for Resource Management, the project dropped the acronym capitalization in 2012. Developed at Lawrence Livermore National Laboratory beginning in 2002, Slurm’s centralized controller (`slurmctld`) maintains a single authoritative view of resource allocations. At very large scale, operators may partition fleets or federate schedulers to keep scheduling latency, policy isolation, and failure domains manageable.

Slurm’s architecture consists of a central controller daemon (`slurmctld`) that maintains the global view of cluster state and makes scheduling decisions, and per-node daemons (`slurmd`) that manage local resources and execute jobs. This centralized architecture provides the authoritative allocation model discussed in section 8.1.1: the controller is the source of truth for resource assignments, reducing the risk of conflicting allocations. The cost is a potential single point of failure (addressed through active-passive failover) and a scheduling-throughput limit. As fleets grow, organizations may partition the cluster or federate schedulers to bound scheduling latency and failure impact.

A typical ML cluster configuration defines Slurm partition configuration by accelerator type and interconnect, as table 8.1 shows:

Table 8.1: Slurm Partition Configuration: Partitions organize heterogeneous accelerators into logical pools matched to workload characteristics. NVLink-connected partitions support tensor parallelism, while PCIe partitions serve workloads that rely primarily on data parallelism. Separating inference and debug partitions prevents experimental workloads from impacting production serving.

Partition	GPUs/Node	Interconnect	Typical Use
dgx-a100	8 × A100	NVLink + IB NDR	Large LLM training
a100-pcie	4 × A100	PCIe + IB HDR	Medium training
inference	2 × A10G	Ethernet	Model serving
debug	1 × V100	Ethernet	Development

Those partitions make GPU allocation policy concrete, and Slurm provides several mechanisms for controlling placement. The `--gres=gpu:N` flag requests N GPUs per node, while `--gpus=N` requests a total GPU count for the job. Naive allocation can fragment nodes: if jobs request 6 GPUs on 8-GPU nodes, each job wastes 2 GPUs per node, reducing effective capacity to 75 percent. Slurm’s `select/cons_tres` plugin enables GPU-aware consumable-resource scheduling, tracking individual GPUs rather than treating nodes as indivisible units. The `--gpus-per-node` flag requests a fixed GPU count on each allocated node when NVLink communication patterns make partial-node allocation counterproductive, while `--gpus-per-task` distributes GPUs evenly across tasks for data-parallel workloads.

The interaction between GPU allocation and node selection creates subtleties that affect both performance and utilization. A job requesting `--gpus=16 --gpus-per-node=8` will always receive exactly 2 complete nodes, ensuring all 8 GPUs within each node communicate via NVLink. The same job requesting `--gpus=16` without the per-node constraint might receive GPUs spread across 3 or 4 partially occupied nodes, degrading intra-node communication performance. For training jobs using tensor parallelism, the per-node constraint is essential; for data-parallel jobs that communicate only through AllReduce, the flexibility of unconstrained placement improves the scheduler’s ability to find valid allocations and reduces fragmentation.

The **fair-share scheduling** mechanism prevents any single user or project from monopolizing resources over time. The core insight is that past usage should affect future priority: heavy users should yield to lighter users when the cluster is contended. The effective-priority heuristic combines base priority, the user’s target fair share (F_{target}), the user’s recent actual consumption (F_{actual}), and a small stabilizing constant (ϵ):

$$\text{Priority}_{\text{effective}} = \text{Priority}_{\text{base}} \times \frac{F_{\text{target}}}{F_{\text{actual}} + \epsilon} \quad (8.1)$$

The fair-share formula in equation 8.1 naturally deprioritizes heavy users while allowing burst access when resources are idle. A researcher who has consumed twice their fair share sees their priority halved, pushing new submissions behind colleagues who have used less. Conversely, a researcher who has used no resources recently receives maximum priority, allowing rapid access when they return to active work.

The time decay of usage history determines how quickly the system “forgives” past heavy usage. A half-life of one week means that a researcher’s heavy usage from two weeks ago contributes only 25 percent to their current usage calculation. Short half-lives create rapid rebalancing but can lead to oscillatory behavior where users alternate between starving and gorging on resources. Long

half-lives create stable priority ordering but may penalize researchers who completed a legitimate large project and now want resources for a smaller one. Most production clusters configure half-lives between 3 and 14 days, balancing responsiveness against stability.

Preemption policies enable high-priority jobs to reclaim resources from running workloads, and for ML training, this requires careful coordination with the checkpoint infrastructure. Slurm can notify selected jobs with SIGTERM and use `GraceTime` to delay final termination, typically giving 60 to 300 seconds for a checkpoint before the eventual SIGKILL. `PreemptMode=REQUEUE` requeues eligible batch jobs (for example, jobs submitted with `--requeue` or clusters with `JobRequeue=1`), and the job's startup path must resume from the latest checkpoint. The checkpoint and recovery infrastructure developed in Chapter 7 makes this preemption practical; without reliable checkpointing, preemption would lose all progress since the last manually triggered save, making preemption economically ruinous for long-running training jobs.

Preemption introduces a scheduling paradox: it improves the scheduler's ability to serve high-priority work but can degrade overall cluster throughput. Every preemption wastes the compute between the last checkpoint and the preemption event, plus the time to restart and reload from checkpoint. If checkpoint intervals are long (for example, hourly) and preemptions are frequent, the wasted compute can be substantial. Production systems balance preemption frequency against checkpoint overhead, often configuring preemption cooldown periods that prevent the same job from being preempted more than once within a configurable interval.

Slurm's strengths for ML training are clear: predictable allocation guarantees, mature fair-share policies, straightforward integration with MPI-based distributed training frameworks, and decades of operational experience in managing large-scale scientific computing. Its weaknesses emerge for inference workloads and mixed training-serving clusters, where the batch-oriented model struggles with the dynamic, latency-sensitive nature of serving traffic. Slurm has no native concept of "a service that should always be running," making it awkward for inference endpoints that must respond to requests continuously. Adding or removing inference replicas requires submitting or canceling Slurm jobs, a much heavier operation than scaling a Kubernetes deployment.

8.2.2 Advanced Slurm configuration for ML

Once Slurm owns batch training, the remaining question is how much ML semantics the batch system can see. Standard partitions and fair-share policies schedule ordinary jobs; large-scale deep learning needs configuration that exposes sweep structure, asymmetric pipeline resources, hardware health at job boundaries, and the economic weight of different accelerator types.

Job arrays transform the chaotic submission of thousands of experimental hyperparameter sweep trials into a coherent, schedulable unit. Instead of flooding the controller with individual sbatch requests, a user submits a single array job: `#SBATCH --array=0-99`. Slurm treats this as a single object for parsing and queuing overhead but schedules each element as an independent task, allowing the scheduler to backfill small holes in the cluster with individual trials. Each task receives a unique `SLURM_ARRAY_TASK_ID` environment variable, which the training script uses to index into a hyperparameter configuration file (for example, selecting learning rate $\eta = 10^{-4}$ for task 0 and $\eta = 3 \times 10^{-4}$ for task 1). This mechanism is common for large-scale ablation studies, enabling researchers to launch 1,000 experiments with a single command while preserving scheduler throughput.

Heterogeneous jobs address the preprocessing bottleneck where expensive GPUs sit idle while CPUs prepare data. Traditional jobs allocate symmetric resources to every node, forcing users to reserve GPU nodes for the entire pipeline. Slurm heterogeneous job support lets a single submission span disparate resource types by separating components with `:` on the command line or `#SBATCH het:job` inside a script. The 64-GPU fine-tuning run for our 175B model (the scheduling-demo workload, not the full 1,024-GPU pretraining run) uses this pattern: it requests a heterogeneous allocation of 8 GPU nodes (64 A100s) for the model and 2 CPU-only nodes for on-the-fly data tokenization. The `srun --het-group=0` command launches the training process on the GPUs, while `srun --het-group=1` launches the data workers, allowing the expensive accelerators to focus purely on gradient computation while cheaper CPU nodes feed them data.

Prolog and epilog scripts serve as the cluster's immune system, running administrative code before a job starts and after it finishes. In ML clusters, a typical prolog script performs a preflight check on allocated hardware: it validates NVLink topology (using `nvidia-smi topo -m`), checks ECC

error counters, and verifies InfiniBand link width. If a node fails these checks, the prolog returns a nonzero exit code, causing Slurm to drain the node and requeue the job elsewhere, preventing a silent hardware fault from corrupting a week-long training run. The epilog script ensures hygiene by killing orphaned Python processes, clearing shared memory segments (`/dev/shm`), and logging final GPU utilization metrics to the accounting database. For the 64-GPU fine-tuning run, the prolog script specifically validates that all 8 GPUs on each node have full P2P bandwidth access, preventing a single degraded NVLink lane from bottlenecking the entire tensor parallel group.

Finally, **Trackable Resources (TRES)** extend Slurm’s accounting beyond simple CPU/memory tracking to assets like GPU-hours, license tokens, or power budget. The capability that matters is economic-weight accounting per accelerator class: each tracked resource carries a billing weight, so fair-share can be driven by actual economic cost rather than raw core counts. This ensures that a team using 100 older GPUs does not deplete its budget as fast as a team using 100 flagship H100s, and it lets organizations implement project billing for expensive resources directly inside the scheduler’s fairness calculation.

These extensions make Slurm more ML-aware while preserving its batch-scheduler model. Kubernetes starts from a different contract: users declare the desired state of services and jobs, and controllers continuously reconcile the cluster toward that state.

8.2.3 Kubernetes: Declarative orchestration

Kubernetes is a common platform for ML infrastructure, particularly for organizations requiring unified management of training and serving workloads (Burns et al. 2016; Cloud Native Computing Foundation 2024). Where Slurm’s model is imperative (“run this job on these resources”), Kubernetes uses a **declarative model** (“ensure this state exists”), using control loops that continuously reconcile desired state with actual state. This fundamental difference shapes every aspect of ML workload management, from job submission to failure recovery.

The declarative model’s power lies in its approach to failure handling. Slurm’s recovery is configuration-dependent and batch-oriented: `slurmd` can detect node failures through `slurmd` heartbeats and requeue jobs when `Requeue=1` is set, but the recovery semantics require explicit configuration to behave like a continuously-reconciling control loop. In Kubernetes, the control loop continuously reconciles desired state (“4 replicas of this serving worker should be running” for a Deployment, or the configured retry policy for a Job) against actual state, automatically creating a replacement pod on a healthy node when divergence is detected. For distributed training specifically, replica-replacement semantics typically come from a higher-level operator such as KubeFlow’s `PyTorchJob` or `MPIJob` rather than core Kubernetes primitives. This self-healing behavior reduces operational burden but introduces complexity: the system’s actions are emergent from control loop interactions rather than explicitly commanded, making debugging more challenging when things go wrong.

Kubernetes’ control loop architecture is built on the **controller pattern**⁷: a controller watches the cluster’s actual state (stored in `etcd`, Kubernetes’ distributed key-value store for API state), compares it to desired state (specified by users through API objects like Deployments, Jobs, and StatefulSets), and takes corrective action to close the gap. This pattern repeats at every level: the Deployment controller ensures the right number of pods exist, the scheduler assigns pods to nodes, the kubelet on each node ensures containers are running, and the node controller detects node failures. Each controller operates independently, communicating only through shared state in `etcd`, which makes the system resilient to individual controller failures but can create emergent behaviors when multiple controllers interact.

Native Kubernetes lacks ML-aware scheduling, but extensions address this gap. GPU scheduling relies on **device plugins** that expose accelerators as schedulable extended resources. The NVIDIA device plugin registers GPUs with the kubelet (the node-level agent), enabling pod specifications that request GPU resources declaratively through the standard Kubernetes resource model. Listing 8.1 shows the resulting pod fragment.

⁷ | **Controller Pattern (Reconciliation Loop):** A “level-triggered” design where the controller continuously compares desired state to actual state, as opposed to “edge-triggered” systems that react to individual events. The distinction matters for ML clusters: if a controller crashes and restarts, it re-reads current state and self-heals without needing an event log. The trade-off is that emergent interactions between multiple independent controllers can create unexpected scheduling behaviors that are difficult to debug sequentially.

Listing 8.1: Kubernetes GPU Allocation: Pod resource specification requesting GPUs through the NVIDIA device plugin. The `nvidia.com/gpu` resource name follows Kubernetes extended resource conventions, where the domain prefix identifies the device plugin vendor. This declarative syntax enables portable GPU workload definitions across any Kubernetes cluster with the NVIDIA device plugin installed.

```
# Kubernetes pod resource specification for GPU allocation
resources:
  limits:
    nvidia.com/gpu: 4 # Request exactly 4 GPUs for this pod
  requests:
    cpu: "32"
    memory: "256Gi"
```

This binary allocation model creates a significant inefficiency for inference workloads. A small model serving occasional requests might need only a fraction of a GPU’s compute and memory capacity, yet Kubernetes allocates an entire GPU, wasting the remaining capacity. For training workloads that saturate GPU compute, full-device allocation is appropriate. For inference workloads with variable and often modest resource needs, it creates the same kind of fragmentation that partial-node allocation creates in Slurm.

Multi-Instance GPU (MIG)⁸ technology addresses this inefficiency by partitioning A100 (80 GB) and H100 (80 GB) GPUs into hardware-isolated instances. Unlike software-based GPU sharing, MIG dedicates memory, cache, and compute resources to each instance, preventing one workload from interfering with another and eliminating the noisy neighbor⁹ effect. The A100 MIG profiles in table 8.2 show the scheduling consequence: a single physical A100 becomes several fixed-size resources that the device plugin can expose as independently schedulable accelerators.

Table 8.2: A100 MIG Profiles: Multi-Instance GPU configurations trade GPU memory and compute resources for increased sharing density. Each profile provides hardware-isolated resources, making MIG suitable for multi-tenant inference clusters where workloads from different teams or customers must not interfere. The SM (Streaming Multiprocessor) count determines compute throughput within each instance.

MIG Profile	GPU Memory	SM Count	Typical Workload
1g.10gb	10 GB	14 SMs	Small inference
2g.20gb	20 GB	28 SMs	Medium inference
3g.40gb	40 GB	42 SMs	Large inference
7g.80gb	80 GB	98 SMs	Training

As section 8.1.5 explains, default Kubernetes pod scheduling is independent, so ML platforms add admission or gang semantics when all-or-nothing startup matters. The default scheduler evaluates pods one at a time, placing each on the best available node. For a distributed training job with 64 pods, this means 64 independent scheduling decisions, with no guarantee that all 64 will succeed. If the cluster has resources for 60 pods but not 64, the default scheduler may place 60 pods and leave the remaining 4 pending, creating exactly the partial-allocation waste that gang scheduling prevents. PodGroup-style abstractions, whether implemented by scheduler plugins or higher-level batch controllers, give the platform a unit of admission that matches the training job rather than the individual pod.

The **Volcano**¹⁰ batch scheduler and **Coscheduling** scheduler plugin address this gap by implementing gang semantics through **PodGroup** abstractions. A PodGroup declares that a set of pods must be scheduled together, specifying a minimum member count that must be satisfiable before any pod in the group starts. The scheduler evaluates the entire group atomically: either all minimum members can be placed, and they are placed simultaneously, or none are placed and the group waits in the queue. This transforms Kubernetes’ pod-level scheduling into job-level scheduling that respects the all-or-nothing requirements of distributed training.

Priority classes control preemption behavior in Kubernetes, establishing a hierarchy that determines which workloads yield resources to which others. A typical production configuration assigns

8 | **Multi-Instance GPU (MIG):** Introduced with the A100 (2020), MIG partitions a single GPU into up to 7 hardware-isolated instances with dedicated memory controllers, L2 cache slices, and compute units (NVIDIA Corporation 2020). The isolation is enforced at the hardware level, not by time-slicing, reducing noisy-neighbor interference relative to software-only sharing. The trade-off is rigidity: partition profiles cannot change without draining all workloads, making MIG poorly suited for clusters with rapidly shifting workload mixes.

9 | **Noisy Neighbor:** A metaphor from multi-tenant housing where one resident’s activity (loud music) disturbs another’s peace. In GPU clusters, this occurs when one job’s bursty network traffic or memory bus utilization slows down a co-located job on the same node. For distributed training, noisy neighbors are fatal to efficiency because the slowest flow dictates the global AllReduce time.

10 | **Volcano:** Open-sourced by Huawei and now a CNCF incubating project, Volcano replaces the Kubernetes default scheduler entirely to add gang scheduling via its PodGroup CRD. The replacement approach provides strong atomicity guarantees for multi-pod ML training jobs but carries operational risk: a bug in Volcano affects all scheduling decisions on the cluster, not just batch workloads.

inference workloads high priority (ensuring serving SLOs are met), training workloads medium priority, and development jobs low priority. The default `PriorityClass` behavior, `preemptionPolicy: PreemptLowerPriority`, allows a higher-priority pending pod to evict lower-priority pods when that would make room for it. A `PriorityClass` with `preemptionPolicy: Never` is non-preempting: its pods can sit ahead of lower-priority pods in the scheduling queue, but they do not evict running pods and can still be preempted by still-higher-priority pods. Organizations must carefully balance the priority hierarchy: overly aggressive inference preemption can thrash training jobs (repeatedly preempting and restarting them), while overly permissive training priorities can starve inference during demand spikes. The Kubernetes priority and preemption system integrates with checkpoint-aware preemption patterns developed later in Chapter 7, where preempted training jobs save state before yielding resources, minimizing wasted computation.

Kueue¹¹, a newer Kubernetes-native job queueing system, represents an emerging approach that separates *admission control* from *scheduling*. Rather than replacing the Kubernetes scheduler entirely (as Volcano does), Kueue manages when jobs enter the cluster, while the default scheduler (or any compatible scheduler) handles where pods are placed. This separation of concerns has practical advantages: Kueue can be deployed alongside existing Kubernetes infrastructure without disrupting running workloads, and it integrates naturally with the ecosystem of scheduler plugins for topology-aware placement and other features.

Kueue provides fair-share scheduling through `ClusterQueues` that represent organizational teams or projects. Each queue has resource quotas, borrowing policies that allow queues to use idle capacity from other queues, and preemption policies that reclaim borrowed resources when the owning queue needs them. A research team queue might borrow idle capacity from a production team queue during off-peak hours, automatically returning resources through preemption when the production team submits urgent work. This borrowing mechanism mirrors the hierarchical fair-share approaches in Slurm but expressed through Kubernetes' declarative model rather than Slurm's imperative configuration.

¹¹ | **Kueue**: Developed by Google, Kueue separates *admission control* (when jobs enter the cluster) from *scheduling* (where pods are placed), unlike Volcano which replaces the scheduler entirely. This less-invasive design can be deployed alongside existing Kubernetes infrastructure without disrupting running workloads, but it lacks Volcano's strong gang scheduling guarantees, forcing teams to choose between deployment safety and scheduling atomicity.

8.2.4 Kubernetes ecosystem for ML training

Kubernetes provides the orchestration primitives, but a specialized ecosystem of operators and plugins is required to bridge the gap between microservice orchestration and high-performance training. Each extension makes one hidden operational constraint visible to the platform: job atomicity, network bypass, checkpoint storage, or telemetry. This ecosystem augments Kubernetes with the batch processing, hardware acceleration, and observability capabilities found in HPC environments.

The **Training Operator ecosystem** simplifies distributed training by extending Kubernetes with job-specific Custom Resource Definitions (CRDs). The KubeFlow Training Operator provides controllers for `PyTorchJob`, `TFJob`, and `MPIJob` resources, automating the complex lifecycle of distributed workloads. A `PyTorchJob` specification defines the number of workers, the container image, and resource requirements; the operator then creates the necessary pods and configures distributed environment variables such as `MASTER_ADDR`, `MASTER_PORT`, `WORLD_SIZE`, and `RANK`. If a worker pod fails, the operator can detect the deviation and create a replacement pod to restore the desired replica count, but training-state recovery still depends on the framework's checkpoint and rendezvous logic.

Achieving high network performance in Kubernetes often requires bypassing networking layers that were designed for ordinary microservices rather than tightly synchronized collectives. CNI configuration, overlay networking, and CPU switching can add latency or reduce effective bandwidth when they sit on the critical gradient-synchronization path. For bandwidth-sensitive training, **host networking** (`hostNetwork: true`) allows pods to bypass the CNI entirely, granting direct access to the host's network namespace and RDMA devices. The NVIDIA Network Operator automates the low-level plumbing required for this performance, managing RDMA device plugins, SR-IOV virtual function assignment, and GPUDirect RDMA configuration. This bypass capability allows containerized workloads to approach bare-metal interconnect performance when the remaining stack is configured correctly.

Storage integration addresses the "checkpoint storm" problem where thousands of GPUs simultaneously write terabytes of state. Kubernetes `PersistentVolumeClaims` (PVCs) abstract the underlying storage fabric, which may be a parallel file system like Lustre or GPFS, or high-performance object

storage via CSI drivers. The critical architectural challenge is preventing these synchronized writes from saturating the storage backend. Storage classes with Quality of Service (QoS) policies and client-side throttling are essential to ensure that a 1,024-GPU training job writing a 2 TB checkpoint does not starve other workloads or crash the storage metadata server.

The **observability stack** for training clusters combines general-purpose cluster monitoring with specialized hardware telemetry. Prometheus and Grafana provide the collection and visualization layer, while the DCGM (Data Center GPU Manager) exporter exposes granular GPU metrics: utilization, memory bandwidth, temperature, and ECC errors. This stack enables the utilization dashboards essential for multi-tenant efficiency, allowing operators to distinguish between true compute saturation and I/O-bound idleness.

The 1,024-GPU pretraining run for our 175B model uses this full Kubernetes stack. The workload is defined as a PyTorchJob with 128 worker pods, each requesting 8 GPUs. Host networking is enabled to allow direct InfiniBand access for the NVLink-connected nodes. A PVC backed by a high-throughput Lustre file system provides access to the 100 TB training dataset and absorbs periodic checkpoints. DCGM metrics stream to Prometheus, triggering alerts if any GPU reports uncorrectable ECC errors or if NVLink bandwidth drops below the expected baseline.

8.2.5 Choosing between paradigms

The choice between Slurm and Kubernetes is rarely binary; it depends on workload composition, organizational context, and the relative importance of different system qualities. Understanding where each paradigm excels guides the architectural decision.

Slurm excels for pure training clusters where predictability and bare-metal performance matter most. Its direct resource management avoids the container overhead that Kubernetes introduces (container networking adds microseconds of latency and reduces effective network bandwidth by 1 to 5 percent), and its batch scheduling model aligns naturally with long-running training jobs that require guaranteed, uninterrupted access to specific hardware. Slurm's centralized scheduler has global visibility into cluster state, enabling sophisticated multi-factor priority decisions that account for fair-share, job size, queue depth, and resource availability simultaneously. National laboratories, university research clusters, and dedicated training infrastructure typically favor Slurm because these environments prioritize maximum hardware utilization and minimal overhead for a relatively homogeneous set of batch workloads.

Kubernetes excels for mixed training-serving clusters where unified management, rolling updates, and service mesh integration reduce operational complexity. Organizations running both training pipelines and production inference endpoints benefit from a single control plane that manages both workload types through a consistent API. Kubernetes' declarative model simplifies operational workflows: deploying a new model version means updating a Deployment specification, and Kubernetes handles rolling updates, health checks, and rollback automatically. Cloud-native organizations, teams deploying ML as microservices, and organizations with existing Kubernetes expertise typically favor Kubernetes because the marginal cost of adding ML workloads to an existing platform is lower than operating a separate scheduling system.

Many production environments recognize that neither paradigm alone satisfies all requirements, and they deploy both systems in complementary roles. A common architecture uses Slurm for dedicated training clusters where raw performance and scheduling sophistication matter, and Kubernetes for inference serving, pipeline orchestration, and lighter training workloads (fine-tuning, small-scale experimentation). The emerging pattern is to use Kubernetes as the outer orchestration layer, submitting Slurm jobs for large training runs through Kubernetes operators. This hybrid architecture achieves unified management and observability without sacrificing Slurm's batch scheduling capabilities for the workloads that need them most.

The Slurm vs. Kubernetes trade-off organizes around the dimensions most relevant to ML workloads in table 8.3:

Table 8.3: Slurm vs. Kubernetes for ML Workloads: The two paradigms reflect different design philosophies optimized for different workload characteristics. Most production ML platforms use elements of both, with Slurm managing dedicated training clusters and Kubernetes managing inference serving and pipeline orchestration.

Dimension	Slurm	Kubernetes
Scheduling model	Imperative: user specifies exact resources and scheduler allocates them	Declarative: user specifies desired state, system reconciles continuously
Failure handling	Configuration-dependent requeue and checkpoint workflows	Self-healing through control loops
Gang/atomic multi-node start	Atomic job allocation plus backfill; Slurm “gang scheduling” specifically refers to time-slicing/preemption	Production clusters commonly use PodGroup-based support such as Volcano, Coscheduling, Kueue, or upstream alpha gang scheduling
Fair-share	Mature multi-factor priority with configurable decay	Kueue provides basic fair-share with ClusterQueue borrowing
Container overhead	None from a container runtime when jobs run directly on nodes	Configuration-dependent networking overhead and container startup time
Service management	No native support for long-running services	Native Deployment, rolling updates, health checks
Ecosystem	MPI, OpenMP, scientific computing libraries	Cloud-native, microservices mesh, observability stack

As table 8.3 illustrates, the choice also reflects organizational trajectory. Teams starting with HPC-focused training infrastructure may begin with Slurm and add Kubernetes for serving. Teams starting from cloud-native application infrastructure may begin with Kubernetes and add HPC-oriented extensions (Volcano, Kueue) for training. Either path can reach a functional hybrid architecture, but the starting point determines which capabilities are strongest and which require the most investment to develop.

8.2.6 Hybrid architectures in practice

While the choice between Slurm and Kubernetes often appears binary, sophisticated engineering organizations increasingly deploy **hybrid architectures** that use the strengths of both systems. These architectures acknowledge a fundamental reality: training workloads behave like HPC applications (batch, synchronous, monolithic), while serving workloads behave like microservices (continuous, asynchronous, elastic). Forcing both into a single paradigm often results in a “lowest common denominator” system that serves neither well.

The **Kubernetes-over-Slurm** pattern wraps the HPC scheduler within a cloud-native control plane. In this architecture, Kubernetes acts as the outer orchestration layer, managing the lifecycle of training jobs through custom operators while delegating the actual pod placement to Slurm. A developer submits a `TrainingJob` Custom Resource Definition (CRD) to Kubernetes, which the operator translates into a Slurm `sbatch` script. The operator then monitors the job status via Slurm’s REST API, streaming logs and metrics back to the Kubernetes control plane. This approach provides the best of both worlds: the unified observability, CI/CD integration, and access control of Kubernetes, combined with the gang scheduling sophistication, topology awareness, and bare-metal performance of Slurm.

The **Slurm-alongside-Kubernetes** pattern takes a coarser-grained approach, maintaining separate clusters for training and serving that draw from a shared pool of physical nodes. A meta-scheduler or capacity broker acts as an arbitrator, dynamically reassigning nodes between the Slurm partition and the Kubernetes cluster based on demand signals. During intensive training campaigns, nodes are drained from Kubernetes and joined to Slurm; during product launches or traffic spikes, the flow reverses. The primary challenge is the mode-switching cost: draining a Kubernetes node, re-imaging or reconfiguring it, and joining it to Slurm (or vice versa) typically requires 5 to 15 minutes. This latency limits the granularity of sharing: the system can adapt to diurnal patterns or weekly cycles but cannot use Slurm capacity to absorb second-by-second inference bursts.

Emerging unified platforms like Ray attempt to eliminate the dichotomy entirely by providing a single runtime for both training and serving. Ray implements its own distributed scheduler that handles actor placement, task scheduling, and resource management natively. This eliminates the impedance mismatch between training (stateful actors) and serving (stateless replicas), allowing a

single Python script to define a training loop that seamlessly transitions into a deployment pipeline. The trade-off is maturity: while Ray excels at orchestration flexibility, its scheduling logic lacks the decades of hardening found in Slurm and the massive ecosystem support of Kubernetes, effectively requiring the platform team to assume more responsibility for reliability and isolation.

Threading these patterns together, consider the lifecycle of our 175B parameter model. The training phase runs on Slurm to maximize NVLink topology efficiency and gang scheduling reliability for the multi-month run. Once trained, the model artifacts are handed off to Kubernetes for serving, where rolling updates and autoscaling ensure high availability for end users. The bridge between them is a Kubernetes operator that monitors training progress; when validation loss stabilizes, it automatically triggers a quantization pipeline and deploys the resulting model to the inference cluster.

The operational impact of these choices is quantifiable, but the numbers depend on workload mix and local platform maturity. A pure Slurm-only environment minimizes batch-job overhead and can keep dedicated training clusters highly utilized, but it requires extra engineering to build production serving infrastructure. A Kubernetes-only environment reduces operational fragmentation by using standard cloud-native tools, but distributed training may need batch extensions to avoid scheduling fragmentation. The hybrid approach targets the efficient frontier: preserving strong batch-training placement guarantees while keeping a unified management surface for serving and pipeline workloads, at the cost of increased architectural complexity.

Systems Perspective 8.3: The convergence of HPC and cloud

The sharp distinction between HPC and cloud-native scheduling is rapidly blurring as both communities adopt features from the other. Kubernetes is evolving batch capabilities through the Volcano and Kueue projects, introducing concepts like queues, priorities, and gang scheduling that were previously unique to HPC. Conversely, Slurm is adopting cloud features like REST APIs, container runtime support, and elasticity. The industry is converging toward a unified fleet operating system: a system that offers the declarative API and fault tolerance of the cloud with the strict placement guarantees and performance of the supercomputer.

This convergence turns the paradigm choice into a workload-specific design decision: teams must decide which scheduling guarantees matter before layering on topology constraints.

Checkpoint 8.1: Scheduling paradigm trade-offs

Before the chapter turns to topology-aware scheduling, review the core trade-offs:

- ☐ **Gang scheduling:** Explain why gang scheduling is essential for distributed training but not for inference workloads, including the property of synchronous data parallelism that creates the all-or-nothing requirement.
- ☐ **Slurm vs. Kubernetes:** Identify the CAP theorem trade-off Slurm makes differently from Kubernetes, and describe how this difference appears during a network partition between the scheduler and a subset of nodes.
- ☐ **MIG partitioning:** Determine when MIG partitioning improves cluster utilization through concurrent inference workloads on fewer GPUs and when it reduces utilization for training jobs that need full GPU memory.
- ☐ **Backfill incentives:** Explain why backfill scheduling depends on accurate job runtime estimates and why users have game-theoretic incentives to provide inaccurate estimates.

The orchestration paradigms treat GPUs as interchangeable units within a partition, but physical location matters as much as count: the same 64 GPUs run far slower scattered across racks than packed into one. Topology-aware scheduling exploits that structure.

8.3 Topology-Aware Scheduling

Randomly assigning 64 GPUs across a massive data center cripples a synchronous training job, causing it to run 15 to 30 percent slower than if those same 64 GPUs were packed into a single rack. The scheduling algorithms discussed so far treat GPUs as interchangeable units, but topology-aware scheduling recognizes that physical proximity in the network fabric is as critical as raw compute.

8.3.1 The topology hierarchy

Modern GPU clusters exhibit a multi-level communication hierarchy, where bandwidth decreases and latency increases at each level. This hierarchy is not an implementation detail that the scheduler can ignore; it is a physical constraint that directly determines training throughput for communication-intensive workloads. Understanding the hierarchy is essential for making placement decisions that translate allocated resources into useful work.

Within a single node, GPUs communicate via NVLink, providing 600 GB/s per GPU on A100 systems and 900 GB/s on H100 systems. This high-bandwidth, low-latency interconnect enables efficient tensor parallelism, where matrix operations are split across GPUs that must exchange intermediate results (activations and gradients) at every transformer layer. The NVLink bandwidth is sufficient to overlap communication with computation for most model architectures, meaning tensor parallel operations can proceed at near-ideal throughput when confined to a single node.

Between nodes within the same rack or **leaf switch domain**, communication traverses InfiniBand or RoCE at 400 Gb/s (NDR InfiniBand), roughly 50 GB/s per link. This represents an order of magnitude reduction from NVLink bandwidth. Data parallelism, which requires AllReduce of gradients after each training step, operates efficiently at this level because the gradient synchronization pattern allows overlap between communication and the next iteration's forward pass. The latency penalty is modest (microseconds vs. nanoseconds), and the aggregate bandwidth is sufficient for gradient tensors that are typically smaller than the activation tensors exchanged in tensor parallelism.

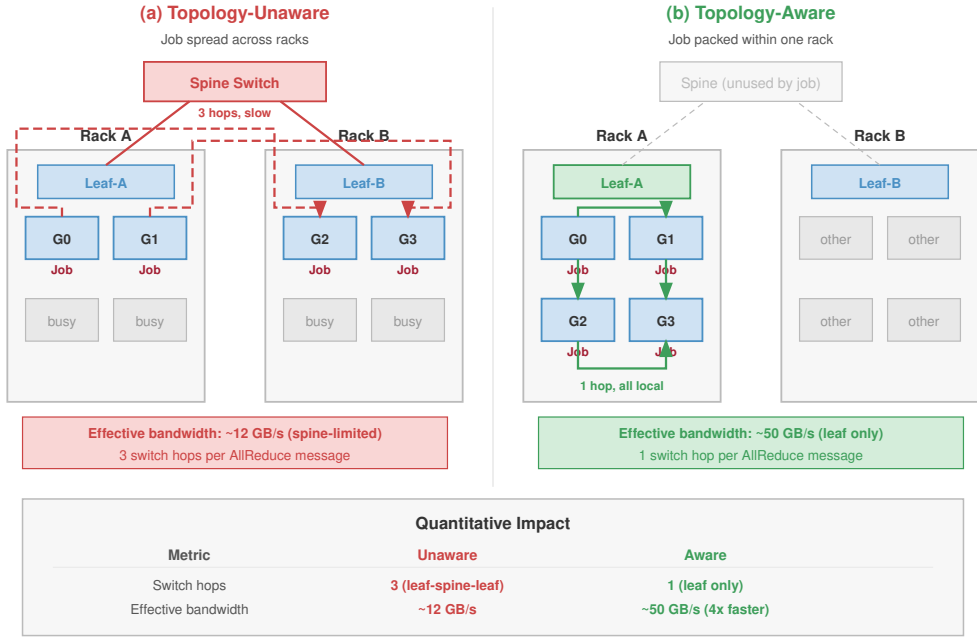

Between racks connected through **spine switches**, communication crosses additional switch hops, introducing both higher latency and potentially reduced effective bandwidth due to network congestion. The fat-tree topologies analyzed in section 3.5.2 provide full bisection bandwidth in theory, but in practice, congestion from concurrent flows, routing inefficiencies, and switch buffer limitations reduce effective cross-rack bandwidth by 10 to 30 percent compared to intra-rack communication. Cross-rack communication also adds tail latency variability: while median latency may be only slightly higher, P99 latency can spike during congestion events, creating straggler effects in synchronous training where the slowest communicator determines the pace for all workers.

This hierarchy means that a 64-GPU job allocated entirely within a single rack (8 nodes, all under one leaf switch) will outperform the same job spread across 8 racks (1 node per rack, crossing spine switches for every AllReduce). The performance difference stems directly from the communication analysis in Chapter 6: ring AllReduce latency scales with the slowest link in the ring, and cross-rack hops introduce both higher latency and increased contention risk. For synchronous training, every iteration waits for the slowest worker to complete its AllReduce, so even occasional cross-rack congestion events create persistent throughput degradation.

The scheduler must therefore model the cluster not as a flat list of compute slots, but as a hierarchical graph with distinct bandwidth cliffs at each level (GPU, Node, Rack, and Pod) corresponding to NVLink, InfiniBand, and spine-switch boundaries. Each boundary crossing introduces an order-of-magnitude bandwidth reduction, and at the rack and pod levels, network oversubscription (often 2:1 or 4:1 at the spine switches) further restricts bisection bandwidth beyond what the raw link speed suggests. A topology-aware scheduler explicitly optimizes for these constraints, treating “locality” as a first-class resource. For a distributed training job requiring 1,024 GPUs, a fragmented placement that scatters workers across random racks can degrade end-to-end training throughput by 15 to 30 percent compared to a compact placement within a single pod.

Figure 8.3 contrasts optimal and scattered placement for a 4-GPU tensor parallel group, showing how the communication path determines whether GPUs use a single leaf switch or must traverse slower leaf-spine-leaf hops.

Topology-aware placement reduces AllReduce latency by 2-4x and eliminates spine contention.

Figure 8.3: Topology-Unaware vs. Topology-Aware Placement: A 4-GPU job placed across two racks (left, topology-unaware) must traverse leaf-spine-leaf hops: 3 switch hops per AllReduce message at about 12 GB/s effective bandwidth. The same 4-GPU job packed within one rack (right, topology-aware) uses a single leaf switch: 1 hop at about 50 GB/s, roughly 4× faster. A quantitative summary beneath the figure reports switch-hop counts and effective bandwidth.

8.3.2 Placement algorithms

The bandwidth gap shown in figure 8.3 is the key constraint: the roughly 4× reduction from intra-rack leaf paths to cross-rack leaf-spine-leaf paths means that scattered placement forces tensor parallel groups to spend more time communicating than computing, a penalty that compounds at every transformer layer in the model. Topology-aware placement algorithms assign jobs to nodes that minimize communication cost, transforming the abstract bin packing problem into a graph optimization problem on the cluster’s physical topology. The simplest approach uses a **locality cost**, defined in equation 8.2, that penalizes allocations spanning multiple topology domains:

$$\text{Cost}_{\text{locality}} = \sum_{i < j} w(d(g_i, g_j)) \quad (8.2)$$

where g_i and g_j are GPUs assigned to the job, $d(g_i, g_j)$ is their topological distance (0 for same node, 1 for same rack, 2 for different racks), and $w(\cdot)$ is a weighting function that increases with distance. The scheduler minimizes this score when selecting an allocation from the set of feasible placements. The weighting function encodes the performance impact of each topology level: $w(0) = 0$ (same node, NVLink, no penalty), $w(1) = 1$ (same rack, one switch hop), $w(2) = 10$ (different racks, multiple switch hops). The tenfold weight difference between same-rack and cross-rack placements reflects the disproportionate performance impact of crossing spine switches.

More sophisticated algorithms distinguish between parallelism strategies, recognizing that different communication patterns have different bandwidth and latency requirements. Tensor parallelism requires the highest bandwidth and lowest latency because it exchanges activation tensors at every layer; it should be confined to NVLink domains within a single node. Pipeline parallelism tolerates moderate latency because it sends activations between stages less frequently (once per microbatch per stage boundary rather than at every layer); it can span nodes within a rack where InfiniBand provides sufficient bandwidth. Data parallelism, with its bulk gradient synchronization

that can overlap with computation, operates efficiently across racks because the communication is less latency-sensitive and can use the available bandwidth effectively.

Algorithm 8.1 combines these pieces into a single decision: the all-or-nothing gang constraint of section 8.1.5, the locality cost of equation 8.2, and the parallelism-to-topology mapping just described. The scheduler enumerates the allocations that fit, scores each by communication cost, and takes the cheapest, leaving the job queued rather than stranding accelerators when none does.

Algorithm 8.1 Topology-aware placement

Require: job requesting N accelerators with tensor-, pipeline-, and data-parallel groups; cluster topology with per-level link costs $w(\cdot)$

Ensure: an all-or-nothing placement of least communication cost, or the job stays queued

- 1: enumerate the feasible slots: sets of N free accelerators that satisfy every resource dimension
 $\triangleright$ *gang: all or nothing*
 - 2: **if** no feasible slot exists **then**
 - 3: leave the job queued without holding any accelerators $\triangleright$ *prevents hold-and-wait deadlock*
 - 4: **end if**
 - 5: **for** each feasible slot **do**
 - 6: map tensor-parallel ranks within an NVLink domain, pipeline stages within a rack,
 data-parallel replicas across racks
 - 7: score the slot by $\text{Cost}_{\text{locality}} = \sum_{i < j} w(d(g_i, g_j))$
 - 8: **end for**
 - 9: **return** the feasible slot of least $\text{Cost}_{\text{locality}} \triangleright$ *topology-optimal, atomic*
-

Scattered placement runs AllReduce 4.8× slower than a topology-aware slot, a gap figure 8.4 breaks out across four placement strategies from random to topology-optimal.

Figure 8.4: Topology Placement Impact: Reducing AllReduce latency by 4.8× through topology-aware scheduling (rack/rail optimization) compared to random placement for a 1 GB gradient sync on 64 GPUs.

A **hierarchical placement** algorithm assigns resources in layers that match this parallelism hierarchy. First, it assigns tensor parallel groups to individual nodes, ensuring that all GPUs in a tensor parallel group share NVLink connectivity. Second, it groups those nodes into pipeline stages within racks, placing consecutive pipeline stages on nodes connected through the same leaf switch.

Third, it distributes data parallel replicas across racks, ensuring that each data parallel group has access to the cluster's full bisection bandwidth for AllReduce operations. This three-level placement mirrors the three-level topology and the three-level parallelism strategy, creating a natural alignment between logical and physical structure.

Napkin Math 8.2: The topology placement impact

The physical location of GPUs on the network switch fabric dramatically impacts collective performance. Consider an AllReduce operation across 64 GPUs:

- **Random placement:** Spread across many racks → Traffic traverses core switches → 120 ms latency.
- **Rack-aware:** Confined to a single rack (Top-of-Rack switch) → 85 ms.
- **Rail-optimized:** Aligned to specialized “rails” (dedicated standard IB switches) → 40 ms.
- **Topology-optimal:** All GPUs on the same leaf switch → 25 ms. Proper scheduling yields a 4.8× speedup purely by respecting the network topology, with zero changes to the model code.

The computational cost of topology-aware placement is nontrivial. Evaluating all possible placements for a 256-GPU job across a 10,000-GPU cluster is combinatorially intractable. Production schedulers use heuristic approaches: greedy algorithms that build placements bottom-up (first fill NVLink domains, then fill racks, then spread across racks), tree-search algorithms with pruning that explore the most promising placements first, or scoring-based approaches that evaluate a sample of feasible placements and select the best. The scheduling latency introduced by topology-aware algorithms (milliseconds to seconds, depending on cluster size and algorithm complexity) is negligible compared to job runtimes of hours to weeks, making the throughput improvement worth the scheduling overhead.

Napkin Math 8.3: Placement impact on 3D-parallel training

Scenario: Consider a 256-GPU training job using 3D parallelism: 8-way tensor parallel, 4-way pipeline parallel, 8-way data parallel.

Good placement (topology-aware):

- Tensor parallel groups: 32 groups of 8 GPUs, each confined to one 8-GPU node (NVLink: 900 GB/s)
- Pipeline stages: 4 consecutive nodes within the same rack (1 switch hop, InfiniBand: 50 GB/s)
- Data parallel replicas: 8 racks (2 switch hops for cross-rack AllReduce)

Bad placement (topology-unaware):

- Tensor parallel groups split across 2 nodes (InfiniBand instead of NVLink)
- Pipeline stages scattered across racks (2 switch hops instead of 1)
- Data parallel replicas randomly distributed

Math: The tensor parallel communication alone illustrates the impact. With NVLink delivering 450 GB/s per direction, a 1 GB activation transfer takes approximately 2.2 ms. Over InfiniBand at 50 GB/s, the same transfer takes approximately 20 ms, a 9× slowdown.

Systems insight: The 4.8× AllReduce-latency gap in figure 8.4 is a communication-only measurement; it does not become a 4.8× end-to-end penalty because synchronous training overlaps much of that communication with the next iteration's compute. Since tensor parallelism communicates at every transformer layer (typically 80+ layers for large models), the residual

exposed communication compounds to 15 to 30 percent total training throughput degradation, the figure to carry forward for 3D-parallel jobs.

8.3.3 Rail-optimized scheduling

Large GPU clusters increasingly use **rail-optimized topologies** where each GPU in a node connects to a different network switch, creating parallel “rails” through the network fabric. This design, analyzed in section 3.5.3, provides balanced bandwidth across all GPUs by distributing traffic across independent switch hierarchies. However, it also creates a scheduling constraint: AllReduce operations are most efficient when communicating GPUs are on the same rail (connected to the same switch chain), because same-rail communication avoids cross-rail traffic that could create congestion at shared switch ports.

Rail-aware scheduling assigns data parallel replicas such that corresponding GPUs across nodes share the same rail. For an 8-GPU-per-node cluster with 8 rails, GPU 0 on every node connects to rail 0, GPU 1 to rail 1, and so on. The scheduler places data parallel rank r on GPU $r \bmod 8$ across selected nodes, ensuring that AllReduce for each data parallel group traverses only a single rail switch hierarchy rather than crossing between rails. This alignment means that AllReduce traffic is confined to independent switch trees, eliminating contention between data parallel groups and providing each group with the full bandwidth of its dedicated rail.

The interaction between rail-aware scheduling and topology-aware placement creates a multi-dimensional optimization problem. The scheduler must simultaneously optimize for intra-node NVLink locality (tensor parallelism requires GPUs on the same node), intra-rack switch locality (pipeline parallelism benefits from minimal switch hops between stages), and rail alignment (data parallelism benefits from same-rail communication). These three objectives are partially conflicting: constraining data parallel replicas to specific GPU positions within each node (for rail alignment) reduces the scheduler’s flexibility to choose nodes based on rack locality, and requiring full-node allocations for NVLink locality prevents sharing nodes between jobs that could improve packing efficiency.

Production schedulers resolve these conflicts using weighted scoring functions that prioritize constraints based on workload characteristics. For large training jobs using 3D parallelism, tensor parallel locality receives the highest weight (because NVLink-to-InfiniBand performance degradation is the largest), followed by rail alignment (because it eliminates congestion for the most frequent communication pattern), followed by rack locality (because the performance benefit is smaller and can be partially compensated by compute-communication overlap). For pure data parallel jobs, rail alignment receives the highest weight. For single-node jobs, topology constraints are irrelevant and the scheduler optimizes purely for packing efficiency.

8.3.4 Topology discovery and dynamic adaptation

Static configuration files like Slurm’s `topology.conf` or Kubernetes node labels provide a baseline map of the cluster, but they represent the *intended* state, not the *effective* state. True **topology discovery** requires runtime introspection to validate that the physical hardware matches the architectural diagram. Libraries like NCCL bypass static configurations entirely, parsing the Linux virtual filesystem at `/sys/class/infiniband` to map the PCIe bus hierarchy, enumerate NVLink connections, and verify NIC proximity. This creates a ground-truth graph where edges represent verified, operational links rather than theoretical cables.

Cluster topology is an operating state, not a fixed schematic. Hardware failures, maintenance windows, and thermal throttling constantly reshape the effective topology available to the scheduler. A single spine switch failure in a Clos network does not sever connectivity entirely, but it drastically reduces the bisection bandwidth available to jobs spanning the affected racks. If a spine switch serving our 175B parameter model’s data-parallel AllReduce group fails, cross-rack bandwidth might drop by 50 percent. The scheduler faces a critical optimization decision: continue training at reduced throughput, effectively wasting 25 percent of the expensive GPU cycles waiting for straggling gradients, or initiate a topology-aware migration.

Migration is not free; it requires a coordinated checkpoint, a job kill, a rescheduling event on healthy nodes, and a warmup phase. This process typically consumes 5 to 15 minutes of idle time.

However, for a multi-week training run, the math often favors migration. If the network degradation creates a 20 percent throughput penalty, the break-even point for a 10-minute migration is less than an hour of training. Sophisticated orchestrators continuously monitor effective bandwidth metrics reported by the collective communication library. When the delta between the assigned topology score and the realized throughput exceeds a threshold, the scheduler triggers a drain-and-migrate workflow, treating network degradation with the same severity as a GPU hardware fault.

Example 8.2: The limping switch

Scenario: A foundation-model training job shows a large throughput regression. The GPUs are healthy, the code is unchanged, and the static topology map says the job has full bisection bandwidth.

Failure mode: A single switch or transceiver can remain technically “up” while producing high CRC error rates, packet drops, or retransmissions. Binary health checks report green; collective communication performance reports red.

Consequence: If the scheduler relies on a static topology map, it continues to schedule communication-intensive jobs onto a degraded rack, assuming full bandwidth that no longer exists.

Systems insight: Binary health checks (up/down) are insufficient. Schedulers need performance-aware topology monitoring that incorporates switch counters, retransmission rates, and collective bandwidth tests. Nodes connected to a “limping” switch should be dynamically marked ineligible for communication-intensive jobs until the hardware is repaired.

The general scheduling idea is quarantine: when runtime evidence says a node, rack, or link is degraded, the scheduler should stop placing sensitive work there even if the nominal resource count still looks available. Kubernetes implements this pattern through **taints and tolerations**¹², while Slurm clusters commonly use drain states, node features, or partition rules. The complementary problem is how jobs adapt when available resources change dynamically. Rather than treating resource allocation as fixed for a job’s lifetime, elastic training allows jobs to grow, shrink, and recover without full restarts.

8.4 Elastic Scheduling

When cluster demand fluctuates, rigid allocation creates two categories of waste. During off-peak hours, a job running on 256 GPUs cannot absorb idle resources to speed up training. During peak demand, the same job cannot release excess resources to accommodate higher-priority work without being fully preempted. The scheduler’s only options are “let it keep all its resources” or “kill it entirely,” with nothing in between.

Elastic scheduling eliminates this binary choice. The recovery mechanics of elastic training developed in section 7.8 show how a distributed job can adjust its worker count, recalibrate batch size and learning rate, and reconstruct its communication group after a failure. From the scheduler’s perspective, the same capability solves a resource-allocation problem under fluctuating demand. A training job might start with 128 GPUs (the minimum needed for reasonable throughput), scale up to 256 when resources become available, and scale back to 192 when higher-priority work arrives, all while maintaining continuous training progress. This flexibility transforms the scheduler’s action space from a *binary* {continue, preempt} to a *continuous* spectrum of resource allocation levels.

8.4.1 The scheduler-framework contract

Elastic scheduling requires a well-defined contract between the scheduler and the training framework. The scheduler guarantees that resource changes are communicated through defined signals, with sufficient advance notice for graceful adaptation. The framework guarantees that it can handle resource changes without corrupting model state, using the batch size adjustment, learning rate recalibration, and communication group reconstruction mechanisms developed in section 7.8.1.

From the scheduler’s side, the contract has three parameters:

- **Elastic range:** $[N_{\min}, N_{\max}]$ specifies the worker counts between which the job can operate.

¹² | **Taints and Tolerations:** Kubernetes primitives for restricting pod placement. A taint on a node repels all pods that do not explicitly tolerate it. For ML fleets, this is the primary mechanism for isolating specialized hardware: by tainting A100 nodes, the orchestrator prevents general-purpose web services from “stealing” expensive GPU capacity, ensuring those nodes are reserved for training jobs that tolerate the taint.

- **Transition cost:** The rendezvous cycle, typically 10 to 60 seconds, determines how frequently the scheduler can resize without the overhead negating the throughput gain.
- **Scaling efficiency curve:** The throughput gained from each added worker determines whether assigning idle GPUs to this job is more productive than holding them for a pending gang-scheduled job.

The contract gives the scheduler enough information to resize a job without treating elasticity as free capacity.

The scheduler must also account for the constraint that elastic scaling changes the effective batch size ($B_{\text{effective}} = B_{\text{per-worker}} \times N$). The two strategies for handling this (constant global batch size vs. adaptive learning rate) impose different limits on how aggressively the scheduler can resize: constant global batch size preserves convergence but may violate per-GPU memory limits at low worker counts, while adaptive learning rate simplifies worker management but introduces convergence risk during rapid scaling.

The scheduler interface to frameworks like TorchElastic exposes these parameters directly, as listing 8.2 illustrates.

Listing 8.2: TorchElastic Launch Configuration: The `--nnodes=4:16` range tells the scheduler that this job can operate with 32 to 128 GPUs. The scheduler places the job at any point within this range based on current cluster load and resizes it as demand changes.

```
# Launch elastic training with min 32 to max 128 workers
torchrun \
  --nnodes=4:16 \
  --nproc_per_node=8 \
  --rdzv_backend=c10d \
  --rdzv_endpoint=head-node:29500 \
  --max_restarts=3 \
  train.py
```

The `--nnodes=4:16` specification declares that the job can operate with anywhere from 4 to 16 nodes (32 to 128 GPUs with 8 GPUs per node). This range is the scheduler’s action space: it can place the job at any point within this range based on current cluster load, and resize it as demand changes.

Systems Perspective 8.4: Elastic vs. rigid scheduling

Consider a congested cluster where a 128-GPU job waits 8 hours for a full gang allocation.

Rigid scheduling: Wait 8 hours, then train for 24 hours at full throughput. Total wall-clock: 32 hours.

Elastic scheduling (min 32, max 128):

- Start immediately with 32 GPUs (throughput = 25 percent of full)
- After 2 hours, scale to 64 (throughput = 50 percent)
- After 4 hours, scale to 128 (throughput = 100 percent)
- Training progresses during the entire wait period

Approximate work completed during the 8-hour “queue wait”:

- Hours 0 to 2: 25% throughput $\times$ 2 hours = 0.5 hours equivalent
- Hours 2 to 4: 50% throughput $\times$ 2 hours = 1.0 hours equivalent
- Hours 4 to 8: 100% throughput $\times$ 4 hours = 4.0 hours equivalent
- Total: 5.5 hours of equivalent full-scale work

The elastic job completes in approximately 26.5 hours (8 hours of scaled-up training plus 18.5 hours at full scale), saving 5.5 hours compared to rigid scheduling. This 17 percent improvement

comes entirely from using resources productively during what would otherwise be idle queue time.

The scheduler cannot treat every job as elastic. The most significant constraint is incompatibility with model parallelism. Elastic scaling is fundamentally a data-parallel operation: the scheduler adds or removes replicas of the model, changing the global batch size but keeping the model architecture constant. For a 175B-parameter job that relies on 8-way tensor parallelism within each node, elasticity operates strictly at the *node* level. The job can scale between 128 nodes (1,024 GPUs) and 32 nodes (256 GPUs) in whole-node steps, changing the data-parallel degree. It *cannot* elastically remove a single GPU from a tensor-parallel group; doing so would require re-sharding the model weights, equivalent to a full checkpoint-and-restart cycle. Pipeline parallelism permits limited elasticity in principle, but adding or removing stages forces a recalculation of the pipeline schedule that often negates the benefit.

The transition cost also constrains the scheduler’s resize frequency. Each scaling event incurs 10 to 60 seconds of reduced throughput while the framework reconstructs its communication group. The scheduler must amortize this cost over the subsequent run duration, so small resize increments are only worthwhile if the job will run at the new scale for significantly longer than the transition window; section 8.4.3 works through the thrashing regime this rule rules out.

8.4.2 Scheduler integration

Elastic training’s value depends critically on scheduler integration. Without scheduler awareness, elastic training is merely a *fault tolerance mechanism* (replacing failed workers). With scheduler integration, it becomes a *scheduling optimization* that fundamentally changes the economics of cluster utilization. The scheduler must understand that elastic jobs can operate within a range of resource allocations, specified as $[N_{\min}, N_{\max}]$ workers, enabling three key scheduling optimizations.

The most immediately valuable benefit is faster job start. An elastic job requesting 32 to 128 GPUs can start as soon as 32 GPUs are available, rather than waiting in the gang scheduling queue for 128 contiguous GPUs. In congested clusters where large-job queue times can be hours to days, starting immediately at reduced scale often completes the job sooner than waiting for full-scale allocation, a trade-off the elastic scaling decision below works through quantitatively. The scheduler can compute it dynamically, choosing the start time and initial scale that minimizes expected total time (wait time plus execution time).

Opportunistic scaling enables the scheduler to use elastic jobs as flexible capacity absorbers. When resources become available (other jobs complete, spot instances are provisioned, preempted jobs release resources), the scheduler can expand running elastic jobs to improve their throughput. When resources are needed (higher-priority job arrives, reserved capacity is reclaimed), the scheduler can shrink elastic jobs without preempting them entirely. This bidirectional flexibility converts elastic jobs into a buffer that absorbs utilization variance, smoothing the gap between allocated and productive capacity.

Graceful preemption transforms the scheduler’s response to resource pressure. Instead of killing a training job outright to reclaim resources, the scheduler can request a scale-down, reducing the job’s resource allocation to release capacity for higher-priority work. The job continues with fewer workers, maintaining progress at reduced throughput rather than losing all progress since the last checkpoint and incurring restart overhead. This provides the scheduler with a continuous spectrum between “full resources” and “fully preempted,” rather than the binary choice of traditional scheduling. Graceful preemption composes well with checkpoint-based preemption: if the scheduler needs to reclaim all resources, it first scales the job down to its minimum size, then initiates a checkpoint-and-preempt sequence, minimizing the amount of lost work.

The trade-off for all of these benefits is complexity. Elastic training requires framework support (not all training frameworks support it), introduces potential convergence concerns from batch size changes (requiring validation that elastic scaling does not degrade model quality), and complicates performance modeling (a job’s throughput is no longer constant, making capacity planning harder). Not all workloads benefit equally from elastic scaling: jobs with high communication-to-computation ratios see diminishing returns from additional workers (because communication overhead grows

with worker count) and thus benefit less from scale-up, while compute-bound jobs with low communication overhead scale more linearly and benefit more from opportunistic scaling. The scheduler must model these scaling characteristics per-job to make optimal elastic scaling decisions.

8.4.3 Elastic scaling policies

Adding resources to a running job does not always accelerate time-to-convergence. The naive assumption that throughput scales linearly with worker count collapses under the weight of communication overhead, requiring the scheduler to enforce elastic scaling policies based on empirical efficiency curves rather than resource availability alone. A job's scaling efficiency $\eta_{\text{scaling}}(k)$, defined as the ratio of observed throughput at k workers to the ideal linear speedup, typically exhibits three distinct phases: a linear phase where compute dominates communication, a sublinear phase where gradient synchronization latency begins to mask compute, and a saturation phase where the AllReduce ring becomes the bottleneck. A scheduler that blindly assigns available GPUs to a job in the saturation phase wastes cluster capacity that could have cleared the queue; conversely, running a job below its **minimum viable scale** forces it to hold onto memory and network leases for disproportionately low progress.

The decision to scale is therefore a function of marginal utility, not vacancy alone. For our 175B parameter model, the efficiency curve is derived from profiling: it scales linearly from 64 to 512 GPUs, becomes sublinear between 512 and 1,024, and hits diminishing returns beyond 1,024. Consequently, the scheduler enforces an elastic range of [256, 1024]. If the cluster has free resources but the job is already at 1,024 GPUs, the scheduler withholds the extra nodes, predicting that the 5 percent marginal throughput gain does not justify the re-sharding overhead or the opportunity cost of starving a pending job. Similarly, if only 128 GPUs are available, the scheduler may choose to queue the job rather than run it, as the training intensity per GPU would be too low to hide the communication latency.

This logic extends to the temporal dimension, where the scheduler must weigh the immediate progress of a smaller allocation against the deferred gratification of waiting for a larger one. If a 512-GPU job can start immediately with 128 GPUs, or wait two hours for the full request, the optimal choice depends on the integration of throughput over time. The preemption overhead (the cost of stopping, checkpointing, and restarting to resize) must be amortized over the subsequent run duration. A policy of "opportunistic scaling" that resizes a job every time a single node becomes free often yields net negative progress due to the constant thrashing of the distributed process group.

Elastic scaling's benefit flattens into saturation.

Napkin Math 8.4: The elastic scaling decision

Consider a large language model training job with a target batch size that requires 512 A100s for peak efficiency. Three scheduling strategies are evaluated over a window of 24 hours.

Given: Throughput at 128 GPUs is 1 epoch/hour (baseline). Throughput at 256 GPUs is 1.8 epochs/hour (90 percent scaling efficiency). Throughput at 512 GPUs is 3.2 epochs/hour (80 percent scaling efficiency). Re-scaling cost is 10 minutes (0.17 hours) to checkpoint, re-shard, and restart.

Strategy 1 – immediate start (no scaling): The job starts immediately with 128 GPUs and runs for the full 24 hours. Total work: $24 \times 1.0 = 24$ epochs.

Strategy 2 – wait for capacity (gang scheduling): The job waits in the queue for 4 hours until 512 GPUs become available, then runs for 20 hours. Total work: $20 \times 3.2 = 64$ epochs.

Strategy 3 – elastic scaling (step-up): The job starts immediately with 128 GPUs. After 4 hours, 256 GPUs become available. The job pauses, scales up, and resumes. Phase 1: $4 \times 1.0 = 4$ epochs. Phase 2: $(24 - 4 - 0.17) \times 1.8 \approx 35.7$ epochs. Total work: $4 + 35.7 = 39.7$ epochs.

The elastic strategy completes nearly 1.7× the epoch-equivalent work of the immediate small-scale run, but still trails gang scheduling by about 38 percent. That gap shrinks when queue waits grow or peak capacity stays scarce; re-scaling overhead is only 10 minutes, and if that tax exceeded 2 hours (due to slow checkpoint transfer or compilation), Strategy 3 would fall further behind Strategy 2.

The placement and elasticity mechanisms discussed so far address individual job efficiency, optimizing how each job uses its allocated resources. Fleet economics shifts the objective to the collective level: an allocation policy must maximize useful work across all jobs when every placement, preemption, and reservation creates opportunity cost.

8.5 Cost Optimization

The utilization-to-dollars relationship established in section 8.1 now becomes the orchestrator's objective function. A 10,000-GPU cluster represents a capital investment of roughly \$300 million and consumes millions more in monthly power and cooling. If poor scheduling leaves 20 percent of those GPUs idling in fragmentation gaps or waiting for data, roughly \$60 million in deployed capital sits unused, and at cloud-equivalent rates the same idleness burns approximately \$35 million per year in operating cost. Cost optimization forces the fleet orchestrator to treat the cluster as a massive financial asset whose return on investment (ROI) must be maximized.

Figure 8.5 makes this waste concrete by plotting annual wasted cost as a function of cluster size and utilization level. At 10,000 GPUs with 50 percent utilization, the annual waste exceeds \$87 million under the chapter's \$2/GPU-hour accounting scenario. Published measurements from production clusters show that underutilization is a real operational problem: Microsoft's Philly cluster study (Jeon et al. 2019) measured mean GPU utilization of approximately 52 percent, and Li et al. (2023) found that 50 percent of jobs on NERSC's Perlmutter supercomputer used less than 25 percent of allocated GPU memory. The 30 to 70 percent shaded band in the figure is an illustrative operating range for the cost model, not a universal empirical claim about all production clusters. Moving from 50 percent to 70 percent utilization on a 10,000-GPU cluster saves over \$35 million annually in this scenario without purchasing a single additional GPU.

Figure 8.5: The Cost of Idle GPUs: Annual wasted cost as a function of cluster size for different GPU utilization levels, assuming \$2/GPU-hour (cloud equivalent). The shaded region between 30 percent and 70 percent is an illustrative operating range for the scenario analysis. At 10,000 GPUs with 50 percent utilization, the model yields \$87.6M in annual wasted capacity. The Microsoft Philly data point marks the published mean GPU utilization of 52 percent. Data sources: (Jeon et al. 2019; Li et al. 2023).

The idle-capacity figure establishes the economic target; the remaining cost controls explain how the scheduler moves toward it. Interruptible capacity lowers the price of tolerant work, reservation and quota policy decide which jobs deserve scarce guaranteed capacity, and accountability mechanisms make idle GPUs visible to the teams that create demand.

8.5.1 Spot instances and preemptible VMs

Cloud providers offer **spot instances**¹³ (AWS) or **preemptible VMs** (GCP) at 60 to 90 percent discounts compared to on-demand pricing, with the caveat that instances can be reclaimed with as little as 30 seconds to 2 minutes notice when the provider needs the capacity for on-demand customers. At \$0.70/GPU-hour instead of \$2/GPU-hour, spot instances transform the economics of large-scale training, potentially reducing the cost of a multi-week pretraining run from hundreds of thousands of dollars to under one hundred thousand.

The viability of spot instances for ML training depends on two factors that determine whether the discount translates into actual savings: the cost of each interruption (checkpoint overhead plus restart time plus lost work since the last checkpoint) and the frequency of interruption (which varies by instance type, region, time of day, and overall cloud demand). Equation 8.3 gives the **effective cost** of spot training:

$$C_{\text{effective}} = C_{\text{spot}} \times \frac{T_{\text{total}}}{T_{\text{productive}}} \quad (8.3)$$

where T_{total} includes productive training time plus checkpoint overhead plus restart overhead after interruptions, and $T_{\text{productive}}$ is the time spent advancing training. If interruptions are rare (less than once per day) and checkpointing is efficient (less than 5 percent overhead), effective cost remains close to the spot price and the savings are nearly the full discount. If interruptions are frequent (every few hours) and restarts are expensive (large model, slow checkpoint loading, cold GPU cache), effective cost can approach or even exceed on-demand pricing, turning the apparent discount into a hidden premium.

The relationship between spot savings and fault tolerance infrastructure is circular in an important way. The fault tolerance mechanisms from Chapter 7 (frequent asynchronous checkpointing, fast checkpoint loading, elastic recovery) directly enable spot instance usage by minimizing the cost of each interruption. Elastic training allows jobs to continue with reduced worker count when some spot instances are reclaimed, avoiding full restart entirely. Organizations that invested in fault tolerance for reliability reasons discover that the same infrastructure unlocks significant cost savings through spot instance utilization, providing a return on their fault tolerance investment that goes far beyond avoiding lost work from hardware failures.

The strategic insight is that fault tolerance infrastructure has a double return: it both protects against involuntary losses (hardware failure) and enables voluntary cost savings (spot instances). This double return often justifies fault tolerance investments that would be hard to justify on reliability grounds alone, because the cost savings from spot utilization are concrete and measurable while the cost avoidance from hardware failure protection is statistical and harder to quantify.

8.5.2 Spot instance strategies for ML training

To maximize spot instance utility while minimizing disruption, sophisticated schedulers employ diversification and predictive strategies that go beyond simple “retry on failure” logic. Availability zone diversification reduces the probability of simultaneous fleet-wide reclamation. Cloud providers typically manage spot pools independently per availability zone (AZ). If a training job requires 1,024 GPUs, allocating them as a single block in one zone exposes the job to a complete stop if that specific zone’s spot pool is reclaimed. Spreading the job across multiple AZs ensures that a reclamation event in one zone affects only a fraction of the fleet. The scheduler still must model correlation carefully: independent per-instance interruptions make large simultaneous losses unlikely, but pool-level or AZ-level reclamations can remove hundreds of GPUs at once and must be treated as elastic-shrink or failover events rather than ordinary isolated failures.

Instance type diversification exploits independent spot markets across GPU SKUs. A job that strictly requests one instance type competes in a single, crowded market. A job that accepts multiple equivalent instance types dramatically increases its scheduling probability. The scheduler should maintain a priority-ordered list of acceptable instance types, falling back to larger-memory instances when the primary type is unavailable. While this mix requires careful peer-to-peer bandwidth management, it effectively uses the “upgrade” to maintain progress at a blended cost still far below on-demand rates.

¹³ | **Spot Instances:** Named after commodity trading’s “spot price” (the current market price for immediate delivery), spot instances sell spare cloud capacity at 60 to 90 percent discounts with the provider retaining reclamation rights. The critical asymmetry for ML training is the interruption notice window: AWS provides 2 minutes, GCP provides 30 seconds. A 175B-parameter model requires 3 to 5 minutes to checkpoint, so GCP’s 30-second notice forces either continuous checkpointing overhead or acceptance of lost work on every interruption.

Spot interruption prediction uses the data that cloud providers expose about reclamation likelihood, such as the AWS Spot Placement Score or GCP preemptibility data. Advanced schedulers ingest this feed to estimate the expected interruptions per day for a given instance type and region. If the expected interruption rate rises above a threshold where the overhead of restarts exceeds the cost savings (typically more than 4 interruptions per day for large models), the scheduler should automatically migrate the job to on-demand capacity or a different region, preventing thrashing where a job spends more time recovering than training.

Checkpoint frequency optimization for spot instances differs from the standard reliability logic. The Young-Daly formula developed in section 7.1.2 optimizes for unpredicted hardware failures. Spot interruptions, however, come with a warning: 2 minutes on AWS, 30 seconds on GCP. The optimal strategy is a **two-tier checkpointing** approach: a periodic checkpoint at the Young-Daly interval to protect against hard crashes, combined with an immediate checkpoint triggered by the termination notice. This “panic checkpoint” captures the exact state of training seconds before the node vanishes, reducing lost work to near zero and transforming preemption from a rollback event into a pause-and-resume event.

The same need for contingency planning becomes acute when spot interruptions are correlated rather than isolated.

Systems Perspective 8.5: Correlated spot risk

Context: Spot capacity is cheap because it is reclaimable. That risk is not independent across instances: cloud regions, instance types, product launches, and deadline cycles can create correlated demand.

Failure mode: A fleet that concentrates all interruptible training in one region and one instance type can lose a large fraction of workers at once, even if each individual worker appears restartable.

Consequence: Checkpointing handles isolated interruptions; it does not solve fleet-wide preemption when every retry targets the same exhausted pool.

Systems insight: A robust scheduler must diversify across regions and instance types, monitor interruption risk, and maintain a “break glass” path to on-demand capacity when the spot market becomes toxic.

8.5.3 Capacity reservation strategies

Organizations that rely on cloud infrastructure (or that think about on-premise infrastructure in economic terms) balance three tiers of compute capacity, each offering a different trade-off between cost, availability, and commitment. Table 8.4 compares those tiers across cost, availability, interruption risk, and workload fit.

Table 8.4: Cloud Capacity Reservation Tiers: Capacity tiers trade cost and commitment against availability guarantees and interruption risk, giving the scheduler a price ladder for routing workloads by urgency and restart tolerance.

Capacity tier	Cost and commitment	Availability and interruption risk	Best-fit workloads
Reserved capacity	One- to three-year commitments, with 30–60% discounts versus on-demand.	Guaranteed availability for the committed baseline.	Predictable continuous workloads: 24/7 inference, scheduled training, CI and regression testing, SLA-bound jobs.
On-demand capacity	Full price with no long-term commitment.	Immediate provisioning when queuing or interruption is unacceptable.	Urgent retraining, interactive debugging, and short-lived jobs that do not justify spot management.
Spot capacity	Discounted interruptible capacity.	Availability varies with cloud demand, and workers can be reclaimed.	Restart-tolerant jobs: hyperparameter sweeps, ablations, checkpointed pretraining, and exploratory research.

The optimal mix depends on workload characteristics and organizational priorities. An organization with 60 percent steady-state utilization and 40 percent burst demand might reserve capacity for 60 percent of peak need, use on-demand for latency-sensitive bursts that require immediate provisioning, and use spot for the remainder. The scheduling system must understand these capacity tiers and route workloads accordingly: inference workloads to reserved capacity for guaranteed availability, large training jobs to a mix of reserved (for the base allocation) and spot (for additional workers via elastic scaling), and exploratory work to spot exclusively where the cost savings are maximized and the interruption tolerance is highest.

Systems Perspective 8.6: Spot vs. on-demand training

Consider training a 70B parameter model requiring 512 GPUs for 14 days.

On-demand: $512 \text{ GPUs} \times 336 \text{ hours} \times \$2/\text{GPU-hour} = \$344,064$

Spot (65 percent discount, 5 percent checkpoint overhead, 14 interruptions/day with 30 minutes restart):

- Base cost: $512 \text{ GPUs} \times 336 \text{ hours} \times \$0.70/\text{GPU-hour} = \$120,422$
- Checkpoint overhead: $5\% \times 336 \text{ hours} = 16.8 \text{ hours}$
- Restart overhead: $196 \text{ interruptions} \times 0.5 \text{ hours} = 98 \text{ hours}$
- Total time: $336 \text{ hours} + 16.8 \text{ hours} + 98 \text{ hours} = 450.8 \text{ hours}$
- Total cost: $512 \text{ GPUs} \times 450.8 \text{ hours} \times \$0.70/\text{GPU-hour} = \$161,567$

Savings: \$182,497 (53.0 percent), at the cost of approximately 34.2 percent longer wall-clock time.

The economics are compelling when fault tolerance infrastructure is already in place. Without checkpointing, a single interruption forces restart from scratch, potentially wasting days of compute and negating all savings.

8.5.4 Scheduling for cost efficiency

Cost-aware scheduling extends the scheduler's optimization objective beyond utilization and fairness to include financial efficiency. Traditional schedulers minimize a single objective (for example, average job completion time or maximum wait time), but cost-aware schedulers must navigate multi-objective trade-offs where time, money, and reliability are all decision variables. The scheduler must routinely choose among three decision classes:

- **Wait vs. run now:** Run a job on reserved A100s now, or wait 2 hours for spot H100s that would complete the job $3\times$ faster at half the cost.
- **Preempt vs. pay more:** Preempt a low-priority hyperparameter sweep to make room for a high-priority training run on reserved capacity, or place the training run on more expensive on-demand instances.
- **Fallback vs. elastic shrink:** When spot capacity is reclaimed, migrate the job to on-demand to maintain throughput at higher cost, or scale down elastically to maintain low cost at reduced throughput.

Each decision prices time, money, and reliability differently, so cost-aware scheduling is policy design rather than simple bin packing.

These decisions require the scheduler to model both the time-value of computation (the organizational cost of a 2-hour delay in researcher productivity, product launch schedules, or competitive position) and the financial cost of different resource allocations. The time-value varies enormously by workload type: delaying a production model retrain by 2 hours might violate a service level agreement (SLA) and cost thousands in penalty fees, while delaying an exploratory experiment by 2 hours costs nothing but researcher patience.

Production systems typically define **cost policies** per workload class that encode these trade-offs as configuration rather than requiring per-decision human judgment. Inference workloads are pinned to reserved capacity for guaranteed availability and predictable latency, since the cost of

an inference outage (lost revenue, degraded user experience) far exceeds the premium of reserved pricing. Large training runs use a mix of reserved capacity (for the minimum viable allocation) and spot capacity (for elastic expansion), with automatic fallback to on-demand if spot is reclaimed and the job is within a configurable deadline. Exploratory workloads are restricted to spot to minimize cost, with the understanding that they may be interrupted and must tolerate variable completion times.

Technical optimization must be paired with financial accountability through **ML FinOps**. In many organizations, GPU costs are pooled into a generic “infrastructure” bucket, creating a tragedy of the commons where teams lack visibility into their resource consumption and have no incentive to optimize. Effective governance requires granular tagging to implement **showback** (reporting costs to teams) or **chargeback** (billing teams’ budgets). Metrics must evolve from “GPU hours” to business-aligned units: “Cost per Model Version,” “Cost per Experiment,” and “Cost per 1M Predictions.” This shift transforms cost from an opaque infrastructure expense into a measurable input to product decisions, enabling teams to make informed trade-offs between model quality, training speed, and infrastructure cost. Section 12.7.8 develops the platform machinery that makes these costs visible and attributable; the concern here is narrower, namely how that price signal reshapes the scheduling and quota behavior of the teams competing for the fleet.

8.5.5 The total cost of ownership

Optimizing for spot instance availability or scheduling density addresses only the visible tip of the infrastructure iceberg. The full cost of a machine learning fleet extends far beyond GPU-hours: in high-performance clusters the compute silicon typically accounts for only 40 to 60 percent of total system cost. The remainder is consumed by the supporting infrastructure required to keep that silicon fed and cool: high-bandwidth networking (InfiniBand switches, optics, and cabling), parallel file systems for checkpointing, and specialized power and cooling delivery. A single rack of H100 nodes can draw upwards of 40 kW, ten times the density of a standard web server rack, forcing facilities to deploy liquid cooling or rear-door heat exchangers that reshape the facility’s capital requirements. A scheduler that optimizes GPU-hours alone is therefore blind to most of what the fleet actually costs.

Whether that fixed capacity is worth owning is a question of utilization. Section 12.3 develops the full build-versus-buy analysis, amortizing three years of capital and operational expenditure against cloud rental to find the break-even utilization that decides between them. The consequence for the scheduler is direct: owned hardware only amortizes when it stays busy, so every point of utilization the scheduler reclaims moves the fleet toward the break-even point that justifies its capital, while a cluster left idle by poor packing or fragmentation makes owned infrastructure more expensive than the cloud it was meant to undercut.

Checkpoint 8.2: Cost-aware scheduling trade-offs

Before moving to ML-specific schedulers, review how the cost-optimization mechanisms interact:

- ☐ **Spot break-even:** Determine the checkpoint frequency under which spot training becomes more expensive than on-demand for a 512-GPU, 14-day training job with a 65 percent spot discount, 1 interruption per day, and 30-minute restart overhead.
- ☐ **Double return:** Explain why fault tolerance infrastructure has a “double return” for reliability and cost savings, and identify the minimum fault tolerance investment needed to make spot instances viable.
- ☐ **Reservation sizing:** Determine whether increasing reserved capacity from 40 percent to 60 percent would save or waste money for an organization.

Spot pricing and reservation strategy squeeze the cost of running a job, but they leave a second source of efficiency untouched: the learning dynamics inside the training loop. The cost models so far optimize time-to-completion, yet the metric that matters to a research organization is time-to-accuracy, the wall-clock time until a run reaches a target validation metric. A scheduler blind to

convergence cannot tell whether a run is in its steep early phase or its diminishing-returns tail, so it cannot redirect resources to where they buy the most progress. Closing that gap is the job of the ML-aware schedulers examined next.

8.6 Custom ML Schedulers

General-purpose schedulers treat training jobs as opaque boxes, so they cannot tell whether a model is in the steep early phase of learning or the final diminishing-returns phase. Custom ML schedulers trade implementation complexity for that visibility: they peer inside the training loop to optimize time-to-accuracy rather than only time-to-completion. The selection question is which internal signal addresses the fleet’s binding bottleneck, and the four systems differ less by scheduler sophistication than by the signal they ask the platform to trust: consumed service, iteration boundaries, completion value, or measured goodput.

8.6.1 Tiresias: Duration-agnostic scheduling

Tiresias (Gu et al. 2019) addresses the fundamental problem identified in section 8.1.5: ML job durations are unpredictable, and scheduling policies that rely on exact duration estimates can make poor decisions when those estimates are unavailable or unreliable. Rather than fighting this information asymmetry, Tiresias eliminates the requirement for duration estimates entirely. It uses a **two-dimensional attained service**¹⁴ scheduler that makes priority decisions based on what a job has *already consumed*, not what it *claims it will consume*. Jobs accumulate “service” based on GPU-time consumed, with priority decreasing as service increases. The two dimensions are time (how long the job has been running) and resources (how many GPUs the job uses), capturing both elapsed duration and resource intensity.

A discretized version groups jobs into service bins (for example, less than 1 GPU-hour, 1 to 10 GPU-hours, 10 to 100 GPU-hours, greater than 100 GPU-hours), promoting jobs in lower bins to the front of the queue. This bin structure means that all short jobs (the majority of submitted work) receive high priority and run quickly, while the few long jobs that consume most cluster resources gradually lose priority and are deprioritized relative to new arrivals. The key insight is that this behavior approximates the theoretically optimal Shortest Remaining Processing Time (SRPT) policy without requiring the future knowledge that SRPT demands: jobs that have consumed little service are statistically likely to be short jobs, so prioritizing them is a good heuristic for minimizing average completion time.

Experiments on production cluster traces from Microsoft and Alibaba show 40 to 60 percent reduction in average job completion time compared to FIFO scheduling, with the largest improvements for short jobs that previously waited behind long-running training runs. The improvement is not free: long-running training jobs experience increased completion times because they are systematically deprioritized. However, the aggregate benefit is positive because there are many more short jobs than long ones, and the short-job improvement exceeds the long-job penalty in total.

8.6.2 Gandiva: Iteration-aware scheduling

Gandiva (Xiao et al. 2018) exploits a characteristic that general-purpose schedulers completely ignore: the iterative nature of deep learning training. Each training iteration follows a predictable, repeating pattern: a GPU-intensive forward pass, a GPU-intensive backward pass, a communication-intensive gradient synchronization, and then a CPU-intensive data loading and preprocessing phase before the next iteration. During the data loading phase, the GPU sits partially idle, computing at less than full utilization while waiting for the next batch of data to be prepared.

Gandiva uses **iteration-boundary time slicing**, enabling higher utilization through controlled oversubscription. A cluster with 100 GPUs might support 120 concurrent jobs if each spends 20 percent of its iteration time waiting for data, because the scheduler can interleave data loading from one job with GPU computation from another on the same device. The critical insight that makes this practical is that iteration boundaries provide natural preemption points where GPU state is minimal. Between iterations, only model weights and optimizer state reside on the GPU; the intermediate activations from forward and backward passes have been freed. This minimal state makes context switching cheap (seconds rather than minutes), unlike preempting mid-iteration when the full activation memory is in use.

¹⁴ | **Attained Service Scheduling:** A discipline from OS queuing theory where priority decreases with cumulative resource consumption, approximating the theoretically optimal Shortest Remaining Processing Time (SRPT) policy without requiring the future knowledge that SRPT demands. In ML clusters, this approximation is particularly effective because job durations are heavy-tailed: the majority of submitted jobs are short experiments, so deprioritizing high-service jobs correctly identifies the long-running outliers without requiring users to provide runtime estimates they cannot accurately compute.

Gandiva also implements **grow-shrink elasticity** at a finer granularity than the framework-level elastic training discussed in section 8.4. Gandiva automatically adjusts data parallelism degree based on real-time resource availability, using profiled iteration times to predict the throughput impact of adding or removing workers. When a high-priority job arrives, Gandiva shrinks lower-priority jobs by reducing their worker count rather than killing them entirely, preserving their progress while freeing resources. When resources become available again, it grows jobs back to their preferred parallelism degree. This fine-grained elasticity, informed by actual iteration-level profiling data, enables scheduling decisions that general-purpose systems cannot make because they lack visibility into job internals.

8.6.3 Themis: Finish-time fairness

Traditional fair-share scheduling treats all GPU-seconds equally: a job consuming 100 GPU-hours is treated the same whether those hours represent the first 10 percent of a long training run or the last 10 percent of a nearly complete one. From a resource accounting perspective, 100 GPU-hours is 100 GPU-hours regardless of context. **Themis** (Mahajan et al. 2020) argues this resource-centric view is fundamentally unfair because it ignores the sunk cost of work already performed.

Themis defines a **finish-time fairness** metric that allocates resources to minimize the maximum slowdown any job experiences relative to exclusive access (the hypothetical scenario where the job has the entire cluster to itself). Under this metric, a job that is 90 percent complete and needs only 10 more GPU-hours to finish receives higher priority than a job that is 10 percent complete and needs 90 more GPU-hours. The reasoning is economic: delaying the nearly-complete job by an hour wastes the 900 GPU-hours already invested (because those hours only produce value when the job completes), while delaying the early-stage job by an hour has a proportionally smaller impact on the total investment's return.

This approach benefits shorter jobs and nearly-complete jobs without excessive penalty to longer ones, and it aligns scheduling decisions with the economic value of completing work rather than the simple accounting of resource consumption. Themis implements this metric through an auction mechanism where jobs bid for resources based on their current marginal value (how much their completion time improves per GPU-hour allocated), creating a market-like dynamic that naturally directs resources to their highest-value use.

8.6.4 Pollux: Adaptive resource allocation

Pollux (Qiao et al. 2021) takes the most aggressive approach of the four research schedulers by jointly optimizing resource allocation and training hyperparameters. Where Tiresias, Gandiva, and Themis make scheduling decisions *about* jobs (when to run, how to share), Pollux makes decisions *within* jobs (how many GPUs and what batch size). The key observation is that the optimal number of GPUs for a training job depends on the current batch size, learning rate, and gradient noise level, all of which change during training as the model moves through different phases of convergence.

Pollux dynamically adjusts each job's GPU allocation and batch size to maximize **cluster-wide goodput**, defined as the rate of useful training progress across all jobs simultaneously. The goodput metric folds both sides of the trade-off into one number: statistical efficiency (how much each gradient step advances convergence, which depends on batch size) and system throughput (how many gradient steps per second, which depends on GPU count and communication overhead). A job experiencing diminishing returns from its current GPU count (because communication overhead is growing superlinearly) may have GPUs reassigned to a job that would benefit more (because it is in a phase of training where larger batches improve statistical efficiency).

This co-optimization of scheduling and hyperparameters achieves 37 to 50 percent improvement in average job completion time compared to scheduling with fixed resource allocations. The improvement comes from two sources: better resource allocation (GPUs go to jobs where they produce the most progress) and better batch size tuning (each job runs at a batch size that balances statistical and computational efficiency for its current training phase). The combined effect is greater than either optimization alone.

8.6.5 Scheduler comparison framework

Custom ML schedulers represent a progressive trade-off between implementation complexity and scheduling precision, so the comparison in table 8.5 matters as a deployment filter rather than a

ranking. General-purpose schedulers see declared resources and coarse runtime metadata; these research systems add ML-specific signals such as iteration structure, elasticity, convergence phase, and measured goodput.

Table 8.5: Custom ML Scheduler Comparison: A taxonomy of research schedulers based on the specific workload characteristic they exploit. Tiresias and Themis optimize for queuing metrics (JCT, fairness) using external signals, while Gandiva and Pollux optimize for efficiency using internal profiling data.

Sched- uler	Key Insight	Scheduling Signal	Optimization Target	Overhead	Production Readiness
Tiresias	Attained service predicts remaining time	GPU-hours consumed	Minimize avg JCT	Low (no profiling)	Medium
Gandiva	Iteration boundaries are preemption points	Iteration timing	Maximize utilization	Medium (profiling)	Medium
Themis	Sunk cost matters for fairness	Completion percentage	Minimize max slowdown	Low (job metadata)	Low (auction complexity)
Pollux	Batch size and allocation are coupled	Goodput (stat + sys)	Maximize cluster goodput	High (continuous profiling)	Low (framework integration)

As table 8.5 summarizes, this design space reveals a fundamental tension: scheduler complexity vs. scheduling quality. Tiresias operates with the least information, essentially guessing that “young” jobs will finish soon, yet achieves significant gains simply by preventing large jobs from blocking small ones. It is robust because it requires no cooperation from the user or the training framework. At the other extreme, Pollux requires deep bidirectional integration: the scheduler must know the job’s scaling curve and gradient noise scale, and the job must accept commands to change its batch size and learning rate on the fly. When this integration works, it produces the highest cluster-wide throughput; when the assumptions are violated (for example, a model with unstable convergence dynamics that cannot tolerate batch size changes), the optimization collapses.

Failure modes generally track this complexity gradient. Tiresias fails gracefully: if its assumption (that past usage predicts future usage) is wrong, it simply degrades to a standard fair-share policy. Gandiva’s failure mode is performance jitter: if the profiling phase misestimates iteration variance, it may pack incompatible jobs onto the same node, causing interference. Pollux has the most brittle failure mode because it modifies the training semantics themselves; an incorrect goodput model could theoretically harm model convergence, a risk that most production teams are unwilling to take for a 15 percent efficiency gain.

For our 175B parameter model, these trade-offs dictate a hybrid lifecycle. Pollux offers the highest potential improvement during the early, unstable phase of training where batch sizes are small and the job is elastic; it could dynamically resize the job to fit available holes in the cluster. However, effectively using Pollux requires modifying the training loop to be elasticity-aware. Tiresias offers the simplest deployment path: it would treat the 175B model as a “heavy” job and deprioritize it relative to small experiments, ensuring the cluster remains responsive to researchers without requiring any changes to the 175B model’s code. In practice, most infrastructure teams start with Tiresias-like policies to solve the “blocked queue” problem before attempting the deep integration required by Pollux.

The consistent theme across all four systems is that exploiting domain-specific knowledge about ML workloads (predictable iteration times, diminishing returns from parallel scaling, and inherent checkpoint-restart capability) enables dramatically better scheduling outcomes than static resource requests alone. A generic scheduler sees a job requesting 64 GPUs for 3 days; an ML-aware scheduler sees a stochastic gradient descent process that converges nonlinearly, releases resources if performance plateaus, and can be preempted with minimal loss. The decision framework for selecting among these schedulers depends on the primary bottleneck: for exploratory clusters with high churn, Gandiva’s time-slicing minimizes queuing delay; for production training where job completion time is the primary SLA, Tiresias’s age-based prioritization prevents starvation; for large-scale training where resource efficiency is paramount, Pollux’s adaptive scaling reclaims the “elasticity gap” that static allocation leaves on the table.

The challenge for production systems is incorporating these insights while maintaining the operational reliability, policy flexibility, and organizational governance that production environments

require. Production platforms usually adopt scheduler ideas selectively because reliability, governance, heterogeneous hardware, and user policy constrain pure research designs.

8.6.6 From research to production

Research schedulers become useful in production only when their core signal survives contact with a heterogeneous data center. In research, the cluster is often assumed to be a homogeneous pool of accelerators with uniform interconnect topology, and jobs are well-behaved entities that declare their resource needs accurately. In production, the “cluster” is a geological formation of hardware generations: V100s alongside A100s and H100s, connected by a patchwork of InfiniBand and Ethernet, running jobs that frequently crash, hang, or misrepresent their memory requirements. Consequently, no major hyperscaler simply “installs” a research scheduler; instead, they selectively transplant specific algorithms into standard orchestrators via Kubernetes operators or Slurm plugins.

Consider our 175B-parameter model training run. A pure implementation of Pollux might aggressively resize the job based on global cluster load, scaling the number of GPUs up and down to maximize goodput. However, changing the worker count for a synchronous training job requires a checkpoint-restart cycle, which for a model of this size involves writing terabytes of optimizer state to persistent storage. If the re-scaling interval is too short, the I/O overhead of checkpointing negates the throughput gains. In practice, production teams adopt a hybrid approach: they use Pollux-style adaptive allocation primarily during the volatile early phase of training or for hyperparameter sweeps, but lock the 175B model into a static, topology-aware allocation once the learning rate warmup completes and the job enters its months-long steady state.

The build-vs.-buy decision for a custom scheduler is a substantial capital investment. Developing a robust, fault-tolerant scheduler that outperforms the default bin-packing behavior of Kubernetes requires a specialized team of 3 to 5 systems engineers working for 6 to 12 months. The ROI math is what justifies the effort: if the team can improve overall cluster utilization by 10 percent on a fleet of 10,000 H100 GPUs (approximately \$25,000 per hour in capital depreciation and power), the savings amount to roughly \$22 million per year. This stark return on investment drives the development of internal scheduling platforms at every major AI lab, transforming the scheduler from a mere utility into a primary lever for operational efficiency.

The risk is not only implementation cost; scheduler behavior can also fail to match the execution semantics of distributed training.

War Story 8.1: OpenAI’s gang-scheduling deadlock (2021)

Context: OpenAI scaled Kubernetes clusters to 7,500 nodes for workloads including GPT-3, CLIP, and DALL-E. Their large training jobs used MPI-style execution, where all workers in a group had to be scheduled simultaneously before training could make progress (Sigler 2021).

Failure mode: Default Kubernetes scheduling did not guarantee that all of one job’s workers would be placed before scheduling started filling another job. If two experiments each requested the whole cluster, Kubernetes could schedule half of each job instead of all of one job, leaving both jobs unable to run.

Consequence: The cluster could appear busy while no experiment made useful training progress: a classic gang-scheduling deadlock caused by partial allocation.

Systems lesson: Distributed ML scheduling must encode the job’s execution semantics. For MPI-style training, “some pods scheduled” is not partial progress; it is wasted allocation. Production schedulers need gang scheduling, quota controls, and workload-aware policies rather than generic pod placement alone.

A scheduler designed for general-purpose pod placement will mishandle workloads that require gang semantics, and adding gang awareness alone does not resolve priority conflicts among competing training jobs. Each of the four research schedulers examined above addresses one facet of this problem (runtime estimation, iteration-boundary preemption, fairness across finish times, or joint resource-hyperparameter tuning), but none addresses all facets simultaneously. The design space is therefore a set of explicit trade-offs rather than a single optimal policy.

Checkpoint 8.3: Custom scheduler design space

Consider the trade-offs between the four research schedulers:

- ❑ **Estimate-free scheduling:** Identify the information Tiresias sacrifices by eliminating runtime estimates, and describe when that sacrifice hurts scheduling quality.
- ❑ **Time-slicing limits:** Identify workloads for which Gandiva’s iteration-boundary time-slicing fails, and explain why.
- ❑ **Job starvation:** Assess whether Themis’s preference for nearly complete jobs can starve long-running pretraining jobs indefinitely.
- ❑ **Goodput-model risk:** Describe the failure mode when Pollux’s goodput model is wrong.

Custom schedulers maximize throughput for long-running training jobs, but the operational reality changes drastically when models are deployed for inference. The objective function flips from maximizing cluster utilization to guaranteeing millisecond-level responsiveness. Serving resource management must handle bursty, unpredictable traffic patterns while adhering to strict Service Level Objectives.

8.7 Serving Resource Management

Training jobs are predictable, batch-oriented workloads that run for weeks; serving workloads are volatile, user-facing services that must respond in milliseconds to unpredictable traffic spikes. When an e-commerce platform launches a major sale, the serving fleet must instantly autoscale to handle thousands of requests per second. Serving resource management forces the orchestrator to balance these aggressive latency constraints against raw hardware utilization.

For orchestration, the important serving fact is that inference capacity is a live envelope around user traffic rather than a batch allocation around a training job. The fleet orchestrator manages that envelope by scaling replica counts up and down with demand, isolating serving workloads from interference, and balancing inference resource needs against training’s claims on the same shared infrastructure.

8.7.1 Autoscaling for inference

Kubernetes **Horizontal Pod Autoscaling (HPA)** adjusts replica counts based on observed metrics, adding instances when load increases and removing them when load decreases. The default autoscaling metric for general cloud workloads is CPU utilization, with targets of 50 to 70 percent. This default poorly reflects GPU inference workloads for two reasons. First, GPU utilization is a noisy metric that can be high even when the system is not processing user requests (background maintenance, model warmup). Second, the relationship between GPU utilization and inference latency is highly nonlinear: latency can spike dramatically when utilization crosses a threshold (typically 70 to 80 percent for GPU inference), making utilization-based scaling reactive rather than predictive. The metric choice is therefore the first scheduling decision for serving; table 8.6 lists custom inference metrics that predict user-facing degradation before it occurs.

Table 8.6: Inference Autoscaling Metrics: Custom metrics for GPU inference workloads capture the relationship between load and user-facing performance more accurately than default CPU utilization. Queue depth provides a leading indicator of latency degradation, while pending tokens captures outstanding autoregressive decode work; KV-cache residency and context-length distribution then determine whether that work is also memory-pressure risk.

Metric	Target Range	Considerations
GPU utilization	60 to 80%	Varies by model batch efficiency
Request queue depth	10 to 50 requests	Prevents latency spikes before they manifest in P99 metrics
P99 latency	Below SLO target	Reactive metric that lags demand changes by seconds to minutes
Pending tokens	Model-specific	Tokens queued or currently being decoded across active requests

Beyond the HPA-oriented metrics in table 8.6, **Vertical Pod Autoscaling (VPA)** operates on a different axis, adjusting resource requests and limits for individual pods. Where HPA changes how many instances run, VPA changes how much resource each instance receives. For inference, VPA can right-size memory allocations based on observed usage patterns, preventing over-provisioning of CPU memory and host resources that reduces the number of inference pods that fit on each node. GPU resources cannot be vertically scaled without pod restart (the CUDA context must be reinitialized), limiting VPA's utility for accelerated workloads where model loading takes minutes. However, VPA is valuable for the CPU components of inference pipelines, such as preprocessing, postprocessing, and tokenization, where resource requirements may differ significantly from initial estimates and can be adjusted with a brief pod restart.

Large language model (LLM) inference requires specialized scaling considerations that neither HPA nor VPA fully address, due to the **key-value (KV) cache**¹⁵ memory growth pattern. A 70B parameter model serving long-context requests may require more than 80 GB of GPU memory for KV cache alone, even when the serving engine stores that cache in paged, noncontiguous blocks. The GPU memory bottleneck for LLM serving is therefore not the model weights (which are fixed) but the KV cache (which grows with request count and context length). Scaling decisions must account for both request rate and context length distribution, not just computational load. A sudden increase in requests with long contexts (for example, a shift from short chatbot queries to document summarization workloads) can exhaust GPU memory even at moderate request rates, requiring scale-out despite low GPU compute utilization. Conversely, a burst of many short-context requests may stress compute without threatening memory limits.

This dual resource dimension (compute and memory) suggests that effective LLM autoscaling should monitor both GPU compute utilization and GPU memory pressure, scaling out when either approaches critical thresholds. Some production systems define a composite scaling metric that combines these dimensions, triggering scale-out when the maximum of normalized compute utilization and normalized memory pressure exceeds a threshold. This composite approach prevents the system from being surprised by either type of resource exhaustion.

Autoscaling for inference must also handle **cold start latency**, which creates a tension between cost efficiency and responsiveness that has no simple resolution. The cold-start problem in serving is quantitatively more severe than in standard web services due to the sheer mass of model weights. A 70B-parameter model in FP16 occupies approximately 140 GB, and all of it must reach GPU memory before the first request can be served, a transfer bound by PCIe or NVLink bandwidth. Even at the per-direction PCIe Gen4 x16 speed of 32 GB/s, the raw transfer takes over 4 seconds, and in practice model initialization, graph compilation, and safety checks extend this to 60–120 seconds. Loading from Non-Volatile Memory Express (NVMe) SSDs at 7 GB/s read bandwidth takes roughly 20 seconds; from network storage, it can exceed 2 minutes.

Aggressive scale-down policies that terminate replicas during brief traffic lulls create painful cold starts when traffic returns minutes later, producing latency spikes that violate SLOs and degrade user experience. The fundamental problem is that inference traffic exhibits burstiness at multiple timescales (seconds, minutes, hours), and short-term lulls do not reliably predict sustained low demand. A five-minute quiet period might be followed by a traffic spike, and the cost of a cold start during that spike (degraded latency for all requests while the model loads) can exceed the cost savings from the few minutes of freed GPU capacity.

Production systems address cold start through three complementary strategies:

- **Minimum replica count:** Keeping at least one warm replica above zero eliminates cold starts for the first burst of traffic but incurs a baseline cost even during truly idle periods.
- **Predictive scaling:** Scaling from historical traffic patterns, such as diurnal cycles, day-of-week patterns, and known events, adds capacity before expected peaks rather than reacting after load arrives.
- **Prewarming:** Loading model replicas into GPU memory on standby GPUs reduces activation from minutes of model loading to seconds of process initialization, but standby replicas consume GPU memory that cannot serve other workloads.

¹⁵ | **Key-Value (KV) Cache:** Stores precomputed attention key and value tensors to avoid recomputing attention over the entire sequence for each new token. KV cache grows linearly with sequence length and batch size; for a 70B model with 128K context, the cache can exceed the model weights in memory consumption. This growth pattern creates a scheduling failure mode invisible to compute-based autoscalers: GPU memory exhaustion at low compute utilization, causing requests to stall even when the GPU appears idle.

Organizations with multiple models competing for the same GPU pool must balance the pre-warming overhead against the cold-start penalty, choosing which models to keep warm based on their traffic patterns and latency requirements.

8.7.2 Predictive autoscaling and SLO management

Reactive autoscaling (like Kubernetes HPA) is inherently backward-looking: it observes a metric breach (for example, GPU utilization exceeding 80 percent), waits for a stabilization window, and then triggers a scale-up event. For a container that starts in milliseconds, this lag is negligible. For a 175B parameter model that takes 3 minutes to load weights from disk to GPU memory, this lag is fatal to SLOs. If traffic doubles in 30 seconds, a realistic scenario during a product launch or viral event, the reactive scaler will provision new replicas only after the surge has already saturated the existing fleet, causing a 3-minute window of degraded latency and dropped requests.

During this cold-start gap, continuous batching (also called in-flight batching) functions as a shock absorber. Serving engines that implement continuous batching, such as vLLM or TensorRT-LLM, do not wait for a fixed batch to fill before beginning generation; instead, they interleave new incoming requests into ongoing decode steps whenever a sequence slot becomes free. When load spikes and new replicas are still loading, the engine responds by increasing the live batch size toward the KV-cache memory limit, accepting more concurrent sequences per iteration. This absorbs additional requests without rejecting them, sustaining acceptable latency at the cost of higher per-request memory pressure. The relief is bounded: once the KV cache is fully saturated—meaning active sequences occupy every available memory page—the engine must begin queuing or shedding load regardless of batch elasticity. The scheduler therefore has a narrow window, typically from the moment the autoscaler fires until KV-cache saturation, in which continuous batching buys time. Tuning minimum replica counts and scale-up thresholds to keep that window open is the principal lever for preventing SLO violations during traffic ramps that exceed cold-start duration.

Predictive autoscaling decouples scaling actions from current load. By analyzing historical traffic patterns (diurnal cycles, day-of-week seasonality) and incorporating real-time leading indicators (for example, a surge in login requests often precedes a surge in inference queries), the scheduler can preprovision capacity before the demand arrives. Serving our 175B model with a 500 ms P99 SLO requires this anticipation. If the model takes 3 minutes to become ready, the predictive scaler must issue the scale-up command at least 4 minutes before the expected traffic ramp. This transforms the scaling problem from a *control theory problem* (reacting to error) to a *forecasting problem* (predicting the future).

Effective scaling policies must be **SLO-driven** rather than utilization-driven. Targeting a fixed utilization (for example, “keep GPU at 70 percent”) is a proxy that often fails: a model might hit its latency SLO at 60 percent utilization due to memory bandwidth contention, or it might safely run at 90 percent utilization if the requests are compute-bound and uniform. An SLO-driven policy explicitly targets the metric that matters: “Scale up when P99 latency exceeds 400 ms (80 percent of the 500 ms target).” This approach automatically adapts to changes in workload characteristics. If a new model version is less efficient, the latency metric will rise faster, and the scaler will provision more replicas to maintain the SLO, without requiring manual tuning of utilization thresholds.

To prevent **oscillation**, where the scaler rapidly adds and removes replicas during noisy traffic, production systems implement **hysteresis** and **cooldown periods**. A typical policy scales up aggressively (no stabilization window) to protect the SLO, but scales down conservatively (15-minute cooldown) to avoid thrashing. This asymmetry acknowledges that the cost of an unnecessary scale-up (wasted compute for 15 minutes) is far lower than the cost of a missed scale-up (SLO violation and user churn).

Reactive autoscaling opens an SLO gap during cold start.

Napkin Math 8.5: The autoscaling lag

Consider a serving fleet with 10 replicas, each capable of 5 QPS while meeting the 500 ms SLO. Total capacity: 50 QPS.

Scenario: Traffic ramps from 40 QPS to 80 QPS linearly over 60 seconds. Model load time: 3 minutes (180 seconds).

Reactive scaling: HPA detects overload at $t = 15$ s (when traffic hits 50 QPS). It requests 10 new replicas. These replicas become ready at $t = 195$ s ($15 + 180$ seconds). From $t = 15$ s to $t = 195$ s, demand exceeds capacity. During the ramp, excess demand grows linearly from 0 to 30 QPS; after the ramp reaches 80 QPS, the full 30 QPS overload persists until the new replicas are ready. The area above capacity is approximately 4,725 requests, all of which are queued or dropped and violate the SLO.

Predictive scaling: The scaler forecasts the ramp and triggers scale-up at $t = -180$ s. The 10 new replicas come online at $t = 0$ s, pushing capacity to 100 QPS just as the ramp begins. Zero SLO violations.

8.7.3 Resource isolation

When multiple inference workloads share the same physical hardware, noisy neighbor problems arise when one workload's resource consumption degrades another's performance. On GPUs, interference manifests through four shared resource channels:

- **Memory bandwidth:** One workload's data movement can saturate the HBM interface.
- **L2 cache contention:** One workload's working set can evict another's cached data.
- **PCIe bottlenecks:** Concurrent host-device transfers can compete for bus bandwidth.
- **Thermal effects:** One workload's heat generation can cause thermal throttling that affects all workloads on the same GPU.

For latency-sensitive inference, even minor interference can push P99 latency above SLO thresholds, turning a seemingly well-provisioned system into an SLO-violating one.

MIG sits at the strong-isolation end of this design space. Table 8.2 already showed the fixed profiles; the operational implication is that hardware isolation removes most cross-tenant interference but turns partition choice into a placement constraint. MIG is available only on A100 and later GPUs, profiles cannot change without draining all workloads from the GPU, and fixed partition sizes may not match workload requirements. A workload that needs 15 GB of GPU memory wastes 5 GB on a 20 GB MIG instance or cannot fit on a 10 GB instance.

Software approaches to isolation provide more flexibility at the cost of weaker guarantees. Efficiently sharing GPUs for inference requires navigating a hierarchy of isolation mechanisms, each trading performance for security. At the simplest level, **CUDA time-slicing** allows multiple processes to share a GPU by context-switching the compute resources. While flexible, this incurs high latency penalties (often 10–20 ms) and offers no memory isolation. NVIDIA's **Multi-Process Service (MPS)**¹⁶ improves this by allowing kernels from different processes to run concurrently on the same GPU, improving throughput for small batch inference while providing weaker isolation than MIG (Volta and newer give each client a separate GPU address space, but compute and memory bandwidth remain shared).

GPU memory isolation prevents one model from consuming memory needed by another through explicit memory limits enforced by the container runtime. Without such limits, a memory leak, an unexpectedly large batch (triggered by a request with unusually long context), or a misbehaving custom kernel can consume all available GPU memory and crash colocated workloads. MPS improves utilization for small workloads by eliminating the context-switching overhead of time-slicing, but it adds latency overhead of approximately 5 to 10 microseconds per kernel launch and provides limited protection against memory bandwidth interference.

Furthermore, long-running serving instances suffer from dynamic memory fragmentation. The key culprit is the KV cache in transformer inference, which grows and shrinks with request sequence length. Standard allocators struggle with these highly variable lifetimes, leaving holes in GPU memory too small for new requests but collectively wasting gigabytes. Serving engines increasingly use paged memory management to allocate KV cache in noncontiguous blocks, reducing fragmentation-induced out-of-memory failures; Chapter 10 develops the paged-allocation mechanism in full.

At the CPU level, core pinning assigns specific CPU cores to inference pods, preventing the Linux scheduler from migrating processes between cores in ways that invalidate processor caches. For latency-sensitive workloads, isolating cores using `isolcpus` kernel parameters and `taskset`

¹⁶ | **CUDA MPS (Multi-Process Service):** Enables concurrent kernel execution from multiple processes on a single GPU, eliminating the 10 to 20 ms context-switch penalty of time-slicing. MPS adds approximately 5 to 10 microseconds of overhead per kernel launch but provides no memory isolation: a process that exhausts GPU memory crashes all colocated workloads. This makes MPS suitable for trusted, same-team inference workloads but dangerous for multi-tenant environments where a single misbehaving model can take down its neighbors.

affinity removes OS scheduling jitter that manifests as random latency spikes. Combined with NUMA-aware¹⁷ placement that ensures inference pods access memory through the nearest memory controller (avoiding remote NUMA access that adds 50 to 100 ns per access), this reduces P99 latency by 10 to 30 percent for sub-millisecond inference tasks. The principle is straightforward: inference latency is dominated by memory access patterns, and any source of memory access unpredictability, whether cache eviction from core migration, remote NUMA access, or TLB misses from address space switching, directly degrades tail latency.

The isolation techniques discussed here represent a spectrum from strong (MIG, hardware isolation) to flexible (MPS, software sharing), and the choice depends on the trust boundary between colocated workloads. Multi-tenant inference platforms serving different external customers typically require MIG for security isolation. Single-tenant platforms serving different internal models on the same GPU can use MPS or time-slicing where the isolation requirements are weaker.

8.7.4 GPU sharing economics

The decision to co-locate multiple models on a single GPU defines the efficiency frontier of an inference fleet. This choice operates on a spectrum: at one end, **exclusive access** guarantees isolation but strands capacity; at the other, **aggressive sharing** (via MPS or time-slicing) maximizes utilization but risks latency interference. The physics of this trade-off are dictated by memory fragmentation and compute contention.

Consider an 80 GB A100 GPU serving a 7B parameter model. The model weights in FP16 consume approximately 14 GB. With a typical KV cache and activation overhead, the total runtime footprint is roughly 26 GB. Under an exclusive access policy, this single model leaves 54 GB (67 percent) of the GPU's high-bandwidth memory dark, a waste of silicon capital. Partitioning the GPU with MIG (for example, a 3g.40gb profile) tightens the container, reducing the waste to roughly 35 percent within the partition, but still leaves the remainder of the GPU strictly segmented. Enabling MPS to pack two such models onto the same 80 GB device consumes 52 GB, dropping the aggregate memory waste to just 35 percent. For fleets running hundreds of small models, shifting from exclusive to shared hosting can reduce the required GPU count by a factor of 2–3×

This density comes at the cost of **interference**. When two workloads share a GPU via MPS, they compete for Streaming Multiprocessors (SMs) and memory bandwidth. The degradation is workload-dependent: two compute-bound models (for example, large batch processing) fighting for ALUs often see 15 to 20 percent throughput degradation each. However, a compute-bound model co-located with a memory-bound model (for example, decoding-heavy generation) often coexist peacefully, seeing only 5 percent degradation because they bottleneck on different hardware resources. The scheduler's job thus becomes a multi-dimensional bin packing problem: finding complementary workloads that maximize density while respecting latency SLOs.

For a heterogeneous fleet, this logic dictates a bifurcated strategy. Our 175B parameter model requires about 350 GB just for FP16 weights; on 80 GB A100s that means at least five GPUs before KV cache, activation buffers, runtime workspace, and tensor-parallel granularity are included. In practice, an 8-GPU tensor-parallel replica is the cleaner scheduling unit and is a candidate for exclusive access. Conversely, the dozens of 1B to 7B parameter support models, such as toxicity classifiers, query embedding encoders, and auxiliary generation models, are prime candidates for sharing. By packing these smaller models onto shared “utility nodes,” the orchestrator liberates high-performance clusters for the heavy lifting of foundation model inference.

¹⁷ | **NUMA (Non-Uniform Memory Access):** Local memory access takes approximately 100 ns vs. 150 to 200 ns for remote-socket access, a 50 to 100 percent penalty. For ML inference preprocessing, placing CPU cores on the wrong NUMA domain relative to the GPU's PCIe connection adds this penalty to every host-device transfer, inflating P99 latency by 10 to 30 percent for sub-millisecond inference tasks. The fix is straightforward (CPU pinning and NUMA-aware pod scheduling) but often overlooked in Kubernetes deployments where the default scheduler ignores NUMA topology entirely.

Sharing packs two tenants, cutting wasted memory from 67 percent to 35 percent.

Napkin Math 8.6: GPU sharing ROI

Consider a fleet serving 100 distinct 7B models (26 GB footprint each) and 10 distinct 175B models (350 GB footprint each).

Strategy A – exclusive access (one model per GPU): The 7B models require 100 A100 GPUs (80 GB each), achieving only 32.5 percent memory utilization (100×26 GB used out of 8000 GB total). The 175B models require 80 GPUs (10 models $\times$ 8 GPUs each for tensor parallelism). Total fleet: 180 GPUs.

Strategy B – mixed sharing (MPS for small, exclusive for large): Pack 2 models per A100 for the 7B models ($2 \times 26 \text{ GB} = 52 \text{ GB}$, well within 80 GB), requiring only 50 GPUs at 65 percent memory utilization. The 175B models remain unchanged at 80 GPUs. Total fleet: 130 GPUs. Sharing reduces the fleet size by 27.8 percent (50 fewer GPUs). At \$2/GPU-hour, this saves approximately \$876,000 annually in compute costs, purely through scheduling policy.

8.7.5 Model routing and traffic management

Once resources are isolated, the orchestrator faces the challenge of directing inference queries to the correct model replicas. For a monolithic web service, simple round-robin load balancing suffices. For a 175B parameter language model served across thousands of GPUs, routing becomes a complex distributed systems problem where the “unit of serving” is no longer a single container but a **tensor parallel group**, a collection of 8 GPUs that must function as a single logical entity. The load balancer cannot simply route a request to “GPU 12”; it must route to “TP Group 3,” ensuring the request arrives at the exact moment the group is ready to process it.

Request routing strategies determine cluster-wide throughput. Naive **round-robin** distribution fails for generative workloads because request processing times vary by orders of magnitude based on output token length. A round-robin scheduler inevitably sends new requests to replicas backed up with long-generation tasks, causing tail latency to spike. **Least-outstanding-requests** (LOR) routing improves this by directing traffic to the idlest replicas. However, for large language models, **memory-aware routing** is superior. By tracking the KV cache occupancy of each replica, the router can send long-context requests to replicas with ample free memory and short requests to those near capacity, preventing fragmentation-induced out-of-memory errors and increasing effective batch sizes by 30 to 40 percent compared to blind routing.

Traffic shifting mechanisms like canary deployments and A/B testing are essential for safe model updates. When deploying Model v2, the orchestrator does not simply replace Model v1. Instead, it spins up v2 replicas alongside v1, creating a shadow fleet. The traffic manager routes 1 percent of live requests to v2 (often in “shadow mode,” where the response is computed but discarded) to validate latency and error rates against v1. Only after statistical verification does the orchestrator gradually shift weights (5 percent, 25 percent, 100 percent), draining v1 replicas only as v2 proves stable.

Multi-model serving complicates this further. A single cluster often hosts diverse models: a product recommendation model (10 ms P99 SLO, high throughput) alongside a coding assistant model (2,000 ms P99 SLO, bursty usage). Placing these on the same node invites interference; placing them on separate clusters strands capacity. The optimal strategy uses **latency-aware bin packing**: the orchestrator co-locates latency-critical models with batch-processing jobs (like embedding generation) that can be throttled instantly, ensuring high utilization without violating strict SLOs.

8.7.6 The training-serving resource boundary

The deepest utilization divide in the ML fleet is the wall between training and serving. Most organizations manage these as separate fiefdoms: a “Production Serving” cluster that must handle peak traffic (and sits 50 percent idle at night) and a “Research Training” cluster that is perpetually backlogged. This **static partitioning** is safe but economically inefficient. **Dynamic sharing** unifies these pools, but it introduces a fundamental friction: the mode-switching cost.

Repurposing a GPU from training to serving is not instantaneous. The orchestrator must checkpoint the training job (1 to 5 minutes), kill the container, launch the inference server, load the model weights from storage (2 to 10 minutes), and run warmup queries (1 to 5 minutes) to populate compilation caches. This 5-to-20-minute switching latency means GPUs cannot react to second-by-second traffic bursts. Instead, they must follow diurnal patterns.

Inference traffic typically follows a “human curve”: low at 3 AM, ramping up at 8 AM, peaking at 2 PM, and tapering off at 10 PM. A smart orchestrator forecasts this curve 30 minutes in advance. At 7:30 AM, it preempts low-priority training jobs (like hyperparameter sweeps) to warm up inference replicas. At 10:30 PM, as traffic drops, it drains inference replicas and releases GPUs back to the training scheduler.

Napkin Math 8.7: The diurnal GPU shift

Consider a fleet of 1,024 GPUs managed under two regimes:

Scenario A – static partitioning: The serving pool reserves 400 GPUs to handle peak demand, but average usage is only 150 GPUs (37.5 percent utilization). The training pool reserves 618 GPUs, and backlog ensures 100 percent utilization. Result: 150 GPUs + 618 GPUs = 768 active GPUs. Fleet utilization: 75 percent.

Scenario B – dynamic sharing: Serving claims GPUs strictly as needed (average 150 GPUs). Training reclaims unused serving GPUs (average 250 GPUs), minus a 117-GPU safety buffer. The orchestrator shifts approximately 133 GPUs between roles twice daily based on diurnal forecasts. Result: serving (150 GPUs) + training (618 GPUs + 133 GPUs) = 901 active GPUs (the second training term is reclaimed serving capacity). Fleet utilization: 88 percent.

Dynamic sharing recovers 133 GPUs of effective capacity. At \$2/GPU-hour, this creates approximately \$2.3M per year in value without purchasing a single additional accelerator.

Optimizing isolation for a single deployment is straightforward, but maintaining strict guarantees becomes volatile when thousands of training and serving workloads coexist on the same infrastructure. The collision of high-priority inference SLAs with resource-hungry training jobs creates a noisy neighbor problem that simple containerization cannot solve. Multi-tenancy and quotas become the governance layer that arbitrates fair access and prevents tragedy-of-the-commons scenarios in shared fleets.

8.8 Multi-Tenancy and Quotas

When the computer vision team hoards 500 GPUs for a week while the natural language processing (NLP) team sits blocked trying to push a critical bug fix to production, shared clusters devolve into a tragedy of the commons. Teams with the most aggressive job submission rates, the largest jobs, or the most persistent resubmission scripts consume disproportionate resources, while teams with more modest or intermittent needs find the cluster perpetually occupied. This creates organizational friction, political escalation to management, and underinvestment in slower-moving but potentially higher-value projects whose teams lack the engineering effort to compete for resources.

Multi-tenancy and quotas provide the organizational and technical firewalls needed to prevent this degradation. The quota systems discussed in this section establish formal policies for resource allocation, borrowing, and reclamation, so fair access and high overall utilization become enforceable scheduler properties rather than managerial negotiation.

8.8.1 Hierarchical fair-share

GPU quota allocation typically operates at the namespace or project level, defining how much of the cluster each team is entitled to use. The simplest approach allocates fixed GPU counts per team: Team A gets 500 GPUs, Team B gets 300 GPUs, Team C gets 200 GPUs. This approach is easy to understand and implement but leads to systematic underutilization when teams have variable workloads. If Team A's 500-GPU allocation sits 50 percent idle during a quiet period while Team B's queue overflows with urgent work, the cluster wastes 250 GPUs of capacity that rigid quotas forbid Team B from using. The alternative, allocating less quota to each team, creates a different problem: teams are blocked from running legitimate work during peak periods even when the cluster has overall spare capacity.

Hierarchical quotas resolve this tension by enabling departmental limits with sub-team flexibility and cross-team borrowing. Equation 8.4 bounds the effective quota for any team by both its own allocation and the parent department's capacity that sibling teams have not already claimed, where $U_{\text{allocated}}$ is the resources currently committed to each of the other teams in the department:

$$Q_{\text{effective}} = \min \left(Q_{\text{team}}, Q_{\text{department}} - \sum_{\text{other teams}} U_{\text{allocated}} \right) \quad (8.4)$$

When aggregate demand exceeds capacity, each team receives resources proportional to its share allocation, ensuring that no team is systematically disadvantaged. Unused capacity borrows down

the hierarchy: if Team A uses only 60 percent of its 500-GPU allocation, the remaining 200 GPUs become available to other teams within the same department. These borrowed resources carry lower preemption priority than owned resources: when Team A later submits jobs that need its full allocation, the scheduler reclaims borrowed capacity by preempting jobs running on those resources, returning capacity to its rightful owner.

This borrowing mechanism is essential for achieving high utilization in multi-tenant clusters. Without borrowing, organizations face a painful choice between allocating enough quota to handle each team's peak demand (guaranteeing low utilization when demand is uneven, since peaks rarely coincide across all teams) or allocating less (guaranteeing that some team is always quota-blocked during their peak periods). Borrowing resolves this dilemma by allowing peak-level allocations as *guarantees* while permitting idle capacity to *flow* to where it is needed. A team that is guaranteed 500 GPUs can always get 500 GPUs when needed (through preemption of borrowed jobs), but it does not waste the cluster's capacity when its actual demand is lower.

The preemption dynamics of borrowing require careful integration with the checkpoint infrastructure from Chapter 7. Jobs running on borrowed capacity must checkpoint frequently enough that preemption (when the owning team reclaims resources) does not waste significant work. Shared clusters often distinguish between "guaranteed" and "opportunistic" scheduling tiers: guaranteed jobs run on the team's owned quota and face preemption only from higher-priority work, while opportunistic jobs run on borrowed capacity and accept that they may be preempted when the owning team needs its resources back. Training frameworks that support elastic scaling can respond to borrowed-capacity reclamation by shrinking rather than terminating, further reducing the cost of the borrowing mechanism.

8.8.2 Burst capacity and over-subscription

In a shared GPU cluster, static quotas inevitably lead to the "burst capacity" paradox: Team A has a quota of 64 GPUs but needs 256 for a weekend-long training run, while Team B's allocated 64 GPUs sit idle. The solution requires decoupling "guaranteed quota" from "limit quota." A team is guaranteed 64 GPUs, which they can access instantly, but can burst up to 512 GPUs if the cluster has slack capacity. This "over-subscription" model relies on preemption: if Team B wakes up and reclaims their guaranteed share, the scheduler must immediately terminate Team A's burst jobs.

Burst capacity handling enables teams to temporarily exceed their quotas when cluster-wide resources are available, providing a more aggressive sharing mechanism than quota borrowing. Where borrowing reassigns idle capacity from one team to another, burst capacity allows teams to exceed the total allocated capacity by exploiting the gap between *requested* resources and *actual* utilization. Over-commitment ratios such as 1.2–1.5 $\times$ are plausible when admission controllers track actual vs. requested resources and intervene when contention materializes. When contention occurs, jobs using burst capacity face preemption first, protecting guaranteed allocations within each team's owned quota.

To manage this safely, clusters must implement strict priority classes:

- **Production serving:** Priority 0 workloads are nonpreemptible.
- **Production training:** Priority 1 workloads handle core model updates and are only preemptible by serving outages.
- **Interactive/debug:** Priority 2 workloads get high scheduling precedence but short time limits.
- **Batch/research:** Priority 3 workloads are fully preemptible and fault-tolerant.

This hierarchy ensures that a massive hyperparameter sweep fills the cluster's cracks but evaporates instantly when a critical retraining job arrives.

The appropriate over-commitment ratio depends on workload characteristics and requires careful observation of actual resource utilization patterns. If most jobs request 100 percent GPU utilization but actually achieve 70 percent (due to data loading phases, communication overhead, memory allocation gaps, or suboptimal kernel scheduling), a 1.3 $\times$ over-commitment ratio improves cluster-wide utilization without significant contention because the total actual demand (70 percent $\times$ 1.3 = 91 percent) remains below physical capacity. If jobs are genuinely compute-bound and sustain near-100 percent GPU utilization, over-commitment leads to resource contention and performance degradation for all colocated workloads. The over-commitment ratio should therefore be calibrated

empirically based on cluster-wide utilization telemetry, not set based on theoretical assumptions about workload behavior.

8.8.3 Resource accounting and observability

The 64 GPUs that sat idle for a weekend because a researcher forgot to cancel a reservation represent invisible waste in a multi-tenant cloud fleet. In a dedicated cluster, such waste is at least visible: the lights are on, but the fans are quiet. In a shared environment, the cost is hidden and compounds across thousands of jobs. Effective governance requires moving beyond simple “allocation” metrics to a tiered accounting model that distinguishes between what was requested, what was used, and what was useful.

Three tiers of measurement expose this gap:

- **Allocated capacity:** The resources the scheduler has reserved for a job are unavailable to others.
- **Compute utilization:** The percentage of time GPU kernels are active measures hardware busyness.
- **Productive utilization:** The fraction of time the GPU advances model state excludes data loading pauses, communication overhead, and checkpointing.

The distinction is financial, not merely technical. A team might be “allocated” 500 GPUs but only using 350 (70 percent compute utilization) and only “productively using” 280 (56 percent of allocation). If the organization pays for allocation but measures success by training progress, this 44 percent gap represents pure burn.

Attribution in a shared fleet presents a forensic challenge. A single “training” job might be a shared experiment between three teams, or a platform test run by an SRE. Without granular tagging at the job level, costs default to the “infrastructure” bucket, creating a tragedy of the commons where no one owns the bill. Kubernetes labels and Slurm accounts provide the mechanism for attribution, but the organizational discipline to apply them consistently is the harder problem. Mature organizations enforce “no tag, no schedule” policies, rejecting untagged jobs at the admission controller level.

This data feeds the utilization dashboard, the cluster operator’s primary instrument for fleet health. This view must synthesize per-team utilization against quotas, queue depth by priority class, and the **fragmentation index**, a measure of free GPUs that cannot be allocated due to topology constraints. Crucially, it must track the “cost of chaos”: preemption rates, spot instance interruption frequencies, and the recovery overhead they induce. When these metrics are visible, they drive behavior. A 64-GPU fine-tuning run for our 175B model held for 816 h consumes about \$130,560 of capacity (64 GPUs × 816 h × \$2.50/GPU-hour). Without proper accounting, this cost is invisible to the team that requested it. With chargeback, the team must justify this expenditure against the model’s expected business value.

Automated anomaly detection turns these metrics into actionable signals. A sudden spike in a team’s consumption to 3× their historical norm might indicate a runaway script spawning infinite jobs. A queue that grows faster than it drains signals a capacity shortfall that auto-scaling must address. Conversely, a sudden drop in cluster-wide power consumption typically precedes a mass job failure event, often due to a shared dependency like a storage outage. These alerts allow operators to intervene before the budget is drained or the queue becomes unmanageable.

Allocated, active, and productive utilization drift far apart.

Systems Perspective 8.7: The three utilization metrics

To debug cluster efficiency, measure utilization at three distinct layers. **Allocated utilization** is the percentage of physical GPUs reserved by the scheduler; low values indicate a lack of demand or overly restrictive quotas. **Compute utilization** is the percentage of time allocated GPUs are executing kernels (reported by `nvidia-smi`); low values indicate inefficient code, I/O bottlenecks, or communication stalls. **Productive utilization** is the percentage of allocated time spent effectively training (excluding overhead); low values indicate poor distributed scaling, excessive checkpointing, or frequent restarts.

8.8.4 Security and namespace isolation

Multi-tenancy requires not only fair resource allocation but also security isolation that prevents teams from interfering with or observing each other's workloads. The stakes are real: ML models represent significant intellectual property, training data may contain sensitive information subject to privacy regulations, and the models themselves may encode proprietary business logic. Without proper isolation, a compromised or misconfigured workload in one team's namespace could access another team's model weights, training data, or inference traffic.

In Kubernetes environments, namespace separation provides the fundamental isolation boundary. Each team operates within dedicated namespaces with role-based access control (RBAC) limiting visibility to their own resources. RBAC policies control who can submit jobs, view logs, access model artifacts, and modify scheduling policies within each namespace, providing organizational governance over cluster usage.

Network policies extend isolation to the network layer, preventing cross-namespace communication except through explicitly permitted services. Network policies for ML workloads must balance isolation against the communication requirements of distributed training. A practical policy might allow unrestricted all-to-all communication within a namespace (necessary for ring AllReduce as analyzed in Chapter 6, where every worker must communicate with every other worker) while blocking all ingress from other namespaces (preventing external workloads from intercepting gradient traffic or model updates). Egress policies can prevent training jobs from accessing external networks, reducing data exfiltration risk from compromised training code or poisoned dependencies.

Table 8.7 compares GPU virtualization options across isolation strength, resource efficiency, and workload fit.

Table 8.7: GPU Virtualization Isolation Spectrum: GPU sharing mechanisms trade isolation against packing efficiency, so the right mechanism depends on both the trust boundary and the workload's tolerance for interference.

Option	Isolation strength	Efficiency and flexibility	Suitable workload or trust boundary
Time-slicing	Low; workloads share a GPU through software scheduling.	High flexibility and packing efficiency.	Trusted workloads from the same team sharing a GPU for cost efficiency.
MIG	Strong hardware partitioning with fixed GPU slices.	Predictable isolation but less flexible placement.	Multi-tenant inference where different customers share the same physical GPU.
Full device passthrough	Complete isolation through exclusive access to one or more GPUs.	Lowest packing efficiency.	Training jobs that saturate resources or cannot tolerate interference from colocated work.

The choice depends on the trust boundary between colocated workloads and the performance sensitivity of each workload type. Security in multi-tenant environments extends beyond simple resource fairness. Side-channel attacks on shared GPUs are a documented vulnerability; by monitoring contention on shared caches or memory controllers, a malicious tenant can infer the architecture or even data properties of a co-resident model. In highly sensitive environments, hardware isolation mechanisms like MIG or strictly dedicating entire GPU nodes to single tenants become mandatory requirements.

8.8.5 Priority preemption cascades

When a high-priority job enters a saturated cluster, the scheduler must decide which running workloads to terminate to free up resources. This decision is rarely isolated. In tightly packed clusters, evicting a medium-priority job to accommodate a high-priority request often triggers a **preemption cascade**, where the evicted job immediately attempts to reschedule itself by displacing lower-priority workloads. Without dampening controls, a single urgent inference service deployment can ripple through the queue, destabilizing dozens of training jobs and forcing a storm of checkpoint reloads that saturate storage bandwidth.

The engineering cost of preemption extends far beyond the scheduling latency. The **preemption tax** is the sum of lost computation since the last checkpoint, the overhead of persisting state, and

the cold-start penalty upon resumption. For large-scale distributed training, this tax is nonlinear. Consider the 64-GPU fine-tuning run for our 175B parameter model. If preempted, the job loses the work performed since the last snapshot (average 15 minutes). Upon restarting, it requires 20 minutes to reload the massive optimizer state from distributed storage and another 10 minutes of warmup time as data pipelines refill prefetch buffers, just-in-time (JIT) compilers re-optimize kernels, and GPU caches re-populate.

A further hidden cost compounds this tax: reconstructing the state of the distributed data pipeline. Preempting a large-scale training job does not merely interrupt gradient computation—it discards the deterministic state of the data loader, including the random seed used for shuffling, the shuffle order applied to the epoch, and the byte offset into the dataset shards that records exactly which samples have been consumed. Without restoring this state precisely, the restarted job either re-reads samples already processed (poisoning gradient statistics by amplifying certain examples) or uses a different shuffle order (disrupting the statistical independence between epochs). Restoring a petabyte-scale distributed data pipeline to its pre-preemption state typically requires replaying metadata logs across all data loader workers, a process that can extend the effective warmup window well beyond the time consumed by optimizer state reloading alone. Frameworks that store a compact data loader checkpoint—recording the seed, the sampled permutation index, and the current shard offset—reduce this cost significantly, but the majority of production training pipelines require a manual warmup period to approximate the original data ordering before gradient quality returns to baseline.

During this 45-minute recovery window, the GPUs are active but effectively unproductive. At \$2/GPU-hour, a single preemption event costs \$96 in wasted compute capital. If the scheduler allows unlimited preemption, 12 preemptions per day waste 9 hours per day of that job’s allocation, or 576 GPU-hours per day for this 64-GPU run. To mitigate this, schedulers enforce **preemption budgets**. These rate limits constrain disruption frequency, such as preventing a job from being preempted more than once per hour or capping total cluster preemption churn to 5 percent of capacity in any 10-minute window. This forces the scheduler to wait for natural job completions rather than triggering a cascade, trading slightly higher pending times for significantly higher aggregate throughput.

8.8.6 Quota governance and organizational dynamics

Schedulers manage the second-by-second allocation of silicon, but **quota governance** manages the month-by-month allocation of organizational intent. Quotas are the interface between engineering constraints and business priorities. In mature ML organizations, these are rarely static; they are adjusted through periodic **quota review cycles** where allocations are recalibrated based on realized utilization rather than forecasted demand. A team that consistently uses only 40 percent of their 128-GPU allocation is effectively blocking other teams from launching experiments, creating a phantom scarcity that drives up queue times despite ample physical capacity.

The central tension in quota management is the **hoarding problem**. Engineering teams, rational in their desire to minimize wait times, often request maximum capacity “just in case” a project accelerates. This leads to low average utilization and high burst demand. Two ML-specific patterns amplify this behavior beyond generic resource anxiety. The first is the reinforcement learning from human feedback (RLHF) evaluation phase, in which the GPU nodes allocated to the policy model sit largely idle while the team awaits scores from human annotators. The team retains the reservation to avoid queuing again once annotation batches arrive, but the actual GPU occupancy during the annotation window can fall below 10 percent. The second pattern occurs when a team reserves a GPU block for a training run whose preprocessing pipeline has not yet completed. CPU-heavy data tokenization and vocabulary normalization for large corpora routinely takes longer than the team estimated; the GPUs sit reserved and idle while the tokenizer processes the dataset, because releasing the reservation risks losing it to a competing team. Both scenarios are rational from the team’s perspective but represent systematic waste at the cluster level. To counter this, platform teams implement **utilization-based reclamation**: if a quota pool remains underutilized for a set period, the system automatically reduces the allocation, returning resources to the general pool. This technical enforcement shifts the burden of proof back to the team to justify their reservation.

Financial accountability further aligns incentives. Organizations typically begin with showback, a reporting mechanism that exposes the dollar cost of GPU usage to engineering managers without

directly impacting their budgets. This fosters awareness but lacks teeth. As spending scales, organizations transition to chargeback, where compute costs are deducted from team budgets. Chargeback creates immediate pressure to optimize code and release unused quota, though it risks discouraging speculative research if the internal pricing model is too aggressive.

A concrete quota scenario shows how quickly idle reservations become expensive.

Example 8.3: Quota hoarding

Scenario: A team reserves a block of 500 GPUs for a “critical” urgent model refresh.

Failure mode: Upstream data delays postpone the training jobs, but the team retains the reservation to ensure availability “when the data arrives.”

Consequence: The GPUs sit idle for three weeks, a capital waste of roughly \$504,000, while other teams’ queues grow.

Systems insight: The infrastructure team implemented a “use it or lose it” policy. Any reserved quota group operating below 20 percent utilization for 72 consecutive hours is automatically reclaimed and converted to spot capacity for the general pool. Reclaiming the quota requires VP-level approval, effectively eliminating “parking” on idle hardware.

The “use it or lose it” reclamation policy addresses the most visible symptom of quota hoarding, but it raises a second-order question: when idle capacity is lent to another team, the system must distinguish borrowed capacity (preemptible on short notice) from guaranteed reservations (protected by SLOs). Defining borrowing, preemption, and guaranteed tiers as first-class policy primitives is the core multi-tenancy design decision.

Checkpoint 8.4: Multi-tenancy design decisions

Consider a 2,000-GPU cluster shared between a research team (60 percent allocation) and a production team (40 percent allocation):

- ☐ **Idle reclamation:** Decide whether the production team can use the idle 30 percent of the cluster, and describe the preemption behavior when the research team submits a large job.
- ☐ **Priority classes:** Configure priority classes for a production inference workload that needs 100 GPUs with guaranteed latency SLOs and a research training job that can tolerate preemption.
- ☐ **Over-commitment ratio:** Determine the appropriate over-commitment ratio when research jobs average 65 percent GPU utilization and production jobs average 85 percent.

Even with sophisticated multi-tenancy and quota policies in place, the cluster can still fall victim to complex, systemic bottlenecks that defy simple monitoring. When utilization drops inexplicably despite full queues, operators must move from dashboards to systematic utilization debugging.

8.9 Debugging Cluster Utilization

A cluster dashboard shows average GPU utilization stuck at 60 percent, yet developers complain about three-day queue times for small debugging jobs. Hundreds of GPUs sit idle, but no jobs are starting. Bridging this gap between theoretical capacity and production reality requires methodical forensic analysis to untangle the interactions between hardware topology, scheduler policies, and user behavior. As figure 8.6 illustrates, the relationship between utilization and wait time is highly nonlinear: operating above 80 percent causes wait times to explode.

The debugging method is to compare scheduler state with physical capability, inspect job requests against the actual hardware pools, and then test for a policy-infrastructure mismatch. A full queue and idle accelerators can coexist when the scheduler is honoring constraints that the dashboard has

Figure 8.6: The Utilization Paradox: As cluster utilization approaches saturation (100 percent), job wait times increase hyperbolically and diverge near saturation, not linearly. Operating above 80 percent utilization (the Danger Zone) causes unpredictable scheduling delays, especially for large jobs, illustrating why 100 percent utilization is an anti-pattern for interactive research clusters. A dashed line shows target utilization at 75 percent.

aggregated away. The cluster at the center of the worked example below runs the heterogeneous hardware in table 8.8, accumulated across three procurement cycles.

Table 8.8: Cluster hardware inventory: Three procurement generations create distinct resource pools with different capabilities. A100 nodes support tensor parallelism via NVLink, while V100 nodes are limited to data parallelism.

GPU Type	Count	Memory	Interconnect	Nodes
A100-80 GB	400 GPUs	80 GB HBM2e	NVLink (600 GB/s)	50 nodes × 8 GPUs
A100-40 GB	424 GPUs	40 GB HBM2e	NVLink (600 GB/s)	53 nodes × 8 GPUs
V100-32 GB	200 GPUs	32 GB HBM2	PCIe Gen3 (15.8 GB/s)	50 nodes × 4 GPUs

 Example 8.4: Debugging low GPU utilization

Problem: A 1,024-GPU cluster reports 60 percent average utilization, below the 80 percent operating target, despite a full queue with over 50 pending jobs. Dashboards show idle GPUs, but users still wait. Identify the binding constraint and the diagnostic path.

The fleet stack framework in figure 1.13 structures the diagnosis: inspect hardware capability first, then scheduling policy, then the mismatch between them.

The first diagnostic step is infrastructure-layer analysis. The hardware inventory in table 8.8 separates physical capability before the scheduler policy is examined: A100 nodes can run tensor-parallel jobs over NVLink, while the V100 pool is confined to data parallelism over PCIe.

The second diagnostic step is distribution-layer analysis. The Slurm scheduler implements gang scheduling with strict resource type matching. Examining the job specifications reveals the demand pattern:

- 15 large training jobs requesting at least 64 GPUs of A100-80 GB capacity, with aggregate demand of 1,200 GPUs.
- 8 medium jobs requesting 32 GPUs of A100-40 GB capacity, with aggregate demand of 256 GPUs.
- 0 jobs explicitly request V100 resources.

The scheduler's allocation log shows A100-80 GB GPUs nearly saturated by a few running jobs, while the remaining large jobs stay pending because no full 64 GPUs A100-80 GB allocation can be formed. The result is not a standard Slurm partial-allocation deadlock; it is a policy-induced utilization gap where strict resource requests leave A100-40 GB and V100 pools idle while A100-80 GB jobs wait.

Analysis: Multiple pathologies compound to create low utilization:

1. **Over-specification:** Model memory analysis reveals that most large jobs actually require only 35 GB peak memory per GPU, well within A100-40 GB capacity. Users copied job templates specifying A100-80 GB without recalculating requirements.
2. **Pool fragmentation:** The strict homogeneity requirement means a 64 GPUs job requesting "A100-80 GB" cannot use any A100-40 GB GPUs, even when 153 GPUs sit idle.
3. **Stranded resources:** No jobs target V100 hardware because researchers perceive it as "legacy." The 200 GPUs contribute zero productive work despite consuming power and cooling.
4. **Atomic-allocation starvation:** Large jobs remain pending until a full compatible allocation appears, while other resource pools sit idle because policy prevents compatible substitutions or backfill.

Diagnosis: Job templates and organizational practices evolved for a homogeneous A100-80 GB cluster. When infrastructure expanded with heterogeneous hardware, the Distribution Layer policies were never updated. The scheduler correctly implements its configured policy; the policy itself creates the utilization gap.

Solution: Implement tiered resource matching with topology awareness. The policy changes are durable: express capability requirements instead of exact GPU SKUs, reserve NVLink-connected nodes for jobs that need tensor parallelism, backfill compatible smaller jobs into otherwise idle pools, seed appropriate workloads onto older accelerators with lower cost accounting, and make the correct resource request easier than the over-specified template.

Impact: After implementing tiered matching and backfill scheduling, a two-week validation run recovered idle capacity across every pool, with the per-pool before-and-after allocation reported in table 8.9.

Systems lesson: Surface-level diagnosis suggested a scheduling algorithm problem. Deeper analysis showed a policy-infrastructure mismatch: the scheduler correctly implemented policies written for a homogeneous A100-80 GB cluster, but the infrastructure had become heterogeneous. Many utilization problems have this shape. The fix is not always a new scheduler; often it is updating the operational policy so it matches the fleet that actually exists.

Table 8.9: Utilization recovery results: The distinction between “allocated” and “effective” utilization captures the policy-induced utilization gap: before the fix, A100-80 GB GPUs showed high allocation in Slurm but lower actual compute utilization, while strict job templates stranded other capable hardware pools. The A100-80 GB “effective” values are measured utilization of allocated GPUs; cluster-wide utilization is computed over the full heterogeneous fleet.

Pool	Before	After	Change
A100-80 GB	95% allocated, 72% effective	89% allocated, 94% effective	+22 pp
A100-40 GB	64% allocated	88% allocated	+24 pp
V100	0% allocated	71% allocated	+71 pp
Cluster-wide	60%	84%	+24 pp

As table 8.9 shows, this utilization gain adds approximately 246 fully utilized GPUs of productive work. That is equivalent to buying 410 additional raw GPUs if those GPUs ran at the old 60 percent utilization. At \$2/GPU-hour, the equivalent raw capacity represents approximately \$7M in annual recovered value, achieved through policy changes requiring zero additional hardware investment.

8.9.1 Common utilization anti-patterns

High-level metrics often mask deep inefficiencies. A cluster dashboard may report 85 percent allocation, but productive utilization, the share of cycles actually advancing model state, can be significantly lower. Debugging these gaps requires identifying specific signatures in the GPU telemetry that reveal the underlying bottleneck.

The zombie job represents the most egregious waste: a training process that has crashed or deadlocked but continues to hold GPU resources. In a distributed run training a 175B parameter model, a single rank failure can leave 128 GPUs allocated but idling if the process cleanup fails. The signature is high memory allocation (greater than 300 GB) paired with near-zero SM utilization (less than 5 percent) persisting for longer than a heartbeat timeout (typically 10 minutes). This state often results from CUDA context corruption or a driver-level deadlock that prevents the container runtime from successfully reaping the process, requiring forceful node-level remediation to reclaim the device.

The data starvation pattern manifests as a high-frequency sawtooth wave in GPU utilization, where the device oscillates between 100 percent load (forward/backward pass) and 0 percent load (waiting for the next batch). While the average utilization might appear acceptable at 60 to 70 percent, the GPU is effectively idling for a third of its life. This occurs when the CPU-bound data pipeline cannot sustain the throughput required by the GPU, a common scenario in computer vision where JPEG decoding and augmentation saturate host CPUs. A utilization variance exceeding 30 percent standard deviation is the primary diagnostic indicator, signaling the need for active prefetching, increased loader parallelism, or local NVMe caching to saturate the accelerator.

The communication bottleneck reveals itself through periodic, synchronized drops in SM utilization across all ranks in a distributed group. For the 175B model, synchronizing gradients for 350 GB of parameters requires massive bandwidth; if the network is undersized or congested, the GPUs spend more time waiting for AllReduce to complete than performing computation. The diagnostic metric is the step time ratio: if the total iteration time exceeds $1.5\times$ the compute-only time (forward plus backward passes in isolation), the network has become the dominant constraint. Remediation requires topology-aware placement to keep traffic on high-bandwidth switch tiers or algorithmic changes like gradient accumulation to increase the compute-to-communication ratio.

The memory fragmentation trap is an insidious failure mode in long-running inference servers. A 175B model serving diverse request lengths can end up with 80 percent of its HBM allocated to the KV cache, yet be unable to accept a new request because the free memory is scattered in small, noncontiguous blocks. The GPU appears full to the scheduler but underutilized in terms of throughput. This resembles the classic heap fragmentation problem but with higher stakes: a single restart to defragment dumps hundreds of gigabytes of state. Monitoring the ratio of requested token slots to allocated memory bytes often exposes this gap, which paged cache allocators address by

decoupling logical sequence contiguity from physical memory layout, recovering usable memory and boosting serving throughput by 2–4× without adding hardware.

The debugging example illustrates a broader principle that applies to every system discussed in this chapter: scheduling systems are only as effective as the policies they implement, and policies must evolve alongside infrastructure. When infrastructure changes (new hardware generations are added, network topologies are upgraded, workload mixes shift from training-dominant to serving-dominant), the policies encoded in scheduler configuration, job templates, and organizational practices must be re-evaluated and updated. The most expensive scheduling bug is often not a software defect but a policy that was correct for the old infrastructure and was never updated for the new one.

This principle connects scheduling mechanics to fleet governance. Technical policies (GPU type matching, gang scheduling timeouts, preemption grace periods) interact with organizational policies (team quotas, priority hierarchies, cost allocation) and human behavior (job template reuse, resource request habits, queue submission patterns). Effective fleet orchestration requires attending to all three layers simultaneously.

8.10 Fallacies and Pitfalls

Those policy-infrastructure mismatches recur as a small set of misconceptions that can make an apparently healthy scheduler waste expensive fleet capacity. It is tempting to look at a cluster running at 98 percent utilization and declare victory, only to discover that researchers have stopped submitting jobs entirely because wait times have stretched into weeks. Cluster orchestration is riddled with counterintuitive traps like this, where optimizing a single metric destroys overall system value.

Fallacy: *More sophisticated scheduling algorithms always improve utilization.*

Engineers facing low utilization often reach for more advanced schedulers, assuming the algorithm is the bottleneck. As the debugging example in section 8.9 demonstrates, the root cause is frequently policy misconfiguration, not algorithmic limitation. A simple FIFO scheduler with correct policies (capability-based matching, backfill with timeouts, appropriate gang scheduling constraints) often outperforms a sophisticated scheduler with incorrect policies. Before upgrading the scheduler, audit the policies: confirm that users are not requesting resources they do not need, that heterogeneous resources are properly exposed, and that gang-scheduling timeouts are configured.

Pitfall: *Treating all GPU-hours as equal when measuring utilization.*

Cluster dashboards commonly report “GPU utilization” as a single percentage, averaging across all GPUs and all workloads. This metric hides critical information. A cluster might report 80 percent utilization where 60 percent is productive training, 15 percent is idle GPUs allocated to jobs waiting for gang completion, and 5 percent is GPUs running data loading with no active computation. Effective monitoring distinguishes between allocated utilization (GPUs assigned to jobs), compute utilization (GPUs executing kernels), and productive utilization (GPUs advancing useful training or serving requests). Only the last metric correlates with actual value delivered.

Fallacy: *Gang scheduling is always necessary for distributed training.*

Gang scheduling prevents deadlock for synchronous training, but not all distributed training is synchronous. Asynchronous training methods tolerate worker arrivals and departures, and elastic training frameworks handle variable worker counts. For workloads that can operate asynchronously or elastically, relaxing the gang scheduling requirement dramatically improves scheduling flexibility and reduces queue wait times. The trade-off is potential convergence degradation from stale gradients or batch size variability, but for many practical workloads (hyperparameter sweeps, fine-tuning, pretraining with adaptive batch size), this trade-off is favorable.

Pitfall: *Setting static quotas based on peak demand.*

Organizations commonly set team quotas to handle worst-case demand, reasoning that teams need guaranteed access during crunch periods. If Team A’s peak demand is 500 GPUs and Team B’s is 300 GPUs, the cluster needs 800 GPUs with static quotas. In practice, peaks rarely coincide. Hierarchical fair-share with borrowing can serve both teams’ peak demands with a 600-GPU cluster, because when Team A peaks, Team B is typically at moderate demand and can yield borrowed capacity. Static quotas at peak levels waste 25 to 40 percent of cluster capacity on guaranteed-but-unused allocations.

Fallacy: *Spot instances are always cheaper for training.*

The 60 to 90 percent discount on spot instances creates the impression of automatic savings. The effective cost depends on interruption frequency, checkpoint overhead, and restart time. For a large model with 15-minute checkpoint times and 30-minute restart times, a spot interruption costs 45 minutes of productive time. If interruptions occur every 2 hours, the effective cost rises enough that the nominal 65 percent discount shrinks to about 52 percent savings. For 100B+ parameter models with slow checkpointing on clusters with frequent spot interruptions, on-demand instances can actually be cheaper when accounting for all overhead. The decision requires quantitative analysis of the specific workload and spot market conditions, not blanket assumptions about cost savings.

Pitfall: *Ignoring topology when scheduling distributed training.*

Schedulers that treat GPUs as interchangeable units create allocations where tensor parallel groups span nodes (forcing NVLink-speed operations over InfiniBand) or AllReduce groups cross spine switches (adding latency and congestion). The 15 to 30 percent throughput penalty from poor topology placement accumulates over multi-week training runs, potentially wasting more resources than would be lost by waiting for a topology-aware allocation. Topology-aware scheduling increases scheduling complexity and may reduce packing efficiency, but for large distributed training jobs, the throughput improvement often justifies the trade-off.

Fallacy: *GPU utilization alone is a sufficient autoscaling signal.*

GPU utilization is a poor proxy for inference health. A GPU can be 90 percent utilized but still violating latency SLOs because the utilization comes from processing a backlog of queued requests. Conversely, a GPU at 40 percent utilization might be perfectly healthy if it is serving low-latency requests with headroom for bursts. The right metrics are queue depth, P99 latency relative to SLO, and KV cache memory pressure for LLM workloads. Relying on utilization creates a lagging indicator that only triggers scaling *after* performance has already degraded, whereas queue depth and SLO margin provide leading indicators that allow the fleet to scale *before* the user experience suffers. Furthermore, for LLMs, memory exhaustion from KV cache growth can occur at low compute utilization, causing requests to stall or fail. An autoscaler watching only compute utilization will miss this failure mode entirely, leaving the service degraded despite apparent capacity.

Pitfall: *Using elastic training to avoid gang-scheduling decisions.*

Elastic training complements but does not replace gang scheduling. While it allows jobs to resize, the resizing steps themselves often have atomic requirements. Elastic training works for data parallelism but not tensor parallelism (which requires a fixed number of GPUs per group). A 175B model using 8-way tensor parallelism needs exactly 8 GPUs per tensor-parallel group to function; this is a gang constraint that elastic training cannot relax. Elastic training adjusts the number of data-parallel replicas, not the intra-replica parallelism configuration, meaning the scheduler must still enforce gang constraints for the base unit of the model. If a scheduler naively places these 8 GPUs across different racks or fails to allocate them atomically, the tensor parallel group will either fail to initialize or suffer catastrophic performance degradation.

Fallacy: *The scheduler needs no workload-specific validation.*

Scheduler configuration requires continuous tuning as workloads evolve. Default configurations in Slurm or Kubernetes are optimized for generic workloads, often prioritizing simple fairness over throughput. ML-specific tuning (gang scheduling timeouts, topology-aware placement weights, preemption grace periods, and fair-share decay rates) can improve utilization by 15 to 25 percent. Organizations that deploy a scheduler and never revisit its configuration leave significant value on the table. A default preemption grace period might be too short for a large model to checkpoint, causing wasted work, while an untuned topology weight might fragment the cluster unnecessarily. As the cluster grows and the workload mix shifts (for example, from training-heavy to inference-heavy), the effective scheduling parameters shift with it. Treating the scheduler as a set-and-forget appliance lets the fleet drift into inefficiency.

Pitfall: *Treating high utilization as proof of cluster health.*

A cluster running at 95 percent utilization sounds efficient but may indicate a problem: insufficient capacity that is choking experimentation velocity. When utilization consistently exceeds 85 to 90 percent, queue times grow rapidly following the well-known M/M/1 queuing result from stochastic process theory. In this model, average wait time is proportional to $\rho/(1-\rho)$ where ρ is utilization; at 90 percent utilization, average wait is $9\times$ the service time, and at 95 percent, it is $19\times$. Researchers

waiting hours or days for resources conduct fewer experiments, test fewer hypotheses, and iterate more slowly on model designs. This reduced experimentation velocity has real costs that are harder to quantify than GPU-hours but may be larger in aggregate. The effective utilization target balances resource efficiency against researcher productivity, often landing between 70 and 85 percent for training clusters where queue responsiveness directly affects research output. Inference clusters, where requests are served immediately or not at all, often target even lower utilization (50 to 70 percent) to maintain latency headroom for traffic spikes.

Recognizing these fallacies prevents platform teams from chasing false optimizations that look good on dashboards but degrade developer velocity. The core orchestration principles that successfully navigate these trade-offs share a common thread: they treat scheduling as an engineering discipline, not an administrative function.

8.11 Summary

Fleet orchestration transforms raw data center capacity into productive ML infrastructure. The scheduling algorithms, placement strategies, and resource management policies examined in this chapter determine whether thousands of isolated GPUs function as one coherent computing platform or as a fragmented collection of expensive servers. The difference between those outcomes is not hardware capability alone, but the scheduler's ability to maintain useful state under partial failures, network partitions, stale resource views, and competing consistency and availability requirements. Slurm and Kubernetes embody different trade-offs along that spectrum, and large fleets may use both because batch training and self-healing service deployment stress the scheduler in different ways.

The chapter's central technical lesson is that placement is performance. Topology-aware scheduling exploits the communication hierarchy of GPU clusters, improving training throughput by 15 to 30 percent when tensor-parallel, pipeline-parallel, and data-parallel groups are placed on the fabric tiers that match their traffic. Elastic training, preemption-aware checkpointing, and spot-instance policies add economic flexibility, but only when the job can survive changing worker counts or interruptions. Research schedulers such as Tiresias, Gandiva, Themis, and Pollux make the same point algorithmically: ML jobs have observable structure, including iterative progress, heavy-tailed durations, sunk-cost economics, and convergence-dependent scaling, so schedulers that exploit that structure can improve average completion time by 40 to 60 percent over generic policies.

The objective function changes again at serving time. Training clusters can trade queue wait against utilization, but inference fleets must protect tail latency under bursty demand. Autoscaling therefore needs queue depth, P99 latency, and KV-cache pressure rather than GPU utilization alone; multi-tenancy needs MIG, MPS, temporal slicing, quotas, borrowing, and chargeback policies that balance isolation against fleet-wide efficiency. The same scheduler that looks efficient on a utilization dashboard can still be mismanaging the fleet if researchers wait days for experiments, inference SLOs degrade under burst load, or fragmented GPUs cannot form the gang allocations that training jobs require.

Mastery of fleet orchestration is therefore diagnostic and economic as much as algorithmic. Zombie jobs, data starvation, topology mismatch, and resource fragmentation are symptoms of scheduler policy failing to match infrastructure reality; adding more nodes often hides the symptom without fixing the cause. With compute nodes defined, networks connected, storage configured, fault tolerance in place, and schedulers running, the infrastructure layers of the fleet stack now form a coherent platform rather than a rack of independent machines.

Key Takeaways: Scheduling is systems engineering

- **Distributed scheduling is fundamentally hard:** Cluster scheduling faces challenges (partial failures, network partitions, state inconsistency) that single-machine schedulers never encounter. The CAP theorem forces trade-offs between consistency and availability that shape every scheduling system's design.
- **Gang scheduling prevents deadlock but reduces flexibility:** Gang scheduling gives distributed training atomic resource allocation to prevent hold-and-wait deadlocks, but

rigid gang scheduling wastes resources when combined with backfill timeouts and elastic training alternatives.

- **Topology determines performance:** Where GPUs are placed within the cluster hierarchy matters as much as how many GPUs a job receives. NVLink vs. InfiniBand placement decisions can create 15 to 30 percent throughput differences for the same job on the same hardware.
- **ML-specific scheduling outperforms generic approaches:** Exploiting workload characteristics (predictable resource needs, iterative computation, diminishing returns) enables 40 to 60 percent improvements in job completion time compared to general-purpose FIFO or fair-share policies.
- **Utilization is a first-order economic driver:** Improving cluster utilization from 50 percent to 80 percent on a large cluster effectively adds thousands of GPUs worth of capacity. Closing this gap through policy and algorithm work pays back faster than buying additional accelerators.
- **Policies must evolve with infrastructure:** Scheduling algorithms are only as effective as the policies they implement. When infrastructure changes (heterogeneous hardware additions, topology upgrades, workload mix shifts), policies must be re-evaluated and updated.

The fleet now has every physical part it needs: compute, communication, storage, and the resilience to keep them running. None of it produces anything until something decides what runs where, and that decision is pure coordination. A scheduler that chases peak utilization will deadlock the first time two large jobs need the same nodes, so a scheduler that guarantees progress must leave some capacity deliberately unused. That gap, between the throughput a fleet could reach and the throughput it can safely sustain, is the price of coordination, and orchestration is the discipline of spending it where it buys the most finished work. At fleet scale the binding constraint moves up the stack again, from the speed of the hardware to the quality of the policy that hands it out.

What's Next: From orchestration to optimization

We have organized the operational layer of the Machine Learning Fleet, the “who gets what, when, and where” of resource management. Yet the fleet’s purpose is not to run training jobs; it is to produce models that serve users. The next challenge is extracting maximum throughput from the hardware once it has been orchestrated. Chapter 9 examines the techniques that do so: operator fusion, precision engineering, graph compilation, and execution scheduling. These optimizations determine whether the fleet’s expensive silicon delivers its theoretical potential or wastes cycles on inefficient execution. The orchestration layer ensures the right resources are allocated; performance engineering ensures those resources are used effectively.

Research Questions: For further inquiry

- How should a scheduler trade utilization, fairness, topology locality, and deadlock prevention for distributed training jobs?
- How should placement policies incorporate collective costs and fault-domain boundaries?
- When do preemption, spot capacity, and elastic training reduce total cost rather than increase lost work and variance?
- Which signals beyond accelerator utilization should drive autoscaling and cluster health decisions?

III

DEPLOYMENT AT SCALE

Deployment-at-Scale Principles

Parts I and II built the Fleet and trained the model. Production deployment now becomes the test of operational accountability. Part III shifts the focus from the single, massive training run to the global inference fleet: the thousands of geographically distributed servers and billions of edge devices that serve model outputs to users in real time. This transition from training to production fundamentally changes the engineering constraints: from maximizing throughput on a static dataset to minimizing latency on a dynamic stream of requests, all within the physics of global serving.

In this regime, engineering becomes a negotiation with the user's experience. The system can optimize for high batch throughput in the data center, but at the risk of violating the user's latency budget. Deploying a model to the edge eliminates network latency, but introduces the tight memory and power envelopes of mobile and Internet of Things (IoT) hardware. These principles govern the performance engineering and operational economics of deploying intelligence at scale.

The first constraint is imposed by the mechanics of generation itself.

Principle 14: The Autoregressive Bottleneck

Invariant: In low-batch dense transformer decode, throughput is memory-bandwidth bound because the model weights must be streamed across the device for *every generated token*. Higher batch sizes amortize weight streaming, and key-value (KV) cache traffic shifts the binding constraint at long context.

Implication: Throughput initially improves with batch size by amortizing weight reads across requests, until per-device latency budgets, KV cache capacity, or sustained compute become the binding ceiling. Serving systems therefore need batching, cache-management, and memory-layout policies that keep bandwidth useful without violating latency SLOs.

The same accounting extends from device bandwidth to fleet economics.

Principle 15: The Serving Cost Dominance Law

Invariant: For high-traffic production models, cumulative inference cost can exceed the one-time training cost by 10–100× over the model's lifetime.

Implication: Inference efficiency often becomes the dominant lifecycle optimization target. Optimization efforts (quantization, distillation, sparsity) should be focused on the inference path when traffic volume, product lifetime, and retraining cadence make serving cost dominate.

At scale, routing policy becomes another lever for protecting latency.

Principle 16: The Power of Two Choices (P2C)

Invariant: Under an idealized balls-into-bins model with R replicas, querying just two random replicas and selecting the least-loaded one reduces the maximum load on any replica from $\Theta(\log R / \log \log R)$ to $\Theta(\log \log R)$.

$$\Theta(\log R / \log \log R) \rightarrow \Theta(\log \log R)$$

Implication: Simple randomized load-balancing algorithms produce dramatically lower maximum-load bounds with $\mathcal{O}(1)$ coordination overhead. Under serving queueing assumptions, the lower maximum load translates into reduced tail latency at scale.

Part III takes the trained model from the cluster to the world. The path begins with performance engineering, where precision choices, kernel behavior, and compilation determine how much of the hardware's theoretical capacity the system can actually use. It then moves to inference at scale, where request batching, cache management, routing, and sharding turn single-device efficiency into fleet-level latency control. Edge intelligence pushes the same discipline into devices with much smaller memory, power, and connectivity budgets, while operations at scale closes the loop by monitoring the deployed fleet, coordinating platform ownership, and responding when production behavior diverges from design assumptions. Together, these chapters develop the operational discipline that turns a trained model into a durable production system.

Purpose

How do we make billion-parameter models run on millisecond timescales?

Model compression reduces the size of the model's computation. Performance engineering reshapes that computation to match the physics of the hardware. The distinction matters: a quantized model loaded naively into an accelerator kernel that reads every weight from off-chip memory wastes the very bandwidth savings that quantization was designed to provide. Real performance comes from understanding the full path a tensor travels, from registers through on-chip memory to high-bandwidth memory and back, and then engineering each step to eliminate wasted movement. This chapter develops the system-level optimization techniques that bridge the gap between a theoretically efficient model and a production artifact that saturates hardware. The levers are operator fusion and tiling strategies that keep data in fast local memory, precision formats that double effective bandwidth, compilation frameworks that automate kernel selection, and algorithmic innovations like speculative decoding and sparse expert routing that change the performance equation. Together, they transform a model that should be fast into one that is fast, often by an order of magnitude. That order of magnitude comes entirely from the compute term of the C³ taxonomy: performance engineering extracts more useful work from the cycles the fleet already owns.

Learning Objectives

- Apply roofline analysis to classify ML kernels as compute-bound, memory-bound, or launch-limited on target accelerators
- Analyze prefill, decode, and batch-size regimes to predict latency-throughput behavior in LLM serving
- Design fusion, tiling, and CUDA graph strategies that reduce HBM traffic and launch overhead
- Select precision, compilation, and runtime optimizations from bandwidth, quality, and deployment constraints
- Evaluate speculative decoding and MoE routing using acceptance rates, batching limits, and AllToAll costs
- Diagnose serving bottlenecks with profilers, roofline plots, and fleet-efficiency metrics
- Synthesize a 70B serving optimization plan across compute, communication, coordination, and quality trade-offs

9.1 The Memory Wall and Roofline Diagnosis

AN H100 GPU capable of 989 TFLOP/s of FP16 compute can still show single-digit compute utilization during small-batch language-model decode. The processor is not short on arithmetic; it is starving for data. Performance engineering operates inside that constraint: the memory wall, where moving bytes from memory to compute units can cap throughput long before Tensor Cores reach their advertised peak.

Placement, synchronization, recovery, and scheduling can put the workload on the right hardware and keep it alive. The remaining problem is local execution: expensive silicon can still sit idle after work arrives. In the fleet stack shown in figure 1.13, performance engineering is the optimization discipline within the Serving Layer, reaching down into the Distribution and Infrastructure layers when kernels, memory hierarchy, interconnects, or framework overhead determine achieved throughput. The answer is usually data movement, so performance engineering begins with the memory hierarchy and then follows the consequences through fusion, precision, compilation, and algorithmic changes that move fewer bytes, launch less overhead, or do different work entirely.

9.1.1 The iron law of ML performance

The memory wall is one term in a larger budget. Equation 9.1 states the iron law of ML system performance, decomposing execution time into three competing costs:

$$T = \frac{D_{\text{vol}}}{\text{BW}} + \frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}} + L_{\text{lat}} \quad (9.1)$$

In overlapped execution, the roofline-style simplification replaces the sum of compute and data movement with the slower exposed term:

$$T \approx \max \left(\frac{O}{R_{\text{peak}} \cdot \eta_{\text{hw}}}, \frac{D_{\text{vol}}}{\text{BW}} \right) + L_{\text{lat}}$$

The inherited iron law decomposes execution time into three terms. The compute fraction represents the total floating-point operations divided by realized hardware throughput. The data fraction represents total bytes transferred divided by memory bandwidth. The roofline approximation then asks which exposed term dominates at a given operating point: increasing compute throughput for a memory-bound workload, for example, does not materially improve performance until the memory term is reduced. The overhead term captures everything else: kernel launch latency, synchronization, communication, and software stack inefficiency. PyTorch training loops expose a particularly large slice of this term: every kernel launch must traverse the Python Global Interpreter Lock (GIL) and the framework's CPU dispatcher before reaching the GPU command queue, spending tens

of microseconds in Python dispatch per operation before any GPU work begins. This is precisely why ML framework developers prioritized `torch.compile(mode="reduce-overhead")` and CUDA Graphs: both trace away the Python dispatch path entirely, converting repeated GPU submissions into a single native replay that bypasses the GIL and dispatcher on every step.

Standard model compression (pruning, quantization, distillation) shrinks the model’s intrinsic work, performing fewer operations on smaller data. System optimization addresses the complementary problem: shrinking the gap between that work and the hardware’s peak by moving the same terms through implementation rather than model change, keeping data in fast memory, packing each transfer more densely, and removing software overhead.

Several levers map directly to those terms. When memory traffic dominates, operator fusion and tiling reduce the exposed data-volume term by eliminating intermediate HBM round-trips. A fused sequence that keeps its intermediates in SRAM can shrink the exposed memory-access term dramatically, often by 10–30× for attention computation. Precision engineering attacks the same numerator from a different angle: FP8, INT4, and KV-cache compression (storing the per-token attention keys and values in fewer bytes) represent each value in fewer bytes, so the same physical bandwidth carries more useful model state.

Other levers change the overhead or compute terms. Graph compilation, including `torch.compile`, Accelerated Linear Algebra (XLA), and TensorRT, reduces overhead by eliminating kernel launch gaps, fusing operations, and optimizing memory allocation across the graph. Communication-computation overlap makes distributed communication concurrent with useful work, removing it from the critical path when $T_{\text{comm}}(N) - T_{\text{overlap}} \leq T_{\text{compute}}/N$ (that is, communication finishes before the next layer’s computation completes). This inequality is the exposed-time test, not a new law: overlap helps only when useful computation is large enough to cover the communication. Algorithmic innovations such as speculative decoding and mixture-of-experts (MoE) change the compute term itself by making the model perform a different computation that preserves the output contract at lower exposed cost.

Each technique attacks a different term, and this taxonomy guides optimization strategy: diagnose which term dominates (using the roofline model from section 9.1.5), then apply the technique targeting that term. Applying a technique that targets the nondominant term wastes engineering effort.

Before using this diagnostic process, check how each term in the iron law maps to a practical optimization lever.

Checkpoint 9.1: The iron law of performance

Verify your understanding of system-level performance diagnosis:

- ☐ **Memory-bound limit:** Determine whether increasing the GPU’s clock frequency (increasing FLOP/s) improves a memory-bound workload.
- ☐ **Quantization term:** Identify which term in equation 9.1 changes when quantization moves the representation from FP16 to INT4.
- ☐ **Overhead term:** Define the “Overhead” term in the iron law and explain why graph compilation targets it specifically.
- ☐ **Compute-bound bandwidth:** Evaluate the claim that memory bandwidth is irrelevant to the performance of a compute-bound system.
- ☐ **Iron-law decomposition:** For a step that is 60 percent data movement, 30 percent compute, and 10 percent latency, estimate which single optimization buys the most wall-clock time, and what the iron law predicts once you halve that dominant term.

The same diagnostic process can be codified as a decision flowchart, mapping each bottleneck to its corresponding optimization technique. The flowchart in figure 9.1 makes the sequencing explicit: rule out I/O, CPU, and communication overheads before classifying the remaining workload as compute-bound or memory-bound.

D C L

Autoregressive transformer decode is often memory-bound: the data-movement term dominates the iron law.

Figure 9.1: Iron Law Diagnostic Flowchart: A training-slow-down troubleshooting flow that starts from observed symptoms (slow training, low GPU utilization), branches through I/O, CPU, and communication-overhead checks, and classifies the workload as compute-bound or memory-bound at the leaves. Compute-bound paths point to precision engineering and algorithmic change; memory-bound paths point to operator fusion and tiling. Overhead-bound symptoms (graph dispatch, communication) are surfaced earlier in the flow and addressed before the final compute/memory classification.

The central lesson of figure 9.1 is that profiling must precede optimization: applying operator fusion to a compute-bound workload, or precision engineering to an overhead-bound one, yields zero improvement regardless of implementation quality. Misdiagnosis is not only wasted effort; a performance change shipped blind can move the system to the wrong point on its operating boundary.

That boundary is the **efficiency frontier**, the Pareto-optimal curve of model quality vs. system throughput. A model on the frontier cannot improve throughput without sacrificing quality, or vice versa. Thompson et al. (2021) show why this frontier matters for deep learning: quality improvements have required rapidly increasing compute, making efficiency gains central to continued progress. Performance engineering pushes the frontier outward by making each quality level achievable at higher throughput, or equivalently, by making each throughput level achievable at higher quality. An organization’s goal is not merely to reach the frontier but to find the point on it that best matches their latency, throughput, cost, and quality requirements.

The multi-dimensional nature of this frontier makes optimization challenging. Table 9.1 identifies the five dimensions that performance engineers must balance before choosing an optimization target.

Table 9.1: Efficiency Frontier Dimensions: Performance optimization balances measurable throughput, latency, cost, quality, and memory constraints rather than a single hardware-utilization number.

Dimension	How it is measured	What it constrains	Typical tension
Throughput	Tokens/second or requests/second	How much work the system completes per unit time	Larger batches improve throughput but often degrade latency
Latency	Time-to-first-token and inter-token latency	How quickly the system responds to individual requests	Lower latency can require smaller batches and higher per-token cost
Cost	Dollars per million tokens	Economic efficiency of the system	Cheapest configurations may miss latency or quality targets

Dimension	How it is measured	What it constrains	Typical tension
Quality	Perplexity, benchmark accuracy, or human preference	Accuracy and usefulness of model outputs	Precision reduction and speculation require quality guardrails
Memory	Peak GPU memory	Feasible batch size and sequence length	Larger contexts and batches consume capacity needed for model state

The dimensions in table 9.1 interact in nonobvious ways. Increasing batch size improves throughput and cost efficiency but degrades latency. Reducing precision improves throughput and memory but may degrade quality. Speculative decoding improves latency but may increase per-token cost. The performance engineer’s task is to navigate these trade-offs guided by the application’s specific requirements.

A real-time chatbot prioritizes latency (time-to-first-token under 200 ms, inter-token latency under 50 ms) and may tolerate higher per-token cost. A batch processing pipeline for document summarization prioritizes throughput and cost, tolerating seconds of latency. A medical diagnostic system prioritizes quality above all else, accepting lower throughput and higher cost. Each application maps to a different optimal point on the efficiency frontier, and the performance-engineering toolbox provides the methods for reaching that point. To make this concrete, consider two deployment configurations for the same 70B large language model (LLM).

Configuration A is latency-optimized: FP16 weights, batch size 1, speculative decoding enabled. The model replica produces approximately 50 tokens/second with 20 ms inter-token latency while occupying 8 H100 GPUs for a single user stream. Cost: approximately \$0.12 per 1,000 output tokens.

Configuration B is throughput-optimized: INT4 weights, batch size 64, no speculation. Each H100 serves approximately 4,000 tokens/second aggregate throughput across all batched requests, with 120 ms inter-token latency per request. Cost: 4 GPUs serving 64 concurrent users, approximately \$0.002 per 1,000 output tokens.

Configuration B achieves $60\times$ lower cost per token than Configuration A, but at $6\times$ higher latency. Neither configuration is objectively “better”; they represent different points on the efficiency frontier, optimized for different applications. Performance engineering is the discipline of navigating between these points.

9.1.2 The memory wall

The efficiency frontier establishes what we are optimizing toward. The physics of memory bandwidth determines where we start. Many accelerator-based ML performance problems begin with the same observation: memory bandwidth, not compute, is the bottleneck. Consider a single autoregressive decoding step in a large language model. The model reads its full weight matrix from High Bandwidth Memory (HBM)¹ to generate a single token, performing only one or two multiply-accumulate operations per weight loaded.

An NVIDIA H100 delivers 1979 TFLOP/s of FP8 compute but only 3.35 TB/s of memory bandwidth. If every byte loaded from memory does fewer than 590.7 FLOP/byte arithmetic operations, the compute units sit idle, starved for data. This gap between compute capability and memory delivery rate is the memory wall, and it defines the landscape within which all performance engineering operates.

The memory wall represents a fundamental physical constraint rather than a temporary engineering limitation. Moving data costs energy proportional to distance. Accessing a value from on-chip SRAM (L1 cache) costs approximately 0.5 pJ, while fetching the same value from off-chip HBM costs roughly 640 pJ, a ratio of $1280\times$. Manufacturing constraints limit the amount of SRAM that can sit close to the compute units. HBM provides capacity (the H100 offers 80 GB) but at physically greater distance, requiring the data to traverse longer wires. The fundamental tension is that models need gigabytes of parameters and state, but physics dictates that only kilobytes of data can be near the compute units at any given moment.

The capacity-bandwidth tension shapes the optimization space. Operator fusion reduces the number of trips to HBM by combining operations so that intermediate results stay in SRAM. Precision engineering reduces the number of bytes per trip by representing values in FP8 or INT4 instead

¹ **HBM (High Bandwidth Memory):** Achieves its bandwidth by vertically stacking DRAM dies connected through thousands of through-silicon vias (TSVs), a 3D packaging technique first commercialized by SK Hynix in 2013. Despite the “high bandwidth” label, HBM’s 3.35 TB/s on the H100 is still $200\text{--}600\times$ slower than on-chip SRAM access, making the memory hierarchy gap the central constraint of performance optimization.

Access energy climbs from registers out to HBM.

of FP16. Tiling strategies restructure algorithms to maximize data reuse within SRAM. Graph compilers automate these transformations. Each technique attacks a different term in the same fundamental equation: minimize the ratio of bytes moved to operations performed.

9.1.3 The GPU memory hierarchy

To understand why the memory wall exists, consider the physical structure of a GPU memory system. Table 9.2 summarizes the four levels by scale, access cost, and the optimization constraint each one imposes.

Table 9.2: GPU Memory Hierarchy Constraints: Faster GPU storage is smaller, closer to the compute units, and more explicitly managed, while HBM supplies capacity at much higher latency and energy cost.

Level	Scale on H100	Access cost	Optimization constraint
Registers	256 KB per SM across 132 SMs, about 33 MB total	One clock cycle and ~0.01 pJ per access	Private to each thread; FP32 accumulators can force register spilling to L1/shared memory at 20–30 clock cycles per access
Shared memory (SRAM)	Up to 228 KB configurable shared memory per SM	20–30 clock cycles (~20 ns) and ~0.5 pJ per access	Shared within a thread block; operator fusion is profitable when intermediates fit here instead of returning to HBM
L2 cache	50 MB on-chip buffer	About 200 clock cycles (~130 ns)	Captures reuse automatically across SMs but cannot be explicitly managed by kernel authors
High Bandwidth Memory (HBM)	80 GB at 3.35 TB/s bandwidth	About 300 ns and 640 pJ per access	Supplies model and activation capacity, but reading the full device takes about 24 ms, far longer than real-time inference latency targets

The table makes register pressure a first-class design constraint in custom Triton and CUDA kernels: tile size controls both arithmetic intensity and register demand. It also explains why shared memory and L2 reuse matter so much for attention. If KV cache entries or fused intermediates remain on chip, the kernel avoids the slow, high-energy HBM round trip that dominates low-arithmetic-intensity operations.

The energy cost of data movement has a direct economic consequence at data center scale. Consider a training cluster of 1,000 H100 GPUs, each performing approximately 10^{12} memory accesses per second during a memory-bound workload. If each access reads from HBM at 640 pJ, the memory subsystem alone consumes approximately 640 W per GPU, a significant fraction of the H100's 700 W TDP. If operator fusion moves half of those accesses from HBM to SRAM (at 0.5 pJ each), the per-GPU memory power drops by approximately 320 W. Across 1,000 GPUs, this saves 320 kW, equivalent to powering roughly 250 homes. This is not a secondary consideration; at cloud electricity prices, the annual cost difference is substantial, and it scales linearly with cluster size. The physics of data movement is not merely a performance constraint; it is an economic one.

The performance engineering challenge reduces to a data placement problem: keep the data that the compute units need in the fastest memory that can hold it. When a kernel reads a tensor from HBM, processes it, and writes the result back to HBM, the HBM round-trip dominates execution time for any operation with low arithmetic intensity. Every technique here shares the same goal: keeping data closer to compute for longer.

Systems Perspective 9.1: Analogy: The scholar's library

The GPU memory hierarchy parallels a scholar researching in a library:

- **Registers** (33 MB) are *working memory*: instant access, but capacity is small enough to hold only a few values at once.
- **Shared Memory (SRAM)** is a *desk*: very fast to reach, but capacity fits only a few open references.

- **L2 Cache** (50 MB) is a *book cart* beside the desk: a small access cost, holding a moderate working set.
- **HBM** (80 GB) is the *library basement*: holds everything that could be needed, but each round trip costs hundreds of nanoseconds.

Performance engineering is the art of minimizing trips to the basement.

9.1.4 The widening gap

The memory wall is not static; in the accelerator generations compared here, compute throughput has grown faster than off-chip memory bandwidth. Memory bandwidth improves more slowly because the physics of off-chip signaling and the economics of HBM manufacturing limit how fast data can leave the chip.

Table 9.3 quantifies how the hardware balance shifts across accelerator generations. The key column is the ridge point: as compute grows faster than bandwidth, more operators need higher arithmetic intensity just to remain compute-bound.

Table 9.3: The Widening Memory Wall: Compute throughput has increased 18× from V100 to B200 over seven years, while memory bandwidth has increased only 8.9×. The ridge point has roughly doubled overall (V100 to B200), pulling more workloads into the memory-bound regime over time, though the per-generation movement is not monotonic (B200 sits slightly below H100).

GPU	Year	Peak FP16 (TFLOP/s)	HBM BW (TB/s)	Ridge Point (FLOP/byte)
V100	2017	125	0.9	139
A100	2020	312	2.04	153
H100	2022	989	3.35	295
B200	2024	2,250	8	281

For the FP16/BF16 table as written, the ridge point increased from 139 FLOP/byte on the V100 to 281 FLOP/byte on the B200, about a 2× increase. An operation with arithmetic intensity of 200 FLOP/byte was compute-bound on the V100 and A100, but memory-bound on the H100 and B200. Performance engineering techniques targeting memory efficiency, fusion, precision, and tiling therefore become more important as the ridge point rises, not less. The systems lesson is not that one named kernel lasts forever, but that reducing exposed memory traffic becomes more valuable when compute grows faster than bandwidth.

9.1.5 The roofline model

Section 2.3.2 introduced the Roofline Model² (Williams et al. 2009) and arithmetic intensity as the framework for diagnosing whether a workload is compute-bound or memory-bound on a given accelerator, and computed the H100’s ridge point. We recall it here only to push it to fleet scale: how the ridge point shifts across hardware generations, how FP8 moves it, where production ML workloads fall relative to it, and how batch size walks a workload across it. As a reminder, the model plots achievable performance as a function of arithmetic intensity, the ratio of floating-point operations to bytes transferred from memory, and the intersection of the two regimes is the ridge point³.

Definition 9.1: Arithmetic intensity

Arithmetic Intensity (I) is the ML workload ratio of floating-point operations performed to the number of bytes transferred from memory (FLOP per byte).

1. **Significance:** It characterizes the computational density of a workload. It is the independent variable in the Roofline Model, determining whether a system operates in the bandwidth-bound (BW) or compute-bound (R_{peak}) regime.

² | **Roofline Model:** The original framing targets multicore CPUs, but the same ceiling diagram applies to accelerators: two numbers (peak FLOP/s and peak bandwidth) define the entire performance envelope. This same simplicity informs GPU purchasing decisions for ML inference, where the ridge point determines whether a workload benefits from faster compute or faster memory.

³ | **Ridge Point:** The intersection of the memory-bound and compute-bound lines on a Roofline plot. It represents the minimum arithmetic intensity required to reach peak hardware performance (R_{peak}). For an H100 GPU (FP16), the ridge point is roughly 295 FLOP/byte; if an operator’s intensity is below this “ridge,” it will never saturate the Tensor Cores, regardless of how much compute is available.

2. **Distinction:** Unlike peak throughput (a hardware property), arithmetic intensity is an algorithmic property that measures how effectively a workload reuses data once it is loaded into the processor.
3. **Common pitfall:** A frequent misconception is that arithmetic intensity is fixed for a model. In reality, it varies by implementation: techniques like operator fusion increase arithmetic intensity by keeping data in local registers, while increasing batch size increases arithmetic intensity for layers with high parameter reuse.

For a given accelerator with peak compute R_{peak} (in FLOP/s) and peak memory bandwidth BW (in bytes/s), equation 9.2 gives the achievable performance of a workload with arithmetic intensity I (in FLOP/byte):

$$\text{Achievable FLOP/s} = \min(R_{\text{peak}}, \text{BW} \times I) \quad (9.2)$$

Equation 9.3 locates the ridge point where these two limits intersect:

$$I_{\text{ridge}} = \frac{R_{\text{peak}}}{\text{BW}} \quad (9.3)$$

Workloads with $I < I_{\text{ridge}}$ are memory-bound: their performance is limited by how fast data can be loaded, not how fast it can be processed. Workloads with $I > I_{\text{ridge}}$ are compute-bound: the arithmetic units are the bottleneck. Figure 9.2 illustrates this relationship graphically.

H100 SXM5 reference: 3.35 TB/s HBM3 bandwidth · 2,000 TFLOP/s FP8 Tensor Core

Figure 9.2: The Roofline Model: Achievable performance (y-axis) as a function of arithmetic intensity (x-axis) on a log-log plot. The sloped line represents the memory bandwidth ceiling; the flat line represents the compute ceiling at the labeled precision (FP8 tensor-core throughput on H100, approximately 1979 TFLOP/s); their intersection is the ridge point at roughly 590.7 FLOP/byte for FP8. Most transformer inference operations fall in the memory-bound region (left of the ridge point), while large batched GEMMs fall in the compute-bound region (right). The corresponding FP16 ridge point is roughly 295 FLOP/byte (989 TFLOP/s divided by 3.35 TB/s).

The ridge point of the NVIDIA H100 at FP16 precision follows directly from the same peak-compute and bandwidth values used in table 9.3:

$$I_{\text{ridge}}^{\text{H100, FP16}} = \frac{989 \text{ TFLOP/s}}{3.35 \text{ TB/s}} \approx 295 \text{ FLOP/byte}$$

Any operation performing fewer than 295.2 FLOP/byte floating-point operations per byte loaded is memory-bound on the H100 at FP16. At FP8 precision, where compute doubles to 1979 TFLOP/s and bandwidth remains 3.35 TB/s, the ridge point rises to approximately 590.7 FLOP/byte. The A100, with 312 TFLOP/s and 2.04 TB/s, has a lower ridge point of approximately 153 FLOP/byte at FP16. Across the generations in table 9.3, compute has outgrown bandwidth and the ridge point has roughly doubled (V100 to B200), so more workloads fall into the memory-bound regime over time; the per-generation movement is not monotonic, however, because each chip pairs its own compute and bandwidth (the B200 ridge sits slightly below the H100). The durable trend, not any single step, is what makes memory-efficiency techniques more valuable as hardware advances.

Figure 9.3 overlays the roofline models for four GPU generations on a single log-log plot, making the generational ridge-point shift tabulated earlier visible at a glance. An operation like naive self-attention, with an arithmetic intensity near 10 FLOP/byte, is memory-bound on every generation and falls progressively further below the ridge with each new chip. More critically, operations near 200 FLOP/byte, such as some matrix multiplications and fused blocks, can change regime as hardware changes. The same kernel can change performance regime across hardware generations, a fact that demands re-profiling whenever hardware is upgraded.

Figure 9.3: The Shifting Roofline Across GPU Generations: Overlaid FP16/BF16 roofline models for V100 through B200 show the ridge point growing from 139 to 281 FLOP/byte. Operations near 200 FLOP/byte can change regime as the roofline shifts. The same kernel can change performance regime across hardware generations.

9.1.6 Where ML workloads fall

ML operations span three orders of magnitude in arithmetic intensity, and the position of each operation on the roofline determines which optimization strategies apply.

Large general matrix multiply (GEMM) operations are the most compute-intensive operations in ML. A square matrix multiplication of dimension 4096×4096 in FP16 performs approximately 137.4 billion FLOPs while loading roughly 100.7 MB of data, yielding an arithmetic intensity of

approximately 1365.3 FLOP/byte. This sits well above the H100's ridge point, making large GEMMs firmly compute bound.

Element-wise operations tell the opposite story. A Gaussian Error Linear Unit (GELU) activation applied to a 4096×4096 tensor performs roughly 5 operations per element but must load and store each element, yielding an arithmetic intensity of approximately 1.2 FLOP/byte. The GPU spends almost all its time waiting for data transfers rather than computing, making these operations profoundly memory-bound.

Autoregressive LLM decoding at batch size one represents the extreme case. Each decoding step reads the entire weight matrix (gigabytes of data) to produce a single output token. With a hidden dimension of 4096 and batch size 1, the arithmetic intensity is approximately 1 FLOP/byte, deep in the memory-bound regime. The arithmetic intensity explains why LLM token generation achieves a tiny fraction of peak FLOP/s: the GPU spends nearly all its time reading weights, not multiplying them.

Table 9.4 reveals the central pattern behind these examples: batched GEMM can reach the compute-bound regime, but attention, element-wise work, and batch-1 decode sit below the ridge point and are governed by bytes moved rather than FLOPs advertised.

Table 9.4: Arithmetic Intensity of Common ML Operations: Many transformer inference operations, aside from large batched GEMMs, fall below the H100's ridge point and are therefore memory-bound. Performance engineering focuses on reducing the memory traffic of these operations.

Operation	Arithmetic Intensity	H100 FP16 Regime	Primary Bottleneck
GEMM (4096×4096)	~1,365 FLOP/byte	Compute-bound	Tensor core throughput
Self-Attention (seq=2048)	~50–200 FLOP/byte	Memory-bound	HBM bandwidth
Element-wise (GELU, LayerNorm)	~1–3 FLOP/byte	Memory-bound	HBM bandwidth
LLM Decode (batch=1)	~1–2 FLOP/byte	Memory-bound	HBM bandwidth

The majority of operations in a transformer inference pipeline are memory-bound. Training workloads with large batch sizes shift more operations into the compute-bound regime because GEMM dimensions scale with batch size. Inference, however, especially autoregressive generation, is dominated by memory-bound operations. Fusion, tiling, reduced precision, and algorithmic shortcuts all target the same fundamental problem: reducing bytes moved per operation.

The memory-bound nature of inference also explains a common source of confusion: GPU benchmarks reporting peak TFLOP/s often fail to predict real inference performance. Two GPUs with different TFLOP/s but identical memory bandwidth will achieve virtually identical LLM decode throughput at batch size 1, because decode is entirely memory bound. The correct metric for comparing GPUs for LLM inference is not FLOP/s but rather the combination of memory bandwidth and memory capacity. Bandwidth determines the token generation rate, and capacity determines the maximum batch size (and therefore throughput). Only at large batch sizes, where decode approaches the compute-bound regime, do the FLOP/s differences between GPUs translate into throughput differences.

9.2 Serving Regimes: Batch Size and Prefill-Decode

Diagnosis locates a workload on the roofline; the serving regime determines which knobs move it. Two structural features of LLM inference, the batch dimension and the split between prompt processing and token generation, decide whether decode stays pinned to the memory-bound slope or climbs toward the compute roof. Both are levers the rest of the chapter's techniques act through.

9.2.1 Batch size as the universal control knob

For memory-bound LLM serving, batch size is often the first performance lever to test, and also one of the most constrained. Increasing the batch size transforms the arithmetic intensity of every operation. For an LLM decode step, the arithmetic intensity scales linearly with batch size:

$$I_{\text{decode}}(B) = \frac{2PB}{Ps_{\text{param}} + Bd_{\text{model}}s_{\text{elem}}}$$

Here, P is parameter count, B is batch size, d_{model} is hidden width, s_{param} is bytes per stored parameter, and s_{elem} is bytes per activation element. At batch size 1, the denominator is dominated by the weight term (Ps_{param}), and $I \approx 2/s_{\text{param}} \approx 1$ FLOP/byte for FP16. At batch size 256, the weight term still dominates, but the same weight bytes are amortized across more requests, so $I \approx 2 \times 256/s_{\text{param}} \approx 256$ FLOP/byte, approaching the compute-bound regime.

At large batch sizes, the GPU transitions from memory-bound to compute-bound, and utilization increases dramatically. A single H100 achieving 5 percent utilization at batch size 1 may achieve 40 percent utilization at large batch sizes. The economic implication is stark: the cost per token decreases by roughly $8\times$ as batching carries the workload from the memory-bound to the compute-bound regime.

The constraint is memory: each additional request in the batch requires its own KV cache (the per-request store of attention keys and values for every token generated so far), and the total KV cache across all requests must fit in GPU memory alongside the model weights. The 70B-model-on-8-H100 deployment introduced here is the chapter's recurring example, revisited with full quantitative detail in the precision dividend (section 9.4.3) and the case study (section 9.10.3). A 70B model with 140 GB of weights in FP16 must be sharded across multiple GPUs; on an 8-GPU node that leaves about 62.5 GB per GPU for KV cache before overhead. The precision engineering techniques in this chapter address exactly this constraint: INT4 weight quantization reduces the per-GPU weight footprint to about 4.4 GB and frees roughly 13 GB per GPU for KV cache, enabling batch sizes that transform the economics of serving.

A serving scheduler can keep the effective batch full by adding new requests as older requests finish, but that policy only works when memory is available for the active requests. Performance engineering's role is to make that scheduler's job feasible by minimizing the per-request memory footprint, primarily through KV cache compression and weight quantization. Inference serving (Chapter 10) develops the full scheduler; the local point here is that memory optimization expands the batch sizes the scheduler can safely admit.

A critical enabler for large batch sizes is **PagedAttention**⁴, vLLM's paged KV cache management technique (Kwon et al. 2023). Traditional KV cache implementations preallocate contiguous memory for each request's maximum possible sequence length.

If the maximum is 4,096 tokens but the average is 500, approximately 88 percent of the allocated memory is wasted. PagedAttention divides the KV cache into fixed-size blocks (pages), allocated on demand as the sequence grows. This eliminates memory fragmentation and enables near-100 percent utilization of the KV cache memory budget. The performance impact is indirect but substantial: by reducing memory waste, PagedAttention enables $2\text{--}4\times$ larger effective batch sizes, which in turn improve throughput and GPU utilization through the batch size mechanism described earlier.

PagedAttention and KV cache quantization interact multiplicatively. PagedAttention reduces memory *waste* (from fragmentation), while quantization reduces memory *usage* (from precision). Together, they increase the effective batch size by $8\text{--}16\times$ compared to a baseline system with preallocated FP16 KV caches, fundamentally changing the economics of LLM serving.

9.2.2 The prefill-decode decomposition

Modern LLM serving systems decompose each request into two distinct phases with fundamentally different performance characteristics. The distinction between these phases drives system architecture and optimization strategy.

The **prefill phase** processes the entire input prompt in parallel. If the prompt contains S tokens, the prefill phase executes a single forward pass over all S tokens simultaneously. The GEMM operations have shape $[S, d_{\text{model}}] \times [d_{\text{model}}, d_{\text{model}}]$, making the batch dimension equal to S . For a prompt of 1024 tokens, this is arithmetically intensive: the arithmetic intensity is approximately $2 \times 1024/2 = 1024$ FLOP/byte for FP16 weights, well into the compute-bound regime. Prefill is therefore limited by Tensor Core throughput, not memory bandwidth.

⁴ **PagedAttention**: Named by direct analogy to OS virtual memory paging, where the OS maps noncontiguous physical pages to contiguous virtual addresses. The vLLM paper presented this insight at SOSP 2023: the same mechanism eliminates internal fragmentation in KV caches, recovering the 60–80 percent of GPU memory wasted by worst-case preallocation (Kwon et al. 2023). This single abstraction transformed LLM serving economics by enabling $2\text{--}4\times$ larger batch sizes without any change to model weights or precision.

The **decode phase** generates output tokens one at a time, autoregressively. Each step has a batch dimension of 1 (for a single request) or the number of concurrent requests (for batched serving). At batch size 1, decode is deeply memory-bound as analyzed in section 9.1.6.

The prefill-decode decomposition has direct implications for system design. A system optimized for prefill (maximizing FLOP/s utilization) would use large matrix sizes and high compute throughput. A system optimized for decode (maximizing bandwidth utilization) would use aggressive quantization and memory optimization. A real serving system must handle both phases, often simultaneously across different active requests.

Disaggregated serving addresses this mismatch by running prefill and decode on separate hardware pools. Here, disaggregation is evidence that prefill and decode have different bottlenecks; Chapter 10 develops the routing, admission-control, and serving-policy machinery. Prefill servers are optimized for compute (fewer, higher-FLOP/s GPUs), while decode servers are optimized for memory bandwidth and capacity (more memory per GPU, aggressive quantization). The KV cache computed during prefill is transferred to a decode server, which handles the subsequent autoregressive generation. This disaggregation allows each phase to use hardware and software configurations tuned for its specific bottleneck.

The performance characteristics of each phase determine which optimization techniques apply. FlashAttention provides its largest gains during prefill, where the quadratic attention computation dominates. KV cache quantization and speculative decoding apply exclusively to the decode phase. Precision engineering (FP8/INT4 weights) benefits both phases, but through different mechanisms: prefill benefits from doubled compute throughput (FP8 Tensor Cores), while decode benefits from doubled effective bandwidth (half the bytes per weight read).

A quick decode calculation shows why the memory wall dominates even when the accelerator has abundant unused FLOP/s.

Napkin Math 9.1: The Roofline diagnostic

Problem: A 70B parameter LLM is deployed on $8 \times$ H100 GPUs with tensor parallelism. At batch size 1, each GPU holds approximately 8.75B parameters in FP16 (17.5 GB of weights). Each decode step reads its weight shard to produce one token. What is the achieved arithmetic intensity, and what is the theoretical maximum token generation rate?

Math:

Step 1: Arithmetic intensity. Each decode step per GPU: $\text{FLOPs} = 2 \times 8.75 \times 10^9 = 17.5\text{B FLOPs}$.
 $\text{Bytes loaded} = 8.75 \times 10^9 \times 2 \text{ bytes} = 17.5 \text{ GB}$.

$$I = \frac{1.75 \times 10^{10} \text{ FLOP}}{1.75 \times 10^{10} \text{ bytes}} = 1 \text{ FLOP/byte}$$

At 1 FLOP/byte, the operation sits far below the H100 ridge point of ~ 295 FLOP/byte: deeply memory-bound.

Step 2: Token rate. Since the operation is memory-bound, performance is limited by bandwidth, not compute:

$$t_{\text{decode}} = \frac{17.5 \text{ GB}}{3.35 \text{ TB/s}} \approx 5.2 \text{ ms per token}$$

This yields approximately 191.4 tokens/s per GPU, or about 191.4 tokens/s for the model (since tensor parallelism does not multiply throughput for memory-bound decode). In practice, overheads from KV cache reads and NVLink synchronization reduce this substantially below the ideal bandwidth-only limit.

Systems insight: At batch size 1, only about 0.3 percent of the H100's FP16 FLOP/s are in use. The improvement paths all attack the same weight-streaming cost: larger batches amortize each weight read across more requests, quantization reduces the bytes read for each weight, and speculative decoding tries to obtain multiple accepted tokens from one target-model weight pass.

The roofline model establishes the physics that constrains all subsequent optimization. The first and most impactful strategy for breaking through the memory wall is keeping data in SRAM instead of round-tripping through HBM.

9.3 Operator Fusion and Kernel Engineering

Consider the simple sequence of operations $Y = \text{LayerNorm}(\text{GELU}(XW + b))$. In a naive implementation, the GPU writes the output of the matrix multiply back to main memory, reads it back for the GELU, writes it out again, and reads it one final time for the LayerNorm. This redundant data movement shatters performance. **Operator fusion** eliminates these intermediate round-trips by keeping results in ultra-fast registers, executing the entire sequence in a single trip to memory.

Systems Perspective 9.2: Analogy: The short-order cook

Imagine a kitchen where one chef chops vegetables, puts them in the fridge (HBM), then another chef takes them out to boil them, puts them back in the fridge, and a third chef takes them out to plate them. This is unfused execution: the bottleneck is not the cooking but the constant walking to the fridge.

Operator fusion assigns the recipe to a single chef who keeps the ingredients on their cutting board (SRAM/Registers) and performs all three steps consecutively without ever returning to the fridge until the final dish is ready.

9.3.1 The kernel launch problem

Each GPU kernel launch involves overhead: the CPU must prepare launch parameters, dispatch to the GPU command queue, and the GPU must schedule thread blocks across its streaming multiprocessors (SMs). For a small element-wise operation on an accelerator such as an H100, this overhead can be 5–20 μs , a time during which a memory-bound kernel might have already completed its useful work. When a transformer layer comprises dozens of small operations (add, multiply, normalize, activate), the cumulative launch overhead becomes significant.

Each unfused kernel must also materialize its output in HBM. Consider a sequence of three operations: $Y = \text{LayerNorm}(\text{GELU}(XW + b))$. Without fusion, this requires three passes through HBM:

1. **GEMM kernel:** Read X and W from HBM, compute $XW + b$, write result Z_1 to HBM.
2. **GELU kernel:** Read Z_1 from HBM, compute $\text{GELU}(Z_1)$, write Z_2 to HBM.
3. **LayerNorm kernel:** Read Z_2 from HBM, compute $\text{LayerNorm}(Z_2)$, write Y to HBM.

Intermediate tensors Z_1 and Z_2 each occupy the same memory as the output Y . For a hidden dimension of 4096 and batch size of 2048 in FP16, each intermediate tensor is 16.8 MB. The unfused execution materializes 33.6 MB of intermediate tensors and performs 67.1 MB of intermediate HBM traffic, writing and then rereading each tensor. A fused kernel avoids that traffic entirely by holding Z_1 and Z_2 in registers or shared memory (SRAM) within the SM. Figure 9.4 contrasts these two execution paths, making the HBM traffic savings visible.

As figure 9.4 makes concrete, fusion reduces HBM round-trips from six to two per layer, a roughly 3 $\times$ reduction in off-chip memory traffic for this layer block. In a naive implementation without operator fusion, executing one transformer layer requires roughly 50 separate kernel launches. If each launch incurs a 10-microsecond overhead, the system spends 500 microseconds purely on dispatch latency. If the actual arithmetic execution of the layer takes only 2 milliseconds, the launch overhead consumes 20 percent of the total wall-clock time, leaving the GPU compute units idle for one-fifth of the inference cycle. This “launch-bound” regime limits the benefits of faster hardware; doubling the GPU’s FLOP/s does nothing to reduce the 500-microsecond fixed cost. Operator fusion addresses this by compiling these 50 discrete operations into a small handful of fused kernels, often reducing the count to 5–10 launches, thereby reclaiming the lost cycles and shifting the workload away from dispatch overhead and back toward the hardware limits captured by the roofline model.

9.3.2 Fusion categories

Fusion is profitable when the HBM traffic it removes is worth the kernel complexity it introduces. The three common categories differ by that trade-off: how much data movement they eliminate, how much synchronization they require, and how often a compiler can apply them automatically.

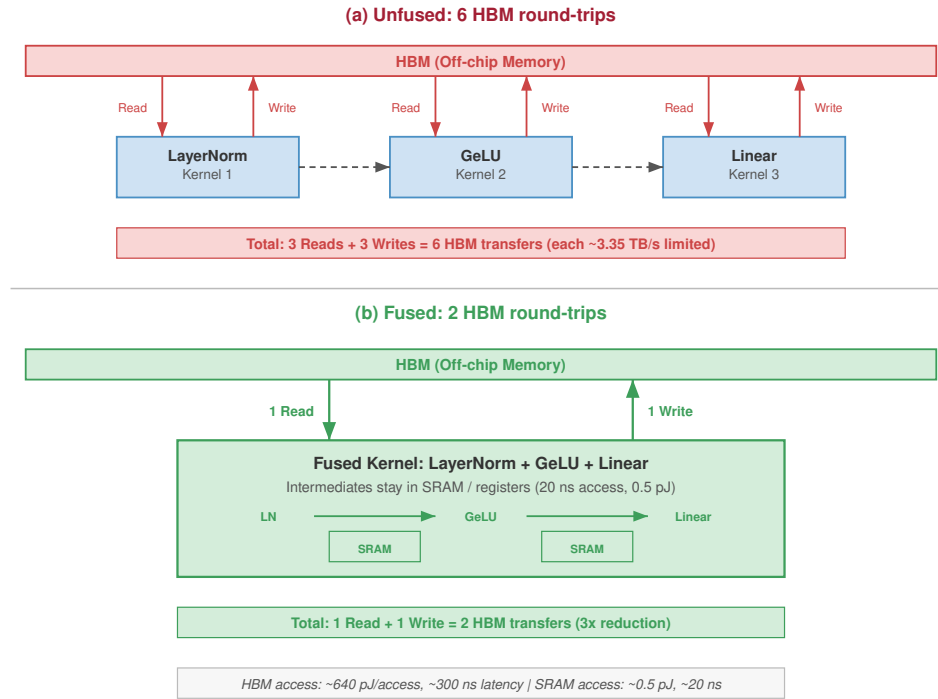

Figure 9.4: Operator Fusion: Before and After: Top: three separate kernels each read from and write to HBM, materializing intermediates Z_1 and Z_2 , with six HBM round-trips along the unfused path. Bottom: a single fused kernel reads inputs once, holds intermediates in SRAM, and writes only the final output, leaving just two HBM round-trips. The fused path delivers roughly a $3\times$ reduction in HBM traffic per layer.

Element-wise fusion sits at the low-complexity end: consecutive element-wise operations (add, multiply, activation functions) combine into a single kernel. Because each output element depends on exactly one input element, this fusion is always legal and straightforward to implement. Deep learning frameworks commonly perform element-wise fusion automatically for supported patterns.

When the sequence includes a reduction, the fusion decision becomes more constrained. Reduction fusion combines an element-wise operation with a subsequent reduction (such as summing elements for a loss function, or computing mean and variance for layer normalization). Reductions require inter-thread communication within the kernel, using warp-level shuffle instructions or shared memory to aggregate partial results across threads. Despite this complexity, the memory savings are substantial: the intermediate tensor before the reduction never materializes in HBM. For layer normalization specifically, reduction fusion avoids writing the large prenormalization tensor to HBM and reading it back for the mean/variance computation.

The highest-payoff case is operator-specific fusion. These are custom kernels designed for a specific sequence of operations, such as fused attention or fused GEMM-bias-activation. The kernel architect must reason about data flow, shared memory allocation, and thread scheduling simultaneously. The payoff is substantial: FlashAttention, which we examine next, removes the quadratic attention workspace and keeps the online softmax state linear in sequence length.

To appreciate the quantitative impact, consider each category applied to a single transformer layer with hidden dimension 4096 and batch size 2048 in FP16. Element-wise fusion of a bias-GELU-dropout chain in this shape eliminates two intermediate tensors of 16.8 MB each, saving 67.1 MB of HBM traffic per layer. Across 80 layers, this reclaims about 5.4 GB of HBM traffic per forward pass. Reduction fusion of LayerNorm avoids materializing large prenormalization tensors and intermediate statistics. Operator-specific attention fusion (FlashAttention) provides the largest single gain by removing the quadratic score and probability matrices that dominate long-context

attention. The cumulative effect of all three fusion categories can remove a large fraction of HBM traffic for a memory-bound transformer forward pass, but the end-to-end speedup must still be verified with profiling because the bottleneck may shift.

9.3.3 CUDA graphs: Eliminating launch overhead

An orthogonal technique for reducing the overhead term in the iron law is **CUDA Graphs**⁵. While operator fusion combines multiple operations into fewer kernels, CUDA Graphs eliminate the CPU overhead of launching those kernels.

In standard PyTorch execution, each kernel launch requires the CPU to push a command to the GPU's command queue. For a transformer decoder layer with 30+ kernels, this CPU-to-GPU roundtrip (typically 5–10 μ s per launch) accumulates to 150–300 μ s per layer. For a 70-layer model, kernel launch overhead alone contributes 10–20 ms per forward pass, a significant fraction of the total time for memory-bound inference.

CUDA Graphs address this by recording a sequence of GPU operations (kernel launches, memory copies) into a replayable graph. The recording happens once during a warmup phase. On subsequent iterations, replaying the graph requires only a single CPU-to-GPU command that dispatches the entire recorded sequence, reducing launch overhead to approximately 5–10 μ s total regardless of the number of kernels.

The benefit is substantial: for a model with 30+ kernels per layer and 70+ layers, the baseline kernel launch overhead can exceed 15 ms per forward pass. CUDA Graphs reduce this to under 0.1 ms, reclaiming 15 ms that translates directly to higher token generation rates.

The constraint is that CUDA Graphs require deterministic execution: the sequence of operations, tensor shapes, and memory addresses must be identical across replays. This conflicts with dynamic inference patterns like variable-length sequences, changing batch sizes, and conditional computation (early exit, MoE routing). In practice, CUDA Graphs are most effective for the decode phase of LLM serving, where the computation pattern is repetitive (same operations per token), and less useful for the prefill phase, where input lengths vary.

The combination of operator fusion (reducing the number of kernels) and CUDA Graphs (reducing the per-kernel overhead) can together eliminate nearly all noncompute overhead from the forward pass. When profiling reveals that kernel launch gaps constitute more than 10 percent of execution time, CUDA Graphs should be the first intervention considered.

9.3.4 FlashAttention: Tiled attention as a system primitive

Standard self-attention computes $\text{Softmax}(QK^T / \sqrt{d_k})V$, where Q , K , and V are matrices of shape [sequence length $\times$ head dimension]. The naïve implementation materializes the full $S \times S$ attention matrix $A = QK^T$ in HBM, where S is the sequence length. For $S = 8192$ and FP16 precision, this matrix alone consumes $8192 \times 8192 \times 2 \approx 134$ MB per attention head, so the quadratic score tensors run to several gigabytes per layer. The canonical accounting below makes this precise for a 64-head Llama-style layer, counting the score and probability traffic alongside the persistent Q , K , V , and output tensors.

FlashAttention (Dao et al. 2022) reformulates attention using tiling. Instead of materializing the full $S \times S$ attention matrix, it processes Q , K , and V in small blocks that fit in on-chip SRAM. The algorithm loads tiles of Q , K , and V , computes partial attention scores, and maintains running statistics (online softmax) to produce the exact result without ever storing the full attention matrix in HBM.

The reduction in materialized attention state is dramatic. For a sequence length of 8192, 64 heads, and head dimension 128 in FP16, the naive implementation materializes and revisits approximately 34.9 GB of HBM-resident tensors for the full layer, or 545.3 MB per head. FlashAttention avoids the quadratic score and probability tensors; its persistent HBM-visible tensors are dominated by Q , K , V , and output Y , totaling approximately 536.9 MB for the full layer, or 8.4 MB per head. This simplified accounting excludes schedule-dependent tile reloads inside a particular kernel, but it captures the important scaling result: a 65 $\times$ reduction in HBM-visible attention state for this configuration.

The key insight behind FlashAttention is the **online softmax**⁶ trick, which makes tiling possible for an operation that appears to require global information. Standard softmax computes $\text{softmax}(s_i) =$

⁵ | **CUDA Graphs**: Introduced in CUDA 10 (2018), originally for graphics rendering pipelines that replay identical command sequences every frame. The strict determinism requirement – identical operations, shapes, and memory addresses per replay – directly conflicts with the dynamic shapes and variable batch sizes of LLM serving, restricting their use primarily to the decode phase where the computation pattern repeats per token.

FlashAttention shrinks attention memory about 65 times.

⁶ | **Online Softmax**: Online here is an algorithmic term meaning the computation processes data incrementally in a single pass without storing the full input – the same sense as in *online learning* or *online algorithms*. This property is what makes tiling possible: the algorithm never needs the complete $S \times S$ score matrix in memory simultaneously, reducing attention memory from $\mathcal{O}(S^2)$ to $\mathcal{O}(S)$ and making long-context inference feasible on fixed-size SRAM.

$e^{s_i} / \sum_j e^{s_j}$, but for numerical stability it first subtracts the global maximum: $\text{softmax}(s_i) = e^{s_i - m} / \sum_j e^{s_j - m}$ where $m = \max_j s_j$. Finding this global maximum seems to require seeing all scores first, which would force materializing the full $S \times S$ matrix.

The online algorithm avoids this by maintaining running statistics that are updated incrementally as each tile is processed. When processing tile t , the algorithm executes four steps:

1. Computes a local block of scores $A_t = Q_{\text{block}} K_t^T$.
2. Updates the running maximum: $m_{\text{new}} = \max(m_{\text{old}}, \max(A_t))$.
3. Rescales the previous running sum and output: multiply by $e^{m_{\text{old}} - m_{\text{new}}}$ to correct for the updated maximum.
4. Computes the local softmax contribution using m_{new} and accumulates into the running output.

After processing all tiles, the running output contains the mathematically equivalent result to the standard algorithm up to the floating-point roundoff of the chosen precision. The rescaling step (step 3) is the critical innovation: it allows the algorithm to “fix up” previous partial results when a new tile reveals a larger maximum value. The algorithm is exact in the mathematical sense, but floating-point execution order can still change the last few bits relative to an unfused implementation.

The cost of this tiling is additional arithmetic: the rescaling operations in step 3 add FLOPs that the standard algorithm does not perform. Because the operation is profoundly memory-bound (standard attention’s arithmetic intensity falls to roughly 1–10 FLOP/byte once its materialized score and probability tensors are counted against the HBM traffic they generate, below the higher regime-dependent figures in table 9.4), the additional compute is “free” in the sense that the GPU’s arithmetic units would otherwise be idle, waiting for HBM data transfers. *Trading extra compute for fewer memory accesses is profitable whenever the operation is memory-bound*, the central principle of this entire chapter.

The mechanism that delivers the materialized-state reduction quantified above is tiling. FlashAttention processes the computation in tiles (typically 128×128 on H100). For one tile, the algorithm loads a block of Q ($128 \times 128 \times 2 \approx 32.8$ KB), a block of K ($128 \times 128 \times 2 \approx 32.8$ KB), and a block of V (32.8 KB), totaling approximately 98.3 KB. This fits comfortably in the H100’s 228 KB of shared memory per SM. The tile score $A_{\text{tile}} = Q_{\text{tile}} K_{\text{tile}}^T$ is computed and consumed entirely within SRAM; it is never written to HBM. The algorithm iterates over $8192/128 = 64$ column tiles for each of 64 row tiles, reloading tiles as required by the kernel schedule. The important point is that the quadratic $S \times S$ score and probability matrices are never materialized: the persistent per-head tensors are Q , K , V , Y , and $\mathcal{O}(S)$ softmax statistics, instead of the hundreds of megabytes of quadratic intermediates the canonical accounting above counted.

FlashAttention-2 (Dao 2023) further optimizes the algorithm for GPU architectures with many streaming multiprocessors by restructuring the parallelism pattern. The original FlashAttention parallelizes over batch and head dimensions, meaning each thread block handles one (batch, head) pair and iterates over the full sequence. FlashAttention-2 additionally parallelizes over the sequence dimension of the query matrix, distributing work across thread blocks more efficiently and achieving better occupancy. It also reduces the number of non-GEMM FLOPs by restructuring the rescaling operations and exploiting the asymmetry between the Q loop (outer) and K/V loop (inner).

Newer FlashAttention-family kernels target Hopper-era hardware features such as FP8 Tensor Cores and the Tensor Memory Accelerator (TMA), a hardware path for asynchronous bulk tensor movement between HBM and shared memory. The systems principle is the same as the original algorithm: as the hardware exposes faster movement and lower-precision execution paths, the attention schedule must be rewritten to use those paths without materializing the quadratic workspace.

The original breakthrough was a change in how engineers understood the bottleneck: the constraint on attention was the memory hierarchy, not the matrix multiplication.

Example 9.1: The FlashAttention breakthrough

Context: In 2022, Tri Dao and coauthors introduced FlashAttention (Dao et al. 2022), showing that the attention mechanism’s performance bottleneck could be treated as an IO-aware data-movement problem rather than only as a matrix multiplication tuning problem.

Mechanism: The bottleneck was memory hierarchy, not compute. Standard attention materialized the massive $S \times S$ attention score matrix in high-latency HBM. FlashAttention restructured the algorithm using tiling to keep running statistics in on-chip SRAM, computing the softmax without ever writing the full matrix to global memory. This reduced memory complexity to linear $\mathcal{O}(S)$ and wall-clock time by $2\text{--}4\times$ on relevant attention workloads.

Systems lesson: FlashAttention matters because it changes where the attention state lives. The durable optimization is not “a faster kernel” but a data-movement reduction that keeps quadratic intermediates out of HBM.

Before turning to the scaling plot, pause on the mechanism: FlashAttention trades a small amount of extra arithmetic for the elimination of quadratic HBM-resident state.

Checkpoint 9.2: FlashAttention mechanics

Verify your understanding of memory-aware attention:

- ☐ **Sequence-length scaling:** Explain why FlashAttention provides a larger speedup for longer sequences (for example, 32K) than for short sequences (for example, 512).
- ☐ **Online softmax storage:** Identify whether the “online softmax” statistics in the FlashAttention algorithm reside in HBM, L2 Cache, or SM SRAM.
- ☐ **FLOPs unchanged:** Evaluate the claim that FlashAttention reduces the total number of floating-point operations (FLOPs) required for attention.
- ☐ **Memory to batch size:** Explain how reducing the attention memory from $\mathcal{O}(S^2)$ to $\mathcal{O}(S)$ enables larger batch sizes for serving.

The $65\times$ figure above is the canonical, full-layer materialized-state reduction; it is the number to carry forward. Figure 9.5 adds only the *scaling shape*: because standard-attention workspace grows quadratically while FlashAttention’s running state grows linearly, the advantage widens with sequence length. The plot’s larger ratios reflect a narrower accounting boundary, comparing only the quadratic score workspace against the linear running statistics rather than the full set of HBM-visible tensors, so they are not directly comparable to the $65\times$ figure; the takeaway is that the gap grows, not its exact value at a given length.

FlashAttention reduces the memory wall within a single GPU by tiling across the SRAM-HBM boundary. For sequence lengths that exceed the memory capacity of a single GPU, the same tiling principle extends across multiple GPUs via Ring Attention (Liu et al. 2023). By distributing the sequence blocks across a ring of accelerators and overlapping communication with computation, Ring Attention enables context windows that would be impractical on single-GPU configurations. Section 5.5.2.3 examines the distributed mechanics of Ring Attention within the broader tensor-parallelism discussion.

9.4 Precision Engineering

Fusion reduces the number of trips through HBM; precision engineering reduces the payload of each trip. Moving FP16 weights through HBM consumes twice as many bytes as FP8. For bandwidth-bound kernels, shrinking weights from 2 bytes to 1 byte can roughly halve weight-read traffic and increase effective memory bandwidth. The engineering decision is where numerical noise can be tolerated to reduce bandwidth pressure and where quality demands higher precision. While section 5.6 examines 8-bit floating point (FP8) as a training-time primitive, here we focus on the quantization techniques that enable efficient inference at scale.

Figure 9.5: FlashAttention Memory Savings: $\mathcal{O}(S^2) \rightarrow \mathcal{O}(S)$. Standard attention allocates the full $S \times S$ score matrix in HBM, while FlashAttention maintains only $\mathcal{O}(S)$ running statistics. The shaded region represents memory freed for KV cache, activations, or larger batch sizes. This workspace-only comparison uses a narrower boundary than the full-layer materialized-state accounting in the text; its point is the widening shape of the gap as context grows, not a headline ratio.

9.4.1 Block-wise quantization

The first inference-side precision decision is how to shrink weights while protecting the channels that carry rare but essential signal. Post-training quantization to INT8 or INT4 delivers even greater bandwidth savings for inference, but LLMs present a unique challenge: **outlier features**⁷. Dettmers et al. (2022) discovered that large language models develop a small number of hidden dimensions (about 0.1 percent of features) with activation magnitudes roughly 3–20 $\times$ larger than the rest. Applying uniform per-tensor INT8 quantization clips these outliers, destroying the information they carry, or expands the quantization range to accommodate them, wasting precision on the majority of near-zero values.

Definition 9.2: Block-wise quantization

Block-wise Quantization is an ML quantization scheme that partitions a weight tensor into nonoverlapping groups of G_{block} elements and computes a per-group scale $s_i = (x_{\max,i} - x_{\min,i}) / (2^b - 1)$, bounding worst-case quantization error within each group independently.

1. **Significance:** With block size $G_{\text{block}} = 64$ and $b = 4$ bits, weights compress from 16 bits to 4 bits (a 4 $\times$ memory reduction) while each FP16 scale adds $16/64 = 0.25$ bits per weight. This yields an effective bit-width of 4.25 bits per weight: 6.25 percent overhead relative to the INT4 payload, or about 1.6 percent of the original FP16 weight size.
2. **Distinction:** Unlike Per-Tensor Quantization, which applies a single scale across the entire weight matrix and forces that scale to accommodate outlier values at the cost of wasting precision on the majority of near-zero weights, Block-wise Quantization contains outlier damage within individual blocks, preventing a single extreme value from degrading quantization fidelity for the whole tensor.
3. **Common pitfall:** A frequent misconception is that block size is a free hyperparameter. Smaller blocks ($G_{\text{block}} = 32$) reduce quantization error but double the metadata overhead

⁷ | **Outlier Features:** Large-scale transformers develop emergent “outlier” dimensions with activation magnitudes up to about 20 $\times$ larger than typical values (Dettmers et al. 2022). While these outliers constitute about 0.1 percent of all features, clipping them during INT8 quantization destroys the model’s reasoning capabilities. This physical property of large models is the reason post-training quantization (PTQ) requires “outlier-aware” strategies like LLM.int8() or Activation-Aware Weight Quantization (AWQ).

vs. $G_{\text{block}} = 64$. At $G_{\text{block}} = 16$, the scale adds 1 bit per weight: 25 percent overhead relative to the INT4 payload, or 6.25 percent of the original FP16 weight size.

The deployment choice is where to pay for outlier protection. Each widely used method protects the same sensitive information, but it moves the cost to a different place in the serving pipeline.

LLM.int8() keeps the outlier cost at runtime by decomposing each matrix multiplication into two parts: a small set of outlier dimensions processed in FP16, and the remaining dimensions processed in INT8. The system identifies outlier dimensions at runtime (those exceeding a magnitude threshold, typically 6.0), routes them to an FP16 GEMM, and routes the remaining dimensions to an INT8 GEMM. The results are combined to produce the final output. This achieves nearly lossless INT8 inference for models that would otherwise degrade substantially under uniform quantization.

GPTQ (Frantar et al. 2023) moves the cost into calibration through weight-only quantization using second-order information. Instead of quantizing each weight independently, GPTQ performs a layer-wise reconstruction pass that uses an approximate Hessian inverse from calibration activations to estimate which quantization errors matter most, then compensates for those errors in the remaining unquantized weights. This produces INT4 weight representations with low accuracy loss for many transformer models. The key insight is that quantization error in one weight can sometimes be offset through correlated weights in the same layer.

AWQ [Activation-Aware Weight Quantization; Lin et al. (2023)] reduces the calibration burden by observing that not all weights are equally important: weights connected to high-activation channels contribute disproportionately to model output. AWQ identifies these salient weights by analyzing activation magnitudes across a calibration dataset, then applies per-channel scaling to protect them before uniform group quantization. This achieves INT4 weight quantization with quality competitive with reconstruction-based PTQ methods while avoiding GPTQ-style Hessian reconstruction.

SmoothQuant (Xiao et al. 2023) shifts the outlier burden from activations to weights before inference. Rather than handling outliers at runtime (LLM.int8()) or through weight optimization (GPTQ, AWQ), SmoothQuant smooths the activation distribution before quantization by migrating the quantization difficulty from activations to weights. The key observation is that activation outliers are channel-specific: certain hidden dimensions consistently produce large values across all tokens. SmoothQuant applies a per-channel scaling transformation that divides the activation by a smoothing factor and multiplies the corresponding weight by the same factor. This mathematically equivalent transformation reduces activation outlier magnitudes at the cost of slightly increasing weight magnitudes, making both tensors more amenable to uniform INT8 quantization. The result is efficient W8A8 (weight-8-bit, activation-8-bit) quantization that exploits INT8 Tensor Cores for both bandwidth and compute benefits.

The practical choice depends on the binding resource and the quality budget. LLM.int8() handles outliers at runtime with mixed-precision decomposition but limits compression to INT8. GPTQ uses second-order information for aggressive INT4 weight compression but requires hours of calibration per model. AWQ reaches similar INT4 quality with minutes of calibration by focusing on activation-aware scaling. SmoothQuant enables W8A8 quantization by preprocessing the weight-activation pairs. For weight-only LLM serving, AWQ is often attractive when calibration time matters; for workloads that need activation quantization and INT8 Tensor Cores, SmoothQuant is the more relevant option.

The choice among these techniques also depends on the deployment target. For GPU inference with Tensor Core support, GPTQ and AWQ produce INT4 weight representations that are dequantized to FP16 during the GEMM computation, using the GPU's FP16 Tensor Cores. For CPU inference or edge deployment, INT8 representations (LLM.int8()) or static per-channel INT8 quantization can directly exploit integer arithmetic units without dequantization overhead.

The storage cost for block-wise quantization is minimal. Storing one FP32 scale (32 bits) for every block of 128 INT8 weights (1024 bits) increases total model size by only 3 percent. This small overhead allows block-wise quantization to isolate the destructive impact of outliers, preserving the effective dynamic range for the 99 percent of normal weights, without the bandwidth penalty of higher-precision formats. At the extreme end of the deployment spectrum, quantization moves from an optimization to a physical necessity. A mobile or federated deployment provides that limiting

case: when the device has only kilobytes or megabytes of memory, precision is no longer a tuning knob after the model is chosen; it is part of the feasibility test.

Lighthouse 9.1: Archetype C (Federated MobileNet): TinyML survival

For Archetype C (Federated MobileNet), quantization is a *prerequisite for survival*, not an *optimization*. On a microcontroller with only 512 KB of SRAM, an FP16 model is physically impossible to load. Binary neural networks (BNNs) and 1-bit quantization push this to the extreme, representing weights as single bits (+1/-1). While this trades significant accuracy, it reduces the weight memory footprint by $16\times$ relative to FP16 ($32\times$ relative to FP32) and the energy per operation by up to $100\times$, enabling intelligence on devices that operate on harvested energy (microwatts).

9.4.2 Post-training vs. quantization-aware training

When a post-training recipe misses the quality budget, the precision decision shifts from calibration to training cost. The trade-off between **Post-Training Quantization (PTQ)** and **Quantization-Aware Training (QAT)** centers on the balance between engineering agility and model fidelity. For a model like Llama-2-70B, PTQ is a common first choice for immediate deployment. Techniques like GPTQ or AWQ process the model layer-by-layer using a small calibration dataset (typically 128–1024 samples) to minimize reconstruction error. This process is computationally cheap, often requiring hours rather than a distributed training run for a 70B model. While PTQ is usually robust at INT8, aggressive quantization to INT4 or INT3 can incur a visible penalty: perplexity may degrade, and reasoning benchmarks such as Massive Multitask Language Understanding (MMLU) can drop several percentage points if the quantization recipe does not protect sensitive layers and outlier channels.

When PTQ fails to meet quality thresholds, QAT provides the remedy by integrating quantization noise directly into the training loop. By simulating low-precision rounding during the forward pass and approximating gradients during the backward pass via the straight-through estimator⁸ (STE), the network learns to adjust its weights to be robust to quantization.

The cost is substantial: QAT is effectively a full fine-tuning run, often requiring hundreds of GPU-hours and a distributed training cluster. For a 70B model, this can mean a multi-day multi-GPU job instead of an hours-scale PTQ calibration run. Adapter-based quantized fine-tuning narrows the gap by freezing the low-precision base model and updating only small low-rank adapter matrices rather than all model weights. This hybrid approach offers some of the quality recovery of QAT with a memory footprint small enough to run on much smaller hardware, but it is a task-adaptation remedy rather than a universal replacement for full quantization-aware retraining.

In many deployment environments, a practical workflow follows a two-stage approach: deploy with PTQ first when it meets quality requirements, then apply QAT or adapter-based quantized fine-tuning if the PTQ model fails at the target precision. This sequence minimizes engineering effort while preserving the option of higher quality when needed.

9.4.3 Weight-only vs. weight-activation quantization

The final precision choice is whether the optimization should stop at the weights or include activations as well. Weight-only quantization (GPTQ, AWQ) reduces weight precision to INT4 or INT3 while keeping activations in FP16. During a GEMM, the INT4 weights are dequantized to FP16 on-the-fly, and the computation proceeds using FP16 Tensor Cores. The benefit is reduced memory for weight storage and reduced HBM bandwidth for weight reads, but the GEMM itself still operates at FP16 precision. This approach is ideal for memory-bound inference (batch size 1 decode), where the bottleneck is reading weights from HBM.

Weight-activation quantization (SmoothQuant, FP8 training) reduces both weights and activations to lower precision, enabling the GEMM to execute using lower-precision arithmetic (INT8 Tensor Cores, FP8 Tensor Cores). This provides both bandwidth and compute benefits but is more challenging to implement without quality degradation, because activation distributions are more dynamic and harder to quantize than weight distributions.

⁸ | **Straight-Through Estimator (STE):** Discussed by Bengio et al. (2013) for hard stochastic neurons, the STE handles a fundamental calculus problem that also appears in quantization: the gradient of a rounding function is zero almost everywhere, making backpropagation through quantized layers impossible by standard rules. The STE passes the upstream gradient through the rounding step as a surrogate gradient, pretending the rounding did not happen. This approximation is useful in practice for training networks with discrete or quantized operations, but it is a heuristic rather than a general convergence guarantee for every QAT setup.

The choice depends on the operational regime. For memory-bound inference (small batch sizes), weight-only INT4 quantization often provides the largest speedup per unit of quality degradation. For compute-bound inference (large batch sizes) or training, weight-activation FP8 quantization provides throughput gains that weight-only quantization cannot match. High-performance serving systems often use different quantization strategies for different operating points: INT4 weight-only at low batch sizes (for latency) and FP8 weight-activation at high batch sizes (for throughput).

The same precision problem extends to the key-value (KV) cache, which determines whether weight savings become larger batches. In decode, weights may be compressed aggressively while per-request cache state still grows with sequence length, so a precision change that leaves the cache untouched may fail to move the serving bottleneck. Numerical compression reduces the bytes stored per cached key or value, while grouped query attention (GQA) reduces how many key-value heads must be cached for each layer. Both mechanisms matter because the scheduler admits requests against the combined memory footprint of weights plus active cache state. The calculation below isolates the local capacity effect before Chapter 10 returns to full serving policy.

A capacity calculation makes the serving impact of precision choices concrete.

Napkin Math 9.2: The precision dividend

Problem: A 70B parameter model is served on $8 \times$ H100 GPUs. The model weights in FP16 consume 140 GB (17.5 GB per GPU). KV cache at FP16 consumes 1.34 GB per request. How does quantizing weights to INT4 and KV cache to INT8 change the maximum batch size?

Before optimization (all FP16):

- Weights: 17.5 GB/GPU
- Available for KV cache: $80 \text{ GB} - 17.5 \text{ GB} = 62.5 \text{ GB/GPU}$
- KV cache per request: 1.34 GB total, or approximately 0.17 GB/GPU
- Maximum batch size: approximately 372 requests

After optimization (INT4 weights, INT8 KV cache):

- Weights: $17.5 \text{ GB} \times (4/16) = 4.4 \text{ GB/GPU}$ (INT4)
- Available for KV cache: $80 \text{ GB} - 4.4 \text{ GB} = 75.6 \text{ GB/GPU}$
- KV cache per request (INT8): approximately 0.67 GB total, or 0.08 GB/GPU
- Maximum batch size: approximately 901 requests

Systems insight: Precision engineering changes serving economics by enabling larger batch sizes. Larger batches amortize the fixed cost of weight loading, shifting operations from memory-bound toward compute-bound. This single optimization can increase throughput by 2.4 $\times$ or more.

Precision engineering reduces the bytes per memory transaction. Operator fusion reduces the number of transactions. Together, they attack the same fundamental bottleneck from complementary directions: when data must traverse a slow bus, *move less of it* (precision) and *move it fewer times* (fusion). The multiplicative interaction between these two techniques explains why high-performance serving stacks often deploy both simultaneously: FlashAttention removes the quadratic attention intermediates, and INT8 KV cache compression further halves the remaining KV-cache bytes. The combined effect exceeds what either technique achieves alone. Because these fusion and precision patterns recur across stable layer structures, the next question is when a compiler can own the transformations across the whole model graph.

9.5 Graph Compilation

After precision and fusion expose repeatable optimization patterns, graph compilation asks whether those patterns are stable enough for the compiler to own. Manually writing fused CUDA kernels for every possible combination of layers in a massive neural network is a Sisyphean task for human engineers. A graph compiler analyzes the model's computational graph and generates optimized,

hardware-aware machine instructions, transforming high-level PyTorch code into specialized kernels when shape stability and replay volume justify the compilation cost.

Systems Perspective 9.3: Hardware-software co-design

The deeper payoff of compilation is spatial, not just arithmetic. A compiler like XLA or TensorRT reshapes the computation to fit the *physical layout* of the target accelerator: it tiles a matrix multiply to the dimensions of a systolic array, places intermediates to match the memory hierarchy, and routes element-wise work to Vector ALUs while reserving the systolic array for GEMMs. This is what makes heterogeneous execution at scale tractable. The same model graph maps onto different silicon by changing the mapping, not the math.

9.5.1 The compilation pipeline

A graph compiler transforms a high-level model definition (Python code) into optimized hardware instructions through a multi-stage pipeline. To visualize this process, consider a standard transformer FFN block consisting of a projection, an activation, a second projection, and a layer normalization: `LayerNorm(Linear(GELU(Linear(x))))`. In standard PyTorch eager execution, this sequence triggers four separate kernel launches, each reading from and writing to HBM.

In the **graph capture** stage, the compiler traces the model's execution to construct a computational graph, a directed acyclic graph where nodes represent operations and edges represent tensor dependencies. For the FFN block, this results in a graph with four primary nodes plus their associated parameter tensors. Dynamic Python control flow (loops, conditionals) must be handled by either tracing through a representative execution path or by using compiler-specific annotations to mark dynamic dimensions.

During **graph-level optimization**, the compiler applies algebraic simplifications and operation rewriting. It identifies that the bias addition in the first `Linear` layer can be folded into the matrix multiplication kernel. It also recognizes that the GELU activation is an element-wise operation that depends only on the output of the first `Linear`. These standard compiler optimizations can reduce graph size by 10–30 percent before any hardware-specific work begins.

The operator fusion pass is the most critical for performance. It identifies sequences of operations that can be combined into single kernels to reduce memory traffic. For the FFN block, the compiler fuses the GELU activation into the tail of the first `Linear` kernel (if supported as an epilogue) or fuses the GELU and the subsequent `LayerNorm` into a single kernel. Instead of writing the intermediate result of the first `Linear` to HBM and reading it back for GELU, the fused kernel keeps the data in the GPU's SRAM or registers. This typically reduces the number of HBM accesses by 30–50 percent, directly alleviating the memory bandwidth bottleneck.

The memory planning pass determines when to allocate and free tensors. Without optimization, a transformer might allocate separate buffers for every intermediate activation. The compiler analyzes tensor lifetimes, recognizing that the input to the first `Linear` is no longer needed after the second `Linear` computes its output, and reuses the same physical memory addresses. For inference and other forward-only workloads, this buffer reuse can turn peak temporary memory from the sum of many layer-local buffers into the maximum live working set. Training activations that must be saved for the backward pass require checkpointing or rematerialization; ordinary buffer reuse cannot make those saved tensors disappear. Memory planning also interacts with operator fusion: fusing two operations eliminates the intermediate tensor between them, which both removes the HBM traffic and removes the memory allocation. The compiler must reason about both effects jointly to make profitable decisions.

The kernel selection pass maps each fused operation to a specific machine code implementation. For the computationally heavy linear projections, the compiler selects a vendor-optimized cuBLAS or CUTLASS GEMM kernel. For the fused GELU-`LayerNorm` sequence, it generates a custom Triton kernel that keeps data in SRAM. The result for the FFN block is a reduction from 4 separate kernels to 2 highly optimized kernels, with a corresponding reduction in global memory traffic.

9.5.2 torch.compile

For workloads already written in PyTorch, `torch.compile` is the least disruptive compiler intervention: it tries to capture enough static graph to fuse memory-bound regions while preserving PyTorch’s dynamic Python execution model. It operates through three components: **TorchDynamo** for graph capture, **TorchInductor** for code generation, and **AOTAutograd** for ahead-of-time backward graph construction when training workloads need compiled backward passes.

TorchDynamo operates at the Python bytecode level⁹, a design choice that distinguishes it from earlier tracing approaches. Previous tracing methods (`torch.jit.trace`, `torch.fx`) operated at the Python source or abstract syntax tree (AST) level, requiring users to avoid unsupported Python constructs. TorchDynamo intercepts the bytecode interpreter itself, capturing a computational graph without requiring the user to modify their model code. When TorchDynamo encounters Python constructs it cannot trace (data-dependent control flow, unsupported operations), it inserts a **graph break** that splits the trace into multiple subgraphs, each compiled independently. The goal is to capture as large a subgraph as possible while gracefully handling dynamic Python behavior.

TorchInductor generates optimized Triton kernels (for GPU) or C++/OpenMP code (for CPU) from the captured graph. Triton is a domain-specific language for writing GPU kernels in Python-like syntax, abstracting away thread block management and memory coalescing while still exposing tiling and fusion decisions. TorchInductor automatically fuses element-wise operations, reduces memory traffic by combining operations that share inputs, and selects tile sizes through autotuning.

A minimal example illustrates the usage:

```
import torch

def transformer_block(x, w1, w2, ln_weight, ln_bias):
    """Unfused transformer FFN block."""
    h = x @ w1 # Linear projection
    h = torch.nn.functional.gelu(h) # Activation
    h = h @ w2 # Output projection
    # Layer normalization
    mean = h.mean(dim=-1, keepdim=True)
    var = h.var(dim=-1, keepdim=True, unbiased=False)
    h = (h - mean) / torch.sqrt(var + 1e-5)
    h = h * ln_weight + ln_bias
    return h

# Compile the function-TorchDynamo traces, TorchInductor optimizes
compiled_block = torch.compile(transformer_block)

# First call triggers compilation; subsequent calls use compiled code
output = compiled_block(x, w1, w2, ln_weight, ln_bias)
```

In this example, `torch.compile` will fuse the GELU activation with surrounding operations, combine the layer normalization mean/variance/normalize steps into a single kernel, and potentially fuse the bias addition with the preceding GEMM. Model code remains standard PyTorch; the compiler handles the optimization.

9.5.3 XLA and TPU optimization

XLA pays for performance with static structure. Used as the backend for JAX and TensorFlow, it generates the High Level Optimizer (HLO) intermediate representation that targets multiple backends, including Google Tensor Processing Units (TPUs), NVIDIA GPUs, and CPUs. Unlike TorchInductor, which generates Triton code targeting NVIDIA GPUs while preserving more Python flexibility, XLA enforces **whole-program compilation**, tracing the entire computation as a single static graph and enabling global optimizations that span across layers and even across the forward and backward passes.

The global view enables XLA’s most distinctive capability: **General and Scalable Parallelization for ML Computation Graphs (GSPMD)**, where SPMD denotes the single program, multiple data execution model in which every device runs the same program over a different shard of the data. In

⁹ | **TorchDynamo Bytecode Interception:** By hooking CPython’s frame evaluation function (PEP 523, added in Python 3.6), TorchDynamo captures the computation graph at the lowest level of the Python interpreter, below any source-level abstractions. This is why it can trace through decorators, closures, and third-party libraries that defeated earlier tracing approaches. The trade-off is tight coupling to CPython internals: TorchDynamo must be updated for each new Python version, and it cannot run on alternative interpreters like PyPy.

distributed training, GSPMD automatically partitions the computation graph across thousands of TPU cores based on a few high-level user annotations. While a PyTorch user must manually wrap models with `DistributedDataParallel` or `FullyShardedDataParallel`, an XLA user defines the computation for a single device and allows the compiler to infer the necessary communication primitives (`AllReduce`, `AllGather`) and insert them into the graph. This allows for complex hybrid sharding strategies that are difficult to implement manually.

For TPU hardware specifically, XLA performs layout optimizations unavailable on other platforms. It maps matrix multiplications onto the TPU's systolic array architecture, padding dimensions to align with the 128×128 hardware units and scheduling instructions to hide the latency of HBM fetches. The impact of these optimizations is visible in MFU metrics. On large-scale LLM training workloads, highly tuned JAX/XLA TPU runs have reported MFU in the 55–65 percent range, while less-tuned PyTorch/GPU setups can sit lower.

The trade-off for XLA's performance is compilation latency and rigidity. Because XLA must analyze the full static graph, initial compilation can take minutes for large models, compared to seconds for `torch.compile`. Any change in input shape triggers a full recompilation. This makes XLA excellent for steady-state production workloads where the graph is static and the model runs for days or weeks, but challenging for research environments involving dynamic shapes or rapid experimental iteration. The choice between `torch.compile` and XLA often follows the hardware and software stack: NVIDIA GPU workflows commonly start from PyTorch, while TPU workflows commonly use JAX or TensorFlow with XLA.

9.5.4 TensorRT: Inference optimization

NVIDIA TensorRT is a specialized inference compiler that treats the model not as a *flexible program* but as a *rigid global optimization problem*. Because inference requires no backward pass and no gradient storage, TensorRT applies aggressive transformations that would be mathematically invalid or impractically slow for training. It performs a calibration pass where it runs the model on representative data to determine the numerical range of every activation tensor.

This calibration enables **mixed-precision quantization** at a granular level. Blindly quantizing all layers of a 70B parameter LLM to INT8 often degrades perplexity. TensorRT can calibrate INT8 ranges from representative data and can build mixed-precision inference engines when precisions are enabled or constrained; for LLMs, layer-wise fallback policies usually require explicit quantization analysis or user-specified precision constraints. TensorRT also eliminates training-only operations (dropout, batch normalization running statistics updates), optimizes for static shapes by generating kernels tuned for exact dimensions, and plans memory precisely since no gradient tensors are needed.

TensorRT performs **kernel autotuning** far beyond simple heuristics. For every operation in the graph, it benchmarks dozens of candidate kernels, varying tile sizes, thread block configurations, and unrolling factors, on the actual target hardware. It selects the fastest implementation for that specific GPU and input shape. The performance gap between TensorRT and general-purpose compilers can be substantial, especially for stable inference workloads where the engine can specialize aggressively to a fixed shape range and GPU architecture.

The trade-off for TensorRT's aggressive optimization is reduced flexibility and high compilation cost. Compilation times are measured in minutes to hours (30–60 minutes for a 70B model), and the resulting engine is strictly tied to the specific GPU architecture and input shape range. Changing any of these requires recompilation. This makes TensorRT a common fit for stable, high-volume production deployments, while `torch.compile` is often a better fit for development and lower-volume services where rapid iteration matters more than extracting the last percentage of throughput.

9.5.5 Compilation overhead and trade-offs

Graph compilation is not free. The compilation process itself takes time, ranging from seconds for small models with `torch.compile` to minutes or hours for large models with TensorRT's full optimization pipeline. This overhead must be amortized over the number of times the compiled model executes.

For training workloads that run for hours or days, compilation overhead is negligible. For inference workloads that serve millions of requests, the one-time compilation cost is similarly amortized. The

problematic case is dynamic or infrequent workloads: a model that is compiled once but serves only a few hundred requests before being replaced by a new version may not recoup the compilation cost.

Graph breaks are a related challenge specific to `torch.compile`. When TorchDynamo encounters Python code it cannot trace (data-dependent control flow, calls to uncompiled libraries, dynamic tensor shapes that change between iterations), it inserts a graph break. Each break produces a separate compiled subgraph with its own compilation overhead and potential optimization boundaries. A model with 50 graph breaks produces 50+ small compiled regions, each potentially too small for meaningful fusion. Reducing graph breaks requires refactoring the model code to be more “compiler-friendly,” replacing Python control flow with tensor operations and ensuring static shapes where possible.

Dynamic shapes present a fundamental tension between compilation and flexibility. A model compiled for input shape `[batch=32, seq=512]` will recompile when it encounters `[batch=16, seq=1024]`. TorchInductor supports “dynamic shapes” by generating kernels with symbolic dimensions, but this generality comes at the cost of reduced optimization compared to kernels specialized for exact shapes. TensorRT sidesteps this by requiring the user to specify a range of input shapes at compilation time, generating kernels that handle the specified range but nothing outside it.

Despite these limitations, graph compilation remains one of the most accessible optimization techniques: it requires no model modifications, no custom kernels, and minimal code changes. For many stable-shape PyTorch workloads with launch overhead or fusible element-wise regions, a single `torch.compile` call can provide 10–40 percent speedup, making it a natural early optimization to test before considering more specialized techniques.

Graph compilation has reshaped the performance engineering workflow. For workloads that match the compiler’s assumptions, a single line of code can capture a significant fraction of the improvement that once required manual kernel optimization, freeing the engineer to focus on algorithmic and architectural optimizations such as speculative decoding, MoE, and precision engineering that compilers cannot automate. The compiler handles routine graph transformations; the engineer handles the workload-specific design choices. As compiler coverage improves, this division of labor makes the higher-level system design skills in this chapter more valuable relative to routine low-level kernel tuning.

9.5.6 Compilation modes and backends

`torch.compile` mode selection is an amortization decision: spend more compile time only when the workload will replay stable shapes enough times to recover that cost. The `default` mode is the development baseline, applying standard optimizations such as element-wise fusion, memory planning, and pretuned kernel selection with compilation times suitable for iteration. The `reduce-overhead` mode is the launch-bound choice, adding CUDA Graphs (discussed in section 9.3.3) to eliminate kernel launch overhead when small models spend a meaningful fraction of time in dispatch. The `max-autotune` mode is the production specialization choice, benchmarking multiple tile sizes, thread-block configurations, and memory-access patterns per operation to select the fastest kernel; the 10–30 minute compile cost is justified only when a stable deployment will reuse the optimized graph many times.

Backend choice follows the same constraint: the more stable and deployment-specific the workload, the more specialized the runtime can be. TorchInductor (the default) generates Triton kernels for GPU and C++ for CPU. For deployment-specific optimization, the model can be exported through `torch.export` to an intermediate representation that can be consumed by TensorRT, Open Neural Network Exchange (ONNX) Runtime, or other inference-specialized runtimes. Each backend applies its own optimization passes on top of the common graph-level transformations.

9.5.7 The triton language

Between hand-written CUDA and fully automated graph compilers sits **Triton**¹⁰, a Python-based language for writing GPU kernels. Triton occupies a middle ground: the programmer specifies the algorithm (tiling strategy, fusion pattern) while Triton handles low-level concerns (thread block scheduling, memory coalescing, shared memory management).

A Triton kernel for fused GELU activation illustrates the programming model:

¹⁰ | **Triton**: Introduced by Tillet, Kung, and Cox as an intermediate language and compiler for tiled neural-network computations (Tillet et al. 2019), and later developed at OpenAI. The key design decision was making the *tile* – not the *thread* – the fundamental programming abstraction. This choice directly mirrors the tiling strategy of FlashAttention: the programmer reasons about blocks of data that fit in SRAM, and the compiler maps those blocks to GPU threads and shared memory. This abstraction reduces exposure to low-level CUDA concerns such as warp divergence, bank conflicts, and coalescing while preserving control over the memory hierarchy decisions that determine ML kernel performance.

```

import triton
import triton.language as tl

@triton.jit
def fused_gelu_kernel(
    input_ptr,
    output_ptr,
    n_elements,
    BLOCK_SIZE: tl.constexpr,
):
    # Each program instance handles BLOCK_SIZE elements
    pid = tl.program_id(0)
    offsets = pid * BLOCK_SIZE + tl.arange(0, BLOCK_SIZE)
    mask = offsets < n_elements

    # Load input tile from HBM into registers
    x = tl.load(input_ptr + offsets, mask=mask)

    # Fused GELU computation (tanh approximation)
    #  $GELU(x) = 0.5 * x * (1 + \tanh(\sqrt{2/\pi}) * (x + 0.044715 * x^3))$ 
    x_cubed = x * x * x
    inner = 0.7978845608 * (x + 0.044715 * x_cubed)
    gelu = 0.5 * x * (1.0 + tl.math.tanh(inner))

    # Store result back to HBM
    tl.store(output_ptr + offsets, gelu, mask=mask)

```

The programmer thinks in terms of tiles (BLOCK_SIZE elements), not individual threads. Triton compiles this to Parallel Thread Execution (PTX)/SASS instructions, handling thread-to-data mapping, memory coalescing, and register allocation automatically. This makes it feasible for ML engineers (rather than GPU specialists) to write custom fused kernels when the automatic compiler misses a fusion opportunity.

The real power of Triton emerges when fusing multiple operations. A Triton kernel that implements `y = LayerNorm(GELU(x))` loads `x` once from HBM, computes both GELU and LayerNorm in registers/shared memory, and writes `y` once to HBM. Without fusion, this sequence requires three HBM round-trips: read `x`, write `GELU(x)`, read `GELU(x)`, write `norm_input`, read `norm_input`, write `y`. The fused kernel reduces HBM traffic by 3×, and for memory-bound operations, this translates directly to a 3× speedup.

The performance-engineering consequence is that Triton turns many custom fusion opportunities into compiler output. When `torch.compile` identifies a fusion opportunity that requires a custom kernel, TorchInductor automatically generates Triton code for the fused operation. Many of the fusion benefits described in this section therefore come through a single `torch.compile` call, without hand-written Triton code. For advanced cases where the compiler's heuristics miss the bottleneck, hand-written Triton kernels provide a middle ground between the accessibility of PyTorch and the performance of hand-tuned CUDA.

A simple profile breakdown shows how compiler optimizations convert overhead into useful throughput.

Napkin Math 9.3: The compilation dividend

Problem: A 13B parameter model is deployed for inference. Without compilation, the PyTorch eager mode processes 120 tokens/s on a single H100. The Nsight Systems trace reveals that 35 percent of step time is spent in element-wise kernels (LayerNorm, GELU, residual additions) and 15 percent is kernel launch overhead. Applying `torch.compile` with the `max-autotune` backend, estimate the new throughput.

Math:

Step 1: Identify the addressable overhead. Element-wise kernels (35 percent) and launch overhead (15 percent) total 50 percent of execution time. `torch.compile` fuses element-wise operations (reducing their time by approximately 70 percent due to eliminated HBM round-trips) and reduces kernel launches (eliminating most launch overhead).

Step 2: Estimate postcompilation time. Original time per token: $1/120 = 8.33$ ms.

- GEMM time (unchanged): $8.33 \times 0.50 = 4.17$ ms
- Element-wise time (70 percent reduction): $8.33 \times 0.35 \times 0.30 = 0.87$ ms
- Launch overhead (80 percent reduction): $8.33 \times 0.15 \times 0.20 = 0.25$ ms

New time per token: $4.17 + 0.87 + 0.25 = 5.29$ ms, yielding approximately 189 tokens/s.

Systems insight: `torch.compile` delivers a 1.58× speedup by fusing element-wise operations and reducing launch overhead, without touching the GEMM kernels. The remaining bottleneck is now the GEMM itself (79 percent of step time), indicating that further improvement requires either precision reduction or batching.

Graph compilation automates what manual kernel engineering achieves for individual operations, applying it systematically across the entire model graph. It also exposes a boundary: compilers can reorganize known operations, but they cannot invent a different computation. The next section turns to optimizations that cross that boundary.

9.6 Algorithmic Performance Transformations

The preceding sections optimized the same dense computation by moving fewer bytes, using narrower formats, or letting compilers reorganize kernels. Algorithmic transformations change the work itself. Speculative decoding attacks the memory-bound decode loop by trying to accept multiple tokens per target-model pass, while MoE attacks dense-model cost by activating only the experts a token needs. Both techniques can improve the iron-law budget, but both can also create new bottlenecks if their extra control logic, communication, or imbalance exceeds the work they remove.

9.6.1 Speculative decoding

Speculative decoding¹¹ is a latency optimization that breaks the sequential bottleneck of autoregressive generation by using a smaller draft model to predict multiple tokens, which are then verified in parallel by the target model (Leviathan et al. 2023; Chen et al. 2023). The performance-engineering relevance is arithmetic intensity: a single target-model forward pass can process K candidate tokens for roughly the same weight-streaming cost as one token, shifting the decode operating point from the memory-bound slope toward the roofline ridge.

Figure 9.6 contrasts the two decode paths: standard decoding advances one token per sequential target-model pass, while speculative decoding lets the draft model propose a block of K tokens that the target model verifies in a single parallel pass, emitting the accepted prefix together and resampling only at the first rejection.

The transformation is useful only when the draft model is accurate enough and cheap enough. If too many draft tokens are rejected, the target model still loads its weights but accepts little useful work. If the draft model is too expensive, verification becomes compute-bound and erases the bandwidth benefit. Batching changes the calculation as well: at large batch sizes the decode phase is already closer to compute-bound, so the marginal benefit of speculation shrinks. This chapter uses speculative decoding to show how an algorithm can alter the performance equation; section 10.4.6 treats it as a serving policy with admission control and SLA consequences.

Speculative decoding shifts decode toward the compute-bound ridge.

¹¹ | **Speculative Decoding:** The draft model may produce tokens that the target model rejects, so the technique trades extra draft-model compute for reduced target-model memory bandwidth pressure. The target model's weights are loaded from HBM once to process K candidate tokens, effectively increasing the arithmetic intensity of the decode phase by $K\times$ when enough tokens are accepted.

Figure 9.6: Speculative Decoding Process: Instead of generating tokens sequentially with the large target model, a small draft model proposes a sequence of K tokens. The target model verifies all K tokens in a single parallel forward pass. Drafted tokens that pass the acceptance test are emitted together; the first rejected token triggers a corrected sample and discards the remaining draft.

Algorithm 9.1 makes the acceptance test precise: after the single target-model pass, each drafted token is accepted with probability $\min(1, p_\theta/q_\phi)$, and a rejection resamples from the normalized positive residual $(p_\theta - q_\phi)_+$, so the emitted sequence is distributed exactly as the target model would have produced unaided. That correctness guarantee is what lets speculative decoding trade draft-model compute for latency without shifting the output distribution.

Algorithm 9.1 Speculative decoding**Require:** target distribution $p_\theta(\cdot | \cdot)$; draft distribution $q_\phi(\cdot | \cdot)$; prefix $y_{1:t}$; draft length K **Ensure:** one or more new tokens distributed as p_θ

```

1: for  $i = 1$  to  $K$  do
2:   draft  $\hat{y}_{t+i}$  from  $q_\phi(\cdot | y_{1:t}, \hat{y}_{t+1:t+i-1})$ 
3: end for
4: run  $p_\theta$  once on the prefix plus all  $K$  drafts to obtain target distributions for the drafted positions
   and final next-token position
5: for  $i = 1$  to  $K$  do
6:    $a_i \leftarrow \min\left(1, \frac{p_\theta(\hat{y}_{t+i} | y_{1:t}, \hat{y}_{t+1:t+i-1})}{q_\phi(\hat{y}_{t+i} | y_{1:t}, \hat{y}_{t+1:t+i-1})}\right)$ 
7:   accept  $\hat{y}_{t+i}$  with probability  $a_i$ 
8:   if  $\hat{y}_{t+i}$  is rejected then
9:     sample one corrected token from the normalized positive residual  $(p_\theta - q_\phi)_+$ 
10:    emit accepted draft tokens and the corrected token; discard the remaining draft; start a
    new round
11:  end if
12: end for
13: if all  $K$  drafts were accepted, emit them and sample one extra token from the target distribution

```

Speculative decoding pays off when the draft model is cheap and its proposed tokens agree with the target model often enough that one target pass validates several tokens. The limiting cost is the rejection rate: rejected drafts waste draft-model work and shorten the accepted run, so the serving system must tune draft length and draft-model quality together rather than treating speculation as free parallelism.

9.6.2 Mixture of experts

A 1-trillion parameter dense model delivers superior reasoning capabilities, but its latency and compute costs are prohibitive for most serving budgets. The Mixture-of-Experts (MoE) architecture resolves this tension by training a massive model but activating only a small, relevant fraction of it for any given token. By routing inputs to specialized sub-networks, MoE breaks the iron link between model size and inference cost.

For performance engineering, the local question is whether active-parameter savings exceed the costs of routing and communication. Sparse activation improves the iron law budget only when inactive experts stay off the critical path and the router avoids creating a new AllToAll or load-imbalance bottleneck.

A standard MoE transformer layer replaces the feed-forward network (FFN) with multiple parallel “expert” FFNs and a lightweight **router** (also called a gating network) that selects which experts process each token. That architecture shifts the performance problem from dense matrix throughput to routing, memory residency, and load balance. When experts are distributed across GPUs, expert parallelism places different experts on different devices, and an AllToAll exchange moves each token’s hidden state to its assigned expert before returning the result. The active-parameter savings are valuable only if that routing traffic and any expert imbalance remain smaller than the dense compute they replace.

9.7 Communication-Computation Overlap

After changing the local work through fusion, precision, compilation, speculation, or sparse expert routing, the next exposed iron-law term is often communication. Section 6.8 established overlap as the technique that removes communication from the critical path when enough useful compute remains to hide it; this section supplies the single-node mechanics those chapters assumed, namely the CUDA streams, SM partitioning, and bucket hooks that actually run computation and communication concurrently on one accelerator.

Consider a concrete example: a 70B model with tensor parallelism across 8 H100 GPUs. Each transformer layer requires two AllReduce operations (one after attention, one after FFN). Each AllReduce transfers approximately $2 \times d_{\text{model}} \times B \times 2$ bytes at FP16 (where $d_{\text{model}} = 8192$ for a 70B

model and B is batch size). At batch size 1, the data volume is $2 \times 8192 \times 1 \times 2 = 32.8$ KB per AllReduce. At 900 GB/s NVLink bandwidth, this transfer takes approximately 36.4 ns. However, the AllReduce launch overhead (approximately 5 μ s) dominates the actual data transfer time by $100\times$. At batch size 1, the AllReduce overhead is dominated by software launch latency, not bandwidth, and overlap provides limited benefit because there is insufficient compute to hide behind.

At batch size 64, the data volume per AllReduce grows to $2 \times 8192 \times 64 \times 2 = 2.1$ MB, taking approximately 2.3 μ s at NVLink bandwidth. The compute path over a shard is now a bundle of kernels, not a single GEMM: the attention and FFN work together take on the order of 20 μ s for this configuration, while the communication remains around 2.3 μ s. Here, the compute time exceeds the communication time by about $9\times$, and overlap becomes highly effective. This illustrates why batch size is the universal control knob: it simultaneously improves arithmetic intensity, GPU utilization, and communication overlap effectiveness.

This per-layer tensor-parallel example is the small-payload side of the overlap problem. Training gradient synchronization uses the same exposed-time test with much larger payloads, so the gradient-overlap calculation switches from activation exchanges to ring AllReduce over the gradient tensor.

9.7.1 Quantifying the overlap opportunity

The potential benefit of communication-computation overlap depends on the relative magnitudes of communication and computation time, which vary dramatically across system configurations.

Consider a 7B parameter model trained on 8 H100 GPUs within a single node connected by NVLink at 450 GB/s per direction. The gradient tensor contains 16.1 GB of FP16 values. By the ring AllReduce analysis in section 6.4.3, synchronization transfers $2 \times (N - 1)/N = 1.75\times$ times the gradient volume, taking approximately 62.5 ms at NVLink bandwidth. The backward pass computation, at 40 percent Model FLOPs Utilization (MFU, the fraction of peak throughput spent on useful model FLOPs, defined in section 5.4), takes approximately 166.3 ms.

Without overlap, the training step requires 311.9 ms (forward + backward + AllReduce). With overlap, the AllReduce is fully hidden behind the backward pass, reducing the step time to 249.4 ms, a $1.25\times$ improvement. This example illustrates a critical property: overlap is most effective when backward compute time exceeds AllReduce time. As figure 9.7 shows, as cluster scale increases from 8 to 1024 GPUs, overlap efficiency degrades from ~ 90 percent to ~ 18 percent because communication overhead eventually exceeds the computation budget. In that figure, each bar is normalized to the fixed compute budget of 100 units, and the bar height grows roughly fivefold across the x-axis because the exposed-communication segment stacked on top of that budget is precisely the portion of communication that overlap can no longer hide. For smaller models or slower interconnects (for example, PCIe at 64 GB/s instead of NVLink at 900 GB/s), the AllReduce would exceed the backward pass, and no amount of overlap can fully hide the communication.

9.7.2 CUDA streams and asynchronous execution

The mechanism enabling overlap on NVIDIA GPUs is **CUDA streams**. A CUDA stream is an ordered sequence of GPU operations (kernel launches, memory copies, NCCL collectives) that execute sequentially within the stream but can execute concurrently with operations in other streams. The application maintains two distinct streams: a compute stream for matrix multiplications and element-wise kernels, and a communication stream for NCCL operations. The workflow proceeds by launching a compute kernel on the first stream and immediately triggering an asynchronous communication call on the second:

```
compute_stream = torch.cuda.Stream()
comm_stream = torch.cuda.Stream()

with torch.cuda.stream(compute_stream):
    output = torch.matmul(A, B)  # Non-blocking compute

with torch.cuda.stream(comm_stream):
    dist.all_reduce(gradients, async_op=True)  # Non-blocking comm

torch.cuda.synchronize()  # Wait for both to complete
```

Figure 9.7: The Overlap Budget: As cluster scale increases (8 to 1024 GPUs), the communication overhead grows, eventually exceeding the computation budget. The overlap efficiency (black line) represents the percentage of communication hidden behind computation, which degrades from ~90 percent to ~18 percent due to inter-node latency and bandwidth constraints on a 70B parameter model.

The GPU hardware scheduler interleaves execution units from both streams, running the GEMM on the SMs while the NVLink engine handles the AllReduce data transfer. However, while streams provide *logical* concurrency, they contend for *physical* resources. The SMs must manage the data movement instructions for the communication kernel. On an H100 with 132 SMs, a heavy NCCL operation might occupy 4–8 SMs solely for protocol processing and memory copying, leading to **SM partitioning**: the available compute throughput is reduced by 3–6 percent during communication. If the compute kernel is dense enough to saturate 100 percent of the SMs, enabling overlap can paradoxically slow down execution due to this resource contention, a phenomenon known as interference. In practice, the 3–6 percent compute throughput reduction is far smaller than the communication time that would otherwise be exposed, making the trade-off overwhelmingly favorable.

In practice, achieving effective overlap requires attention to several details. The communication operation must be launched early enough to overlap with subsequent compute; in backward passes, DDP starts each bucket's AllReduce as soon as that bucket is ready so NCCL launch latency is hidden behind later gradient kernels. Synchronization points (where one stream waits for another) must be minimized, as each synchronization serializes execution.

PyTorch's Distributed Data Parallel (DDP) module implements gradient overlap by registering backward hooks on each parameter. When a parameter's gradient is computed during the backward pass, the hook triggers an asynchronous AllReduce on a separate NCCL stream. DDP synchronizes this communication stream with the main compute stream at the end of the backward pass, so every gradient reduction is guaranteed complete before the optimizer step reads the gradients. This design overlaps gradient communication with gradient computation automatically, without requiring user intervention.

When engineers create their own side streams for custom overlap patterns, a set of PyTorch-specific footguns regularly causes silent correctness or performance failures. The default behavior in PyTorch is that all operations enqueue onto the default stream. A tensor produced on the default stream and consumed on a side stream is not automatically safe: without an explicit `event.record() / event.wait()` barrier between them, the GPU may begin consuming the tensor before it is fully written. Similarly, memory copies launched without `non_blocking=True` insert implicit synchro-

nization points that serialize the streams the engineer was trying to overlap, often eliminating the overlap benefit entirely. DDP avoids these hazards by managing `record_event()` calls inside its bucket hooks, ensuring each AllReduce starts only after the corresponding gradient compute event has completed. Manually written overlap code must replicate this discipline or risk data races that produce incorrect gradients with no error signal at the framework level.

The techniques covered so far – fusion, precision, compilation, speculative decoding, MoE, and communication overlap – address different aspects of the performance equation. Identifying which technique to apply in a given situation requires systematic measurement, and the profiling tools that make this diagnosis possible are the final piece of the optimization toolkit.

9.8 System Profiling

An engineer spends two weeks rewriting a PyTorch module into a custom CUDA kernel to make it $5\times$ faster, only to discover the overall model latency did not budge because the system was entirely I/O bound. Performance engineering without measurement is expensive guesswork. System profiling provides the surgical diagnostics required to identify exactly where the GPU is waiting, allowing us to apply our optimizations with precision.

Systems Perspective 9.4: The physics of profiling (the Heisenberg effect)

Observing a distributed ML system fundamentally alters its behavior. Gathering high-resolution telemetry (such as tracking every CUDA kernel launch or memory allocation) consumes PCIe bandwidth, CPU cycles, and memory capacity. In heavily optimized serving pipelines, the overhead of profiling can artificially induce the very latency spikes the engineer is trying to diagnose. This “Heisenberg Effect” requires a deliberate strategy: deploying low-overhead, sampling-based telemetry for continuous production monitoring, and only enabling high-fidelity, synchronous tracing in isolated diagnostic environments.

The effect is particularly pronounced in PyTorch workloads. Enabling `torch.autograd.profiler` or `torch.cuda.memory._record_memory_history()` instructs the framework to retain references to intermediate activation tensors beyond their normal lifetime so that allocation metadata can be recorded. This prevents the memory allocator from reusing tensor buffers as it normally would, inflating peak HBM consumption and, in borderline cases, triggering Out-Of-Memory errors that do not occur in unobserved execution. Additionally, graph-optimization passes in `torch.compile` detect tensor observation and conservatively disable certain buffer-reuse fusions, causing the profiled execution to follow a slower code path than the production path. The practical consequence is that a profiling run must be treated as a distinct experiment: it characterizes the structure of the computation accurately, but its absolute latency and memory numbers will overstate production measurements.

9.8.1 The profiling hierarchy

Profiling levels are useful only if they guide the drill-down from symptom to intervention. ML system profiling operates at four levels, each providing different granularity and targeting different bottleneck categories. Figure 9.8 makes this drill-down explicit, starting from application-level symptoms and descending toward kernel and hardware-counter evidence.

The drill-down starts at the application level, where end-to-end metrics such as tokens per second, time-to-first-token, P99 latency, and GPU utilization over time reveal that the user-facing system has missed its target. It then descends to distributed profiling across GPUs and nodes, where communication patterns show whether collectives overlap with compute, which operation dominates step time, and whether load imbalance exists across ranks. Trace-level profiling narrows the diagnosis to the timeline of GPU kernels, CPU operations, and data transfers within a training step or inference request, exposing launch gaps, idle bubbles, sequential bottlenecks, and overlap opportunities. Operation-level profiling completes the chain with tools like NVIDIA Nsight Compute, where achieved memory bandwidth, compute utilization, occupancy, and instruction mix determine whether a specific kernel is memory-bound, compute-bound, or limited by implementation details—including whether it is issuing Tensor Core instructions (HMMA for FP16/BF16, IMMA for INT8)

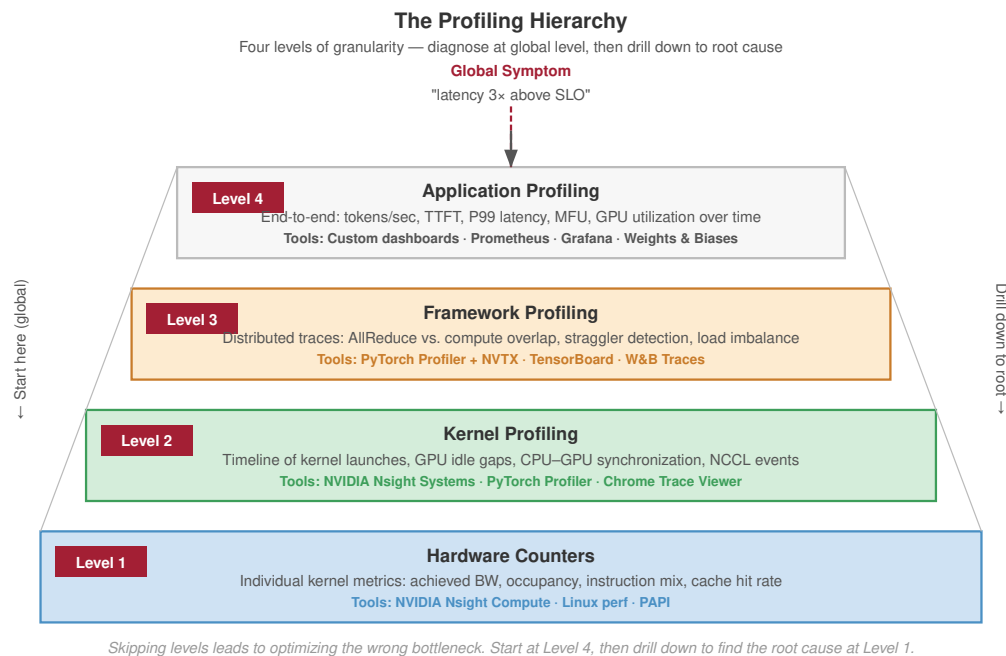

Figure 9.8: The Profiling Hierarchy: Four levels of profiling granularity. Start at Level 4 (Application Profiling) for global symptoms, and drill down through Framework and Kernel profiling to find the root cause at Level 1 (Hardware Counters).

rather than falling back to scalar CUDA Core instructions (FMA/ALU). A matrix multiplication whose hidden-dimension or sequence-length tile is not divisible by the Tensor Core alignment requirement (multiples of 8 for FP16, 16 for INT8) silently bypasses Tensor Cores entirely and executes on CUDA Cores at a fraction of the peak throughput. This shape mismatch is one of the most common silent performance bugs in custom ML kernels and is invisible without inspecting the instruction mix counter.

Diagnosing performance requires a drill-down approach, moving from global symptoms to local causes. When profiling a 70B model serving pipeline, the application level might reveal “end-to-end latency is 150 ms/token, 3× above the SLO.” Descending to the distributed level, traces might show one GPU consistently lagging in AllReduce operations, pointing to a straggler or network congestion. Zooming into the trace level on that specific GPU reveals the timeline of kernel execution, exposing gaps where the SMs are idle due to scheduling overhead. Finally, kernel-level profiling (using Nsight Compute) inspects the specific instruction mix of a single matrix multiplication, revealing cache misses or register pressure. Skipping levels often leads to optimizing the wrong bottleneck: optimizing a kernel is futile if the GPU is spending 40 percent of its time waiting on the network.

9.8.2 Key performance metrics

Metrics are not interchangeable; each answers a different bottleneck question. MFU and MBU diagnose useful hardware work, TTFT and ITL diagnose serving latency, and throughput exposes capacity under batching. Understanding their relationships and trade-offs is essential for performance engineering.

Table 9.5 maps the common metrics to the bottleneck question each one answers.

Table 9.5: Performance Metrics and Their Diagnostic Use: Each metric measures a different layer of the system, so choosing the wrong metric can hide the real bottleneck.

Metric	Definition	Best diagnostic use	Caveat or target
Model FLOPs Utilization (MFU)	Fraction of hardware peak FLOP/s productively used by model computation	Training efficiency across memory limits, launch overhead, communication wait, and software overhead	40–60% is common in well-tuned LLM training; above 60% is excellent
Hardware FLOPs Utilization (HFU)	Total arithmetic operations executed, including recomputation, divided by peak FLOP/s	Separating useful model work from overhead such as activation recomputation	Usually exceeds MFU, and the HFU–MFU gap estimates wasted compute
Time-to-first-token (TTFT)	Latency from request arrival to the first generated token	Interactive serving responsiveness, including queueing, prefill, and initialization	Below 500 ms is generally acceptable; below 200 ms feels responsive
Inter-token latency (ITL)	Time between consecutive generated tokens during decode	Perceived generation speed after the first token	Below 50 ms supports comfortable reading; real-time speech may require below 25 ms
Throughput	Tokens/second for the system, or tokens/second/GPU for per-device efficiency	Aggregate serving or training capacity under batching	Large batches improve throughput but increase per-request latency; section F.1.1 covers the queueing trade-off
Model Bandwidth Utilization (MBU)	Achieved memory bandwidth divided by hardware peak bandwidth	Memory-bound inference, especially decode workloads	An H100 decode step can show 2% MFU but 85% MBU, which indicates a memory-saturated and well-optimized path

9.8.3 Using the roofline for diagnosis

The metric choice in table 9.5 reflects the fundamental bottleneck shift between training and inference: MFU is usually the right training-efficiency lens, while MBU is often the right inference-efficiency lens when decode is limited by HBM traffic. The roofline model from section 9.1.5 becomes a diagnostic tool when combined with profiling data. Diagnosis follows three steps:

1. **Measure** the achieved FLOP/s and memory bandwidth for a kernel using Nsight Compute.
2. **Compute** the operational arithmetic intensity from the algorithm (FLOP/byte).
3. **Plot** the measured performance against the roofline ceiling.

A kernel that falls far below both the compute ceiling and the bandwidth ceiling has an implementation problem: launch overhead, poor memory access patterns, or low occupancy. A kernel that reaches the bandwidth ceiling but falls below the compute ceiling is memory-bound, and further optimization requires reducing memory traffic (fusion, precision) rather than improving compute efficiency. A kernel at the compute ceiling is compute-bound and can only be improved by algorithmic changes (reducing FLOPs) or faster hardware.

Consider a concrete example: a LayerNorm kernel profiled on an H100 reports 15 TFLOP/s of achieved compute and 2.8 TB/s of achieved memory bandwidth. Its arithmetic intensity is $15 \text{ TFLOP/s} / 2.8 \text{ TB/s} \approx 5.4 \text{ FLOP/byte}$. The H100’s ridge point is approximately 295.2 FLOP/byte at FP16. Since 5.4 FLOP/byte is far below 295.2 FLOP/byte, the kernel is strictly memory-bound. Its achieved 2.8 TB/s (83.6 percent of the H100’s 3.35 TB/s peak bandwidth) confirms it is operating near the physical limit of the memory subsystem. The diagnosis is clear: further FLOP-level optimizations will yield little gain; performance can only be improved materially by reducing data movement, either through fusion (eliminating the HBM round-trip) or precision reduction (halving the bytes per element).

9.8.4 PyTorch profiler workflow

The PyTorch Profiler is most useful when application metrics show a slowdown but the responsible layer is still unknown. Its role is to narrow a global symptom to a layer, kernel family, or synchro-

nization point before a heavier tool is used. It integrates with the training loop to capture detailed traces with minimal code modification:

```
import torch
from torch.profiler import (
    profile,
    schedule,
    tensorboard_trace_handler,
)

# Profile 2 warmup steps + 3 active steps
with profile(
    activities=[
        torch.profiler.ProfilerActivity.CPU,
        torch.profiler.ProfilerActivity.CUDA,
    ],
    schedule=schedule(wait=1, warmup=2, active=3, repeat=1),
    on_trace_ready=tensorboard_trace_handler("./profiler_logs"),
    record_shapes=True,
    profile_memory=True,
    with_stack=True,
) as prof:
    for step, batch in enumerate(dataloader):
        if step >= 6: # 1 wait + 2 warmup + 3 active
            break
        output = model(batch)
        loss = criterion(output, labels)
        loss.backward()
        optimizer.step()
        optimizer.zero_grad()
        prof.step()
```

The schedule parameter defines a warmup period where the profiler runs but does not record, allowing CUDA caches and just-in-time (JIT) compilation to stabilize before measurement begins. Without warmup, the first few iterations include one-time costs (kernel compilation, memory allocation, CUDA context initialization) that inflate the measured times and misrepresent steady-state performance.

The resulting trace, viewable in TensorBoard or Chrome's trace viewer, matters only insofar as each view maps to an intervention. Table 9.6 turns those views into a diagnostic checklist.

Table 9.6: Profiler Views and Interventions: PyTorch profiler views are useful when each visual signal points to a concrete next experiment.

Trace view	Diagnostic signal	Likely intervention
Kernel timeline	CUDA kernels, their duration, GPU idle gaps, and unexpectedly long kernels	Fuse operators, use CUDA Graphs, or investigate long kernels with Nsight Compute
Memory timeline	Allocation and deallocation spikes or gradual memory growth	Reuse buffers, plan allocations, or investigate leaks
CPU-GPU synchronization	Points where the CPU waits for the GPU, or the GPU waits for CPU launch work	Remove blocking synchronization and reduce launch overhead
Communication events	NCCL collective duration relative to compute kernels	Tune overlap, bucket sizing, or parallelization strategy

9.8.5 Nsight systems: Reading the timeline

The profiler is therefore a triage tool, not the final performance proof: it identifies whether the next experiment should target fusion, memory planning, CUDA Graphs, or overlap. NVIDIA Nsight Systems answers the trace-level question raised by higher-level profiling: whether the GPU timeline is continuous, whether the CPU is feeding it fast enough, and whether communication overlaps compute. The tool captures every GPU kernel launch, CUDA memory operation, NCCL communication, and CPU thread activity onto a unified timeline.

Nsight Systems becomes useful when the question has shifted from which layer is slow to why the full timeline has gaps. A typical workflow begins with capturing a trace of a few training or inference iterations:

```
nsys profile --trace=cuda,nvtx,osrt,cudnn,cublas \
--output=llm_profile \
--force-overwrite=true \
python3 inference_server.py --num-steps=5
```

The `--trace` flags control which activities are recorded. The `cuda` flag captures kernel launches and memory operations. The `nvtx` flag captures user-annotated regions (PyTorch automatically annotates module boundaries with NVTX markers). The `cublas` and `cudnn` flags capture library-level operations, which helps identify whether a GEMM is using cuBLAS or a custom kernel. The command is useful because these rows expose whether the bottleneck is launch overhead, communication serialization, or kernel implementation.

The resulting `.nsys-rep` file is opened in the Nsight Systems GUI, which presents a multi-row timeline. Four rows carry the most diagnostic weight.

The CUDA HW row shows the actual kernel execution on the GPU. Each colored bar represents a kernel, with width proportional to execution time. Gaps between bars indicate GPU idle time, which represents wasted potential. For a well-optimized inference pipeline, the CUDA HW row should show nearly continuous kernel execution with minimal gaps.

The CUDA API row shows CPU-side CUDA API calls (kernel launches, memory allocations, synchronization). If CUDA API bars are significantly wider than the corresponding CUDA HW bars, the CPU is the bottleneck: it cannot launch kernels fast enough to keep the GPU busy. CUDA Graphs and `torch.compile` address exactly this kernel launch overhead problem.

The NCCL row (for distributed workloads) shows collective communication operations. Comparing the NCCL row with the CUDA HW row reveals whether communication overlaps with computation. If NCCL bars appear during gaps in the CUDA HW row, communication is serialized. If NCCL bars overlap with CUDA HW bars, overlap is working correctly.

The NVTX row shows user-annotated regions, which PyTorch maps to module names (`Linear`, `LayerNorm`, `Attention`). This connects low-level kernel names (often cryptic strings like `volta_fp16_s1688gemm_fp16_256x128_ldg8_f2f_nn`) to the model-level operations that produced them.

Five patterns reveal the most diagnostic information from a Nsight Systems trace. Table 9.7 maps each visual pattern to the bottleneck question it answers.

Table 9.7: Nsight Timeline Diagnostic Patterns: Timeline patterns connect visual structure to utilization, fusion, overlap, allocation, and arithmetic-efficiency questions.

Timeline pattern	Diagnostic question	Optimization direction
Kernel execution vs. idle gaps	How much of the trace is useful GPU execution rather than waiting?	Investigate launch overhead, CPU stalls, or input starvation
Distribution of kernel durations	Are many short kernels fragmenting the workload?	Try fusion, CUDA Graphs, or compiler capture
NCCL alignment with CUDA HW rows	Does communication overlap with computation?	Tune bucket sizes, scheduling, or parallelization layout
Memory allocation spikes	Are tensors being materialized or allocated repeatedly?	Add memory planning, buffer reuse, or fused kernels
GEMM vs. non-GEMM time	How much execution is useful matrix arithmetic vs. overhead?	Move non-GEMM work into fused kernels or reduce memory traffic

Experienced performance engineers develop pattern recognition for these traces, quickly identifying the dominant bottleneck from the visual structure of the timeline. A trace dominated by thin, closely packed kernel bars with minimal gaps indicates a well-optimized pipeline. A trace with large gaps between kernels, or with NCCL bars that do not overlap with CUDA HW bars, immediately reveals the primary optimization target.

9.8.6 Common bottleneck patterns

Profiling is valuable because recurring trace patterns map directly to optimization choices. Table 9.8 turns that pattern recognition into a diagnostic map: first identify the visual signature, then connect it to the likely cause and the intervention that changes the system.

Table 9.8: Common Bottleneck Trace Patterns: Diagnostic map from trace signature to likely cause, intervention, and trade-off. The table is most useful after the profiler has already localized the bottleneck to launch overhead, memory movement, communication, load balance, allocation behavior, or input preparation.

Trace Pattern	Likely Cause	Primary Intervention	Trade-Off to Check
Small gaps between many kernels	Kernel launch overhead dominates	Graph compilation with <code>torch.compile</code> , CUDA Graphs, or fusion	Compilation warmup and debugging complexity
Large memory spikes	Unfused operators materialize intermediate tensors	FlashAttention or custom Triton fusion	Numerical validation and kernel maintenance
Low FLOP/s with high bandwidth	Memory-bound operations dominate	Precision reduction, batching, or algorithmic changes	Accuracy, cache pressure, and quality guardrails
NCCL bars during GPU idle gaps	Communication is serialized rather than overlapped	DDP gradient overlap or pipeline restructuring	Bucket size, schedule complexity, and synchronization
Some GPUs wait for stragglers	Uneven work distribution or MoE load imbalance	MoE capacity tuning, auxiliary loss adjustment, or even tensor-parallel splits	Routing quality and utilization balance
Repeated large allocations	Buffers are recreated rather than reused	Memory planning, preallocated buffer pools, or checkpointing	Recompute cost and allocator behavior
Periodic GPU utilization drops	CPU preprocessing or tokenization is not pipelined	More data workers, preprocessing services, or pretokenized datasets	Storage cost and data freshness

A full decode trace shows how several of these smaller bottlenecks can combine into the dominant loss.

Example 9.2: The profiler detective

Problem: A 7B parameter LLM runs on a single H100 and shows 45 tokens/s during autoregressive generation at batch size 1. The pure FP16 weight-read roofline is higher, but after budgeting roughly 35 GB of total per-token traffic for weights, KV-cache reads, sampling, synchronization, and launch overhead, the bandwidth-limited full-decode ceiling is approximately 96 tokens/s. Where is the remaining 53 percent of realizable decode-step performance hiding?

Investigation:

Step 1: Kernel-level analysis. Run Nsight Compute on the dominant GEMM kernel. Result: achieves 2.8 TB/s effective bandwidth out of the H100's 3.35 TB/s peak. Efficiency: 84 percent. This kernel is performing well.

Step 2: Trace-level analysis. Run Nsight Systems on a full decode step. Result: 42 percent of step time is spent in GEMM kernels. The remaining 58 percent is split between:

- Attention kernels (including KV cache reads): 28 percent
- Layer normalization and activation kernels: 12 percent
- Softmax and top-*k* sampling: 8 percent
- Kernel launch gaps: 10 percent

Step 3: Identify optimization targets.

- The KV cache attention kernel achieves only 1.9 TB/s bandwidth because of irregular memory access patterns. Fix: Implement KV cache quantization (INT8) with better memory layout.

- Kernel launch gaps (10 percent of time) come from 120+ individual kernel launches per layer. Fix: Apply `torch.compile` to fuse element-wise operations, reducing to ~30 kernels per layer.
- Layer normalization and activation kernels are unfused. Fix: Fused LayerNorm-GELU kernel via Triton.

Systems insight: The dominant GEMM is near-optimal, but secondary operations and launch overhead consume over half the execution time. Systematic profiling reveals that the bottleneck is not where intuition suggests (the largest kernel) but in the accumulated overhead of many small operations.

9.8.7 The profiling feedback loop

Effective performance engineering follows an iterative cycle: *profile, diagnose, optimize, verify*. The verification step is critical and often skipped. After applying an optimization, reprofile to confirm that the targeted bottleneck was addressed and that no new bottleneck emerged. Performance optimization is a waterbed problem: fixing one bottleneck often exposes the next.

A common trap is optimizing based on microbenchmarks rather than end-to-end traces. A kernel that appears 2× faster in isolation may deliver only 5 percent improvement in end-to-end throughput if it was not the bottleneck, or if the surrounding code cannot take advantage of its speedup due to data dependencies. Always measure impact at the application level (tokens/second, step time, P99 latency) in addition to kernel-level metrics. The same measurement discipline governs rollout risk: a change that looks local can consume a global resource once it reaches production traffic.

War Story 9.1: The regex that saturated the edge

Context: Cloudflare’s Web Application Firewall runs on edge machines that process HTTP and HTTPS traffic across the global network (Cloudflare 2019).

Failure mode: On July 2, 2019, a newly deployed managed WAF rule caused excessive CPU consumption on every HTTP/HTTPS-handling core across Cloudflare’s network.

Consequence: Cloudflare reported losing most of its traffic until the team identified the WAF as the cause and used a global disable mechanism to restore service.

Systems lesson: Performance engineering includes algorithmic complexity and rollout design. A small rule change can become a global outage when it is deployed everywhere before bounded-runtime checks, canaries, and kill switches catch the cost. ML deployments follow the same pattern: a new model, a recalibrated threshold, or a retrained feature can ship a worst-case latency cliff into production that no unit test catches, which is why canarying, request shadowing, and per-request kill switches are first-class ML serving infrastructure.

Profiling itself can also perturb the system being measured. The PyTorch profiler adds approximately 10–20 percent overhead when recording full traces with memory profiling enabled. Nsight Systems adds less overhead but still affects scheduling. Profile warmup steps before active measurement, and discount the first few profiled iterations where JIT compilation or CUDA context initialization may dominate.

9.8.8 Profiling at scale

Profiling a single GPU is straightforward; profiling a distributed system with hundreds or thousands of GPUs introduces unique challenges. The volume of trace data grows linearly with the number of GPUs: a 5-second Nsight Systems trace for one GPU is approximately 500 MB; the same trace for 1,000 GPUs would be 500 GB, impractical to store or analyze.

Production systems address this through **hierarchical profiling**. At the top level, application-level metrics (MFU, throughput, step time) are collected continuously from every GPU with negligible overhead. These aggregate metrics detect when performance degrades. When a degradation is detected, **targeted profiling** is triggered on a representative subset of GPUs (typically one GPU per

pipeline stage, per data-parallel group) for a short window (a few training steps). The resulting traces are analyzed to identify the specific bottleneck.

Another approach is **statistical profiling**, where each GPU randomly samples a small fraction of its kernels for detailed timing. Over many training steps, the aggregated samples provide a statistically accurate picture of the kernel time distribution without the overhead of full tracing. The approach is analogous to the sampling profilers (like Linux `perf`) used in traditional systems engineering, adapted for the GPU context.

The most challenging profiling scenario is intermittent stragglers: GPUs that are occasionally slow due to thermal throttling, memory errors, or network congestion, but fast most of the time. These stragglers may not appear in a short profiling window but can reduce training throughput by 10–20 percent over hours. Detecting them requires continuous per-GPU step-time monitoring with statistical anomaly detection, a form of profiling infrastructure that operates at the monitoring layer rather than the kernel layer.

The profiling tools and techniques described in this section provide the measurement foundation for all optimization work. Without measurement, performance engineering degenerates into guesswork. With measurement, it becomes a systematic discipline guided by quantitative evidence.

9.9 Measurement at Scale

Optimizing a single node is a prerequisite, but the ultimate test of performance engineering is efficiency at fleet scale. When we move from 8 GPUs to 1,024 GPUs, new sources of overhead emerge that are invisible in local traces. A profiler can explain why one kernel stalls; it cannot by itself say whether thousands of accelerators are converting power, memory bandwidth, and network time into useful model progress. Measurement at scale requires shifting from kernel-level micro-benchmarks to global efficiency metrics that capture the interaction of computation, communication, and hardware variability.

9.9.1 The fleet efficiency metric

While Hardware Utilization reports how often GPUs are busy, it fails to distinguish between useful work and wasted cycles (such as activation recomputation or communication bubbles). Fleet measurement therefore needs a useful-work utilization metric. By focusing on the “useful” FLOPs required by the model architecture, this metric provides an invariant measure of system efficiency that remains comparable across different software stacks and parallelization strategies.

Definition 9.3: Model FLOPs utilization (MFU)

Model FLOPs Utilization (MFU), introduced in section 5.4, is the fraction of the hardware’s theoretical peak throughput (R_{peak}) consumed by FLOPs that directly advance model training or inference, excluding overhead from recomputation, padding, and synchronization. The new content here is its fleet-scale behavior: how the per-node figure aggregates across thousands of accelerators and how the scaling tax pulls it down.

1. **Significance:** At fleet scale, MFU aggregates across all nodes: communication overhead, load imbalance, and pipeline bubbles each compound the utilization loss, so fleet MFU is consistently below single-node MFU. It is the primary diagnostic for whether hardware investment is translating into model progress, and a 1 percent improvement in MFU across a 10,000-GPU cluster reduces cost by the equivalent of 100 GPUs.
2. **Distinction:** Unlike Hardware Utilization (which reports how often the accelerator is “busy”), MFU reports how much of that activity contributes to Model Convergence or inference, excluding waste FLOPs from recomputation, padding, and gradient checkpointing overhead.
3. **Common pitfall:** A frequent misconception is that high GPU utilization implies high efficiency. A system can show 90 percent hardware utilization while achieving 30 percent MFU if it is wasting cycles on communication bubbles or inefficient kernel implementations, making MFU the correct metric for optimization decisions, not raw utilization.

With MFU defined as useful work rather than raw busyness, the next calculation shows how distributed overhead turns a strong single-node number into a weaker fleet-wide result.

Napkin Math 9.4: The scaling tax

Problem: A 70B parameter model achieves 65 percent MFU on a single 8-GPU node. When training scales to 128 GPUs, how much MFU does inter-node communication overhead consume?

- **Local node baseline:** A single 8-GPU node achieves 65 percent MFU.
- **Fleet performance:** At 128 GPUs, the step time increases to 245 ms, dropping MFU to 48 percent.

Math: Both MFU figures come from the same ratio, the useful FLOPs a step performs divided by the FLOPs the cluster could execute at peak in that step's wall time:

$$\text{MFU} = \frac{\text{FLOPs}_{\text{useful}}}{N \times R_{\text{peak}} \times t_{\text{step}}}$$

For the fleet case, a step performs 14.9 PFLOP of useful work, while $128 \text{ GPUs} \times 989 \text{ TFLOP/s per GPU} \times 245 \text{ ms}$ of wall time could execute 31 PFLOP at peak; the quotient $14.9 \text{ PFLOP} \div 31 \text{ PFLOP} \approx 48$ percent. The same substitution on the single node yields 65 percent, and the scaling tax is $1 - \text{Fleet MFU}/\text{Local MFU}$, giving 26.2 percent.

Systems insight: The 26.2 percent scaling tax represents the cost of inter-node communication (InfiniBand latency) and synchronization barriers. In a healthy fleet, this tax should remain stable; a sudden increase in the scaling tax signals a scaling regression, typically caused by a misaligned parallelization strategy or a “gray failure” in the network fabric.

9.9.2 Detecting scaling regressions

At scale, the system is nonlinear. A code change that introduces a minor memory overhead on a single GPU can trigger a catastrophic performance collapse at 1,000 GPUs due to increased garbage collection pauses or exhausted InfiniBand credit buffers. Table 9.9 shows how tiered tests catch that collapse before it becomes a fleet incident.

Table 9.9: Scaling Regression Test Tiers: Fleet performance testing moves from small canaries to production baselines and gray-failure detection so that local changes are checked against distributed behavior.

Testing tier	What it measures	Regression caught
Small-scale canaries	Model behavior on 8 and 64 GPUs to establish a scaling efficiency curve	Code changes that look harmless on one GPU but bend the curve before full-fleet launch
Fleet baseline comparison	Every production run's MFU against the reference baseline for that model architecture	Architecture, compiler, or configuration changes that reduce useful fleet work
Gray failure detection	Distribution of step times across the fleet	Straggler nodes, such as one 10% slower node that can reduce synchronous data-parallel MFU by 10%

Those same measurements also explain why benchmark numbers cannot be copied directly into production capacity plans.

Systems Perspective 9.5: Benchmark vs. reality: The hero run tax

Industry benchmarks like MLPerf are often “hero runs”—highly tuned configurations where logging is disabled, safety checks are bypassed, and the hardware is freshly rebooted.

In production, achieved MFU typically sits 10–20 percent lower than these hero numbers. Essential operational overhead consumes the difference:

- Observability: Metrics collection and logging.
- Reliability: Checkpointing and health heartbeats.
- Entropy: Thermal throttling, memory fragmentation, and multi-tenant network noise.

When planning capacity, engineers must budget for the reality tax. If a benchmark projects 30 days of training, the production plan should assume 35–40 days.

Measurement without action is overhead. The optimization playbook translates node-level traces and fleet-wide MFU into a surgical sequence of interventions, each targeting the specific bottleneck that measurement identified.

9.10 The Optimization Playbook: A 70B LLM Case Study

Consider a raw, unoptimized 70-billion parameter PyTorch model that must serve 1,000 tokens per second in production by next week. The optimization sequence begins with baseline measurement, followed by roofline classification to identify the dominant bottleneck. Applying optimization techniques indiscriminately is ineffective. The optimization playbook requires a systematic, prioritized attack: first unblocking the memory wall, then fusing operators, and finally applying algorithmic techniques like speculative decoding in a specific, compounding sequence.

9.10.1 The diagnostic sequence

Optimization begins by measuring the whole workload before touching individual kernels. End-to-end throughput, an Nsight Systems trace, and Model FLOPs Utilization (MFU) from section 9.9 establish whether the system has substantial headroom. The next diagnostic move is roofline classification: compute arithmetic intensity for the dominant kernels and place them against the machine balance point. That classification determines the primary bottleneck, and the primary bottleneck determines which remedy should be tried first. For memory-bound, compute-bound, and communication-bound workloads, table 9.10 turns that decision into a compact map: identify the binding resource, use the typical setting as a sanity check, and try the interventions in order until a reprofiled trace shows the bottleneck has moved.

Table 9.10: Optimization Paths by Primary Bottleneck: Diagnostic map from bottleneck class to the ordered interventions that should be tried before the next profiling pass.

Primary bottleneck	Typical setting	Optimization path
Memory-bound	Inference, especially token decode	Reduce precision to raise effective bandwidth; fuse operators to eliminate intermediate HBM traffic; compile the graph to catch remaining fusion opportunities; then consider algorithmic changes such as speculative decoding or MoE if the bottleneck remains.
Compute-bound	Large-batch training	Ensure Tensor Cores are in use; apply graph compilation for kernel selection and memory planning; consider FP8 for 2× compute throughput; overlap communication so compute does not idle.
Communication-bound	Distributed training at scale	Overlap gradient communication with the backward pass; compress gradients or use reduced-precision communication; restructure pipeline schedules so stage-to-stage communication is hidden under useful compute; use topology-aware placement to minimize cross-node traffic.

The fourth step is to apply and verify. Implement the highest-impact optimization, reprofile, and verify improvement. Then iterate from the roofline classification step with the new profile, as the bottleneck may have shifted.

9.10.2 Combining techniques

Production systems combine techniques because no single intervention covers every term in the iron law. A highly optimized LLM serving system may use FlashAttention-2 or later FlashAttention-family

kernels to reduce attention memory traffic, INT4 weight quantization with GPTQ or AWQ to reduce HBM reads, and INT8 KV cache compression with per-channel scaling to increase feasible batch size. Compiler and runtime tools such as `torch.compile` or TensorRT then handle element-wise fusion and kernel selection.

The serving layer adds another set of controls. Speculative decoding reduces latency at low batch sizes, continuous batching refills the batch as requests finish (introduced in section 9.2.1), dynamic sequence grouping improves throughput, and tensor parallelism spreads the model across GPUs while overlapping AllReduce. These techniques belong together only when the profile shows that each one moves a currently binding term.

The speedups from these techniques are not additive; they interact in ways that demand careful sequencing. For instance, INT4 weight quantization reduces per-token HBM traffic by 4×, which might shift the bottleneck from memory-bound to compute-bound. Once compute-bound, further bandwidth optimizations (KV cache compression) yield diminishing returns, and compute optimizations (FP8 Tensor Cores) become the priority. This is why the iterative profile-optimize-verify loop is essential: the optimal combination depends on the specific model, hardware, and workload characteristics.

The interaction between optimizations creates a dependency graph that the performance engineer must navigate. Some combinations are synergistic: FlashAttention removes attention intermediates, and INT8 KV cache compression reduces KV cache memory, together freeing enough memory for larger batch sizes that transform the economics of serving. Other combinations are redundant: applying both CUDA Graphs and the `reduce-overhead` mode of `torch.compile` achieves the same result, since `reduce-overhead` internally uses CUDA Graphs. Still other combinations conflict: speculative decoding benefits most at small batch sizes (where decode is memory-bound), while many throughput optimizations work by increasing batch size. At large batch sizes, speculation adds overhead without proportional benefit.

A practical heuristic for sequencing optimizations is to apply the cheapest bottleneck-moving intervention before adding new algorithmic machinery. The first step depends on the measured bottleneck. Compiler-first is a common starting point for stable-shape workloads when memory is not obviously the binding constraint. For batch-1 70B decode, precision comes first because weight bandwidth and KV capacity dominate before graph overhead does.

1. Primary bottleneck fix: apply `torch.compile` when the trace shows launch overhead and stable shapes, or apply weight/KV precision first when the profile is memory-capacity or bandwidth bound.
2. FlashAttention-family kernels (library swap): Apply when attention materialization or attention HBM traffic remains visible in the profile.
3. Weight quantization (INT4/FP8, calibration required): Apply early for memory-bound serving, but validate quality before treating the speedup as usable.
4. KV cache compression (INT8, library support, 2× cache reduction): Apply fourth. Enables larger batches.
5. Speculative decoding (requires draft model, engineering effort): Apply last, only if latency target not met. Most complex to deploy.

This ordering reflects the principle that passive optimizations (compiler, library swaps) should precede active ones (algorithmic changes, new model components). Each step is validated by reprofiling before proceeding to the next.

 Checkpoint 9.3: Optimization strategy

Test your ability to design an optimization plan:

- ☐ **Top optimizations:** Given an LLM serving workload at batch size 1 that achieves 25 percent of peak bandwidth, identify the three most impactful optimizations and their expected interaction.
- ☐ **FP8 on comm-bound:** Explain why applying FP8 quantization to a workload that is already communication-bound provides no speedup.

- ❑ **Profiling workflow:** Describe the iterative profiling workflow and explain why verifying each optimization is as important as applying it.
- ❑ **Compile pitfalls:** Identify a scenario where applying `torch.compile` would degrade performance.

9.10.3 Case study: Optimizing a 70B LLM serving pipeline

To illustrate how the diagnostic sequence and combining principles work in practice, consider the task of optimizing a 70B parameter LLM for production serving. The target is a real-time chatbot application requiring time-to-first-token (TTFT) under 500 ms, inter-token latency (ITL) under 50 ms, and throughput of at least 1,000 tokens/second across the cluster. The model is deployed on a node of 8 H100 GPUs connected by NVLink.

9.10.3.1 Baseline measurement

The initial deployment uses FP16 weights, standard PyTorch eager execution, and tensor parallelism across 8 GPUs. The 70B model in FP16 requires 140 GB of weight storage, distributed as approximately 17.5 GB per GPU. Four baseline measurements reveal the optimization gap:

- **TTFT:** 1,200 ms (well above the 500 ms target)
- **ITL:** 85 ms (above the 50 ms target)
- **Throughput:** 280 tokens/second (below the 1,000 token/second target)
- **Maximum batch size:** 4 (limited by KV cache memory)

A Nsight Systems trace breaks down a single decode step at batch size 1 into five time categories:

- GEMM kernels: 38 percent of step time
- Attention (including KV cache reads): 24 percent of step time
- Element-wise operations (LayerNorm, GELU, residual): 14 percent of step time
- AllReduce communication (tensor parallelism): 12 percent of step time
- Kernel launch gaps and overhead: 12 percent of step time

The roofline analysis confirms that decode is deeply memory-bound, with arithmetic intensity approximately 1 FLOP/byte at batch size 1. The GPU achieves 2.7 TB/s effective bandwidth (80 percent of peak), indicating reasonable kernel-level efficiency but a fundamental algorithmic limitation.

9.10.3.2 Optimization round 1: Precision engineering

The first optimization targets the largest opportunity: reducing the bytes per weight read from HBM. Applying AWQ INT4 weight quantization reduces the per-GPU weight footprint from 17.5 GB to about 4.4 GB on an 8-GPU node. The raw weight-read traffic drops by 4×, and the effective bandwidth for weight reads roughly doubles once on-the-fly dequantization to FP16 is included.

Simultaneously, applying INT8 quantization to the KV cache reduces per-request cache size by 2×. The combined effect on memory budget is dramatic: each GPU now has approximately 75.6 GB available for KV cache, up from 62.5 GB. Under the 4096-token GQA cache calculation from section 9.4.3, this would permit much larger batches; in this deployment, the serving policy reserves memory for longer contexts, fragmentation headroom, and tail-latency protection. With that policy cap, the maximum admitted batch size increases from 4 to approximately 32.

Postoptimization metrics show that batch-1 ITL reaches 48 ms, meeting the 50 ms target, while throughput at batch size 32 reaches 720 tokens/second and remains below target.

The Nsight Systems trace shows that GEMM time decreased by approximately 45 percent due to reduced weight reads, but attention and element-wise operations remain unchanged. The bottleneck has partially shifted.

9.10.3.3 Optimization round 2: Operator fusion

The second round targets the 14 percent of step time consumed by element-wise operations and the 24 percent consumed by attention. Applying `torch.compile` with the `max-autotune` backend

fuses element-wise operations (GELU, LayerNorm, residual additions), reducing their contribution from 14 percent to approximately 4 percent of step time. Simultaneously, enabling FlashAttention-2 replaces the standard attention implementation, reducing attention HBM traffic by approximately $16\times$ for the prefill phase.

For the decode phase, FlashAttention’s impact is more modest because decode attention is dominated by KV cache reads rather than the $S\times S$ score matrix. However, the combination of INT8 KV cache compression and FlashAttention’s efficient PagedAttention kernel reduces attention decode time by approximately 30 percent. The `reduce-overhead` mode in `torch.compile` wraps the decode step in a CUDA Graph, eliminating the 12 percent kernel launch overhead almost entirely.

Postoptimization metrics show TTFT at 380 ms, meeting the 500 ms target; ITL at 32 ms for batch size 1, well below the 50 ms target; and throughput at batch size 32 at 1,050 tokens/second, meeting the throughput target.

9.10.3.4 Optimization round 3: Speculative decoding

With the throughput target met, the team focuses on further reducing ITL for the best user experience. Speculative decoding with a 1.5B draft model (AWQ INT4 quantized to 0.75 GB) is deployed on the same GPUs. The draft model generates 5 candidate tokens in 4 ms (benefiting from the INT4 quantization applied in Round 1). The target model verifies the candidate block in approximately 32 ms, comparable to one optimized autoregressive decode step.

Under the standard geometric-acceptance model, where each draft token is independently accepted with probability p_{acc} and one bonus token always follows the last accepted one, the expected accepted tokens per round for k draft tokens is $(1 - p_{\text{acc}}^{k+1}) / (1 - p_{\text{acc}})$. At $p_{\text{acc}} = 0.78$ and $k = 5$, this gives $(1 - 0.78^6) / (1 - 0.78) \approx 3.5$ tokens per round. The effective ITL becomes:

$$\text{ITL}_{\text{effective}} = \frac{4 + 32}{3.5} \approx 10.3 \text{ ms per token}$$

The result is a $3.1\times$ improvement over the Round 2 ITL of 32 ms. However, speculative decoding interacts with batching. At batch size 32, the verification step is no longer “free” because the GPU is closer to compute saturation. The system therefore applies speculation only when the current batch size is below 16, falling back to standard autoregressive decoding at higher loads. This adaptive policy maintains both the latency benefit at low load and the throughput benefit at high load.

9.10.3.5 Lessons from the case study

This optimization journey illustrates the principle that optimization order matters because each step moves the bottleneck. Precision engineering (Round 1) was applied first because it yields the largest single improvement and enables subsequent optimizations by freeing memory for larger batch sizes. Fusion (Round 2) addressed the new bottleneck exposed by precision engineering. Speculative decoding (Round 3) provided latency improvement once the throughput target was met.

Each optimization changed the bottleneck. Before Round 1, the system was purely memory-bandwidth-bound. After INT4 quantization and batching, the system was partially compute-bound at large batch sizes. After fusion, kernel launch overhead was negligible, making the remaining bottleneck the fundamental memory-bandwidth limit for decode. Each optimization was validated by reprofiling to confirm the bottleneck shift.

The final system combines five distinct techniques: INT4 weight quantization, INT8 KV cache compression, FlashAttention-2, `torch.compile` with CUDA Graphs, and adaptive speculative decoding. These techniques are not independent; they interact. INT4 quantization enables larger batch sizes, which changes whether speculative decoding is profitable. FlashAttention’s benefit depends on sequence length, which grows during generation. The performance engineer must reason about these interactions holistically, guided by profiling data at each stage.

The case study demonstrates how disparate optimizations compound sequentially, transforming an unusable prototype into a production-grade deployment. The path to these speedups, however, is lined with conventional wisdom that often proves disastrous at scale.

9.11 Fallacies and Pitfalls

A team upgrades their inference cluster from A100s to H100s, expecting a $3\times$ latency reduction based on the spec sheet’s teraFLOP/s rating, only to find their generative model barely runs 15

percent faster. The trap is pervasive: assuming that raw compute capacity dictates inference speed when the workload is entirely bound by memory bandwidth.

Fallacy: *More FLOP/s means faster inference.*

The roofline model demonstrates that most inference operations are memory-bound, not compute-bound. A GPU with $2\times$ the peak FLOP/s but the same memory bandwidth will not generate tokens any faster for batch-1 LLM decode. The correct metric for memory-bound workloads is bandwidth, not FLOP/s. This fallacy leads organizations to purchase the most expensive compute hardware when a mid-range GPU with equivalent HBM bandwidth would deliver identical inference throughput.

Pitfall: *Planning FP8 adoption as an automatic training-time halving.*

FP8 doubles the peak TFLOP/s and doubles the effective memory bandwidth, but these gains are realized only for operations that are bottlenecked by compute or bandwidth at FP16. Element-wise operations like activation functions are already limited by kernel launch overhead, not by precision. Communication-bound distributed training steps gain nothing from reduced arithmetic precision if the communication volume (gradient sizes) is not also reduced. The actual speedup depends on the fraction of execution time spent in precision-sensitive operations.

Fallacy: *The largest kernel is the whole performance problem.*

The profiling case study in section 9.10.3 illustrates this pitfall. Engineers naturally focus on the single largest kernel, which is often the GEMM in a transformer layer. When the GEMM is already near-optimal, however, the remaining performance budget is distributed across dozens of smaller operations: normalization, activation, attention scoring, KV cache management, and kernel launch overhead. Collectively, these “small” operations can consume more than half of total execution time. Graph compilation and systematic fusion address this long tail more effectively than further GEMM optimization.

Pitfall: *Applying speculative decoding without considering batch dynamics.*

Speculative decoding excels at batch size 1, where decode is deeply memory-bound and the verification step is essentially “free” (the GPU has ample spare compute). At large batch sizes, decode approaches the compute-bound regime, and the verification step adds meaningful compute cost. Furthermore, the variable number of accepted tokens per request complicates continuous batching schedulers. In high-throughput serving scenarios with large batches, the overhead of speculation may outweigh its latency benefits.

Fallacy: *MoE expert count is a free scaling knob.*

Increasing the number of experts in an MoE model increases total parameters (capacity) without proportionally increasing per-token compute, which seems like a free lunch. Each additional expert, however, increases: (1) total memory requirements, requiring more GPUs; (2) AllToAll communication volume for expert routing; (3) load balancing difficulty, since the router must distribute tokens across more experts; and (4) training instability, as more experts compete for activation. Beyond approximately 64–256 experts, the system-level costs often outweigh the capacity benefits.

Pitfall: *Using graph compilers as a substitute for kernel analysis.*

Graph compilers have improved dramatically, but they remain limited by their cost models and fusion heuristics. FlashAttention required human insight to recognize that attention could be reformulated as a tiled algorithm with online softmax, an algorithmic insight beyond the scope of ordinary compiler rewrite rules. Similarly, speculative decoding and MoE routing require algorithmic innovation that compilers cannot discover. Compilers automate known optimizations; human engineers discover new ones.

Fallacy: *The lowest supported precision is always the best precision.*

Aggressive quantization (INT4 weights, INT4 KV cache, FP8 activations) can degrade model quality in ways that are difficult to detect with standard benchmarks but visible to users. Perplexity on a held-out dataset may change by less than 1 percent, but the model may produce subtly worse responses for edge cases, rare languages, or complex reasoning tasks. The correct approach is targeted quantization: apply the most aggressive precision to the least sensitive components (KV cache, intermediate activations) and preserve higher precision for the most sensitive (first and last layers, attention logits). Calibration on a representative dataset, followed by evaluation on diverse quality benchmarks, is essential before deploying any quantized model to production.

Pitfall: *Measuring throughput without measuring quality.*

A model serving system that generates 200 tokens/second is not twice as good as one generating 100 tokens/second if the first system achieves that throughput by using INT4 quantization that degrades answer quality by 15 percent. Performance metrics must always be reported alongside quality metrics. The correct optimization target is the Pareto frontier of throughput vs. quality, not throughput alone.

Fallacy: *A single profiling run is sufficient to characterize performance.*

ML system performance is nonstationary. GPU thermal throttling reduces clock speeds (and therefore FLOP/s) after sustained workloads, sometimes by 10–15 percent. Memory fragmentation accumulates over hours of serving, gradually reducing effective batch size. Network congestion varies with cluster-wide traffic patterns. A profiling run during a cold start may show different bottleneck patterns than one after hours of production serving. Reliable performance characterization requires profiling under realistic, sustained conditions, ideally sampling multiple times across a production run.

Pitfall: *Optimizing for average case while ignoring tail latency.*

A serving system may achieve excellent average inter-token latency (30 ms) while exhibiting P99 latency of 500 ms due to garbage collection pauses in the Python runtime, CUDA memory allocation stalls, or occasional AllReduce delays from network congestion. For interactive applications, the user experience is dominated by the worst case, not the average. Performance engineering for production systems must profile and optimize tail latency specifically, often through techniques orthogonal to the throughput optimizations in this chapter: preallocated memory pools, CUDA graph replay (which eliminates allocation variance), and priority scheduling for latency-sensitive requests.

9.12 Summary

Recognizing these pitfalls saves teams from wasting months optimizing the wrong layer of the stack. Performance engineering transforms a model that should be efficient into one that is, by attacking a fundamental bottleneck of accelerator-based ML systems: the memory wall. The Roofline Model provides the diagnostic framework, classifying operations as compute-bound or memory-bound based on their arithmetic intensity relative to the hardware’s ridge point. For the NVIDIA H100, this ridge point is approximately 295.2 FLOP/byte at FP16, meaning most transformer operations fall in the memory-bound regime.

The chapter’s techniques form an optimization stack rather than a menu. Operator fusion eliminates redundant HBM round-trips by combining sequences of operations into single kernels. FlashAttention is the canonical example, avoiding the quadratic attention intermediates that dominate long sequences through tiling and online softmax; in the 8K attention example, this is a 65× reduction in materialized attention state. Precision engineering then reduces the bytes in the trips that remain: FP8 formats improve effective bandwidth on H100 hardware, block-wise quantization protects the outlier features that defeat uniform quantization, and KV cache compression directly increases the batch sizes a serving node can admit.

Graph compilation moves those local transformations from hand-written kernels into the model graph. `torch.compile`/TorchInductor generates optimized Triton kernels from standard PyTorch code, XLA provides whole-program optimization for JAX/TPU workloads, and TensorRT specializes stable inference graphs. Communication-computation overlap applies the same bottleneck logic at the distributed boundary, hiding network latency when communication can run under useful compute. Speculative decoding and MoE go one level higher: instead of optimizing the same dense computation, they restructure the computation itself by obtaining more accepted tokens per target-model pass or by activating only the experts a token needs. System profiling closes the loop by showing which term dominates after each change, so the next intervention follows the new bottleneck rather than the old intuition.

The case study in section 9.10.3 demonstrated how these techniques compound in practice: INT4 quantization freed memory for larger batches, which changed the arithmetic intensity, which determined whether further bandwidth or compute optimizations were profitable. Each optimization shifted the bottleneck in a continuous displacement of overhead, requiring reprofiling and a new optimization decision. That profile-optimize-reprofile loop is the discipline of performance engineering: not making hardware faster, but making software match the physics of the hardware it

runs on. The memory wall is a physical constraint that grows wider with each hardware generation, so the engineer's response is to keep data close to compute, reduce precision to the minimum that preserves quality, and restructure algorithms to avoid unnecessary work. *Profiling is not merely the first step; it is every step.*

This iterative mindset also determines which skills endure as hardware evolves. Individual techniques may change as accelerator generations shift the ridge point of the Roofline Model and as architectures alter the dominant computational patterns. The fundamental discipline endures: measure the system, identify the binding constraint, apply the optimization that addresses that specific constraint, and then measure again. Engineers who internalize this cycle treat performance engineering as a continuous practice rather than a checklist, and that practice is what separates systems that merely run from systems that run efficiently at scale.

Key Takeaways: Match the software to the silicon

- **Bytes usually bind:** On H100-class accelerators, the chapter's roofline recap places most transformer work below the FP16 ridge point of 295.2 FLOP/byte, so useful speedups come first from reducing HBM traffic, keeping intermediates in SRAM, and spending compute only when it moves the active bottleneck.
- **Fusion makes locality real:** Operator fusion, CUDA graphs, and FlashAttention are not just kernel tricks; they remove launch overhead and materialized attention state. In the 8K example, tiled attention cuts stored intermediate state by 65×, turning memory pressure into usable throughput.
- **Precision buys bandwidth with risk:** FP8, INT8, and INT4 increase effective bandwidth and batch capacity only when outliers, scale factors, and quality checks are managed. Quantization is a systems contract between numerical format, kernel implementation, serving memory, and acceptable model behavior.
- **Algorithms can move the roofline:** Speculative decoding and mixture-of-experts change how much useful work each target-model pass performs, but they introduce acceptance-rate, routing, AllToAll, and load-balancing constraints. The win is real only after communication and scheduler costs are measured.
- **Profiling is every step:** The 70B case study shows optimization as bottleneck displacement: INT4 changes batch size, batch size changes arithmetic intensity, and the next limit moves. Fleet performance engineering means measure, optimize the binding term, then measure again before believing the speedup.

Hardware is sold by its *peak*. It is paid for by what it *sustains*, and the gap between the two is almost entirely data movement. Every technique here, FlashAttention most visibly, narrows that gap by keeping bytes off the slow path between memory and compute. This is the memory wall again, the same physical limit met one layer up in the stack: in the hardware it set the ceiling, and here it is the thing the software spends all its effort trying to reach. The accelerator's advertised number was always real; this chapter is how much of it the fleet actually gets to keep.

What's Next: From optimization to serving

Operator fusion, precision reduction, graph compilation, and algorithmic innovations like speculative decoding and MoE extract maximum computational efficiency from a single model executing on bare metal. Optimizing an isolated forward pass, however, is merely the precursor to deployment. In production, the same model must handle bursts of concurrent requests, share accelerators with other work, and preserve latency budgets while request lengths and arrival rates change. Chapter 10 transitions from local execution mechanics to the architecture of robust serving systems. The low-level optimizations developed here become the primitives that make high-availability serving possible: they reduce per-request memory, increase useful batch size, and give the scheduler more room to protect tail latency.

 Research Questions: For further inquiry

- How should roofline and profiler evidence decide whether to optimize memory traffic, compute, launch overhead, or communication?
- How do distributed-training and collective-communication costs limit the value of local kernel optimizations?
- When does lower precision improve effective bandwidth without violating quality or latency requirements?
- How should fusion, tiling, FlashAttention, and CUDA Graphs be evaluated when each shifts the next bottleneck?

Purpose

Why does inference cost eventually dwarf training cost, and what does this mean for system design?

Training a model is a one-time expense; serving it is perpetual. A model trained once for millions of dollars may serve billions of requests over its lifetime, and every request consumes compute, memory, network, and energy budget. The serving cost dominance law captures this economic reality: for a successful production model, ongoing inference operating expense can exceed the one-time training capital expenditure by orders of magnitude. That cost structure changes the architecture: optimizations that shave milliseconds from inference latency or percentage points from accelerator utilization compound across billions of requests into substantial savings or costs. Performance engineering supplied the local toolkit—fusion, precision, compilation, and algorithmic changes such as speculative decoding—and this chapter applies those tools at serving scale, where batching, sharding, routing, autoscaling, and isolation must preserve strict latency budgets under live traffic. Reliability requirements intensify as well, because downtime during serving means lost revenue and broken user experiences, not merely delayed experiments. Inference at scale is where ML systems succeed or fail economically. Serving the fleet is a continuous exercise in C³ management: batching compute for throughput while holding coordination overhead within strict tail-latency budgets.

Learning Objectives

- Quantify lifetime serving cost from request volume, token mix, accelerator price, utilization, and latency targets
- Select batching and scheduling policies for vision, LLM, recommender, and streaming workloads
- Analyze attention-cache capacity, fragmentation, and decode-time policies for memory-bound language-model serving
- Compare sharding, disaggregation, and quantized serving designs using communication, memory, and quality constraints
- Evaluate routing, load balancing, and isolation controls against tail latency and noisy-neighbor risks
- Design autoscaling and multi-region failover policies that balance cold starts, cost, and SLO compliance
- Synthesize serving architectures that manage C^3 trade-offs across request, replica, service, and platform layers

10.1 The Economics and Architecture of Inference

IMAGINE a language model that costs \$5 million to train over two months. Once deployed to a global user base serving thousands of queries per second, that same model burns through \$5 million in inference compute every single week. The economics of inference force a radical architectural shift: we are no longer optimizing a temporary batch job; we are operating a perpetual, latency-sensitive factory.

Operator fusion, precision engineering, and graph compilation can maximize throughput on individual forward passes. The next challenge emerges when a single optimized model must serve thousands of concurrent users across a globally distributed fleet. Single-machine inference optimization, including batching, caching, model optimization, and hardware acceleration, provides the building blocks. Distributed approaches become necessary when those techniques reach their limits.

Distributed inference systems must solve problems that do not exist at single-machine scale. Load balancing¹ becomes critical when requests must be distributed across hundreds of GPU instances while maintaining latency guarantees. Request routing must account for model-specific characteristics: recommendation systems with trillion-parameter embedding tables require different placement strategies than large language models that generate responses token by token. Autoscaling must anticipate demand fluctuations that can change request volume by orders of magnitude within minutes while maintaining latency bounds users expect.

The economics of inference at scale differ fundamentally from training economics. Training costs are dominated by compute time and can be amortized over the lifetime of the resulting model. Inference costs are directly tied to user traffic and revenue. An e-commerce recommendation system might serve millions of requests per second during peak shopping periods, with each request contributing directly to potential revenue. The cost of overprovisioning during quiet periods or underprovisioning during peaks translates immediately to business impact. Inference efficiency becomes a first-order concern in ways that training efficiency rarely achieves. Building such a service requires three linked decisions: when distribution becomes necessary, how the architecture preserves latency bounds under varying load, and how resource utilization stays high enough that serving cost does not erode the value the model creates.

10.1.1 When single-machine serving is insufficient

Three distinct signals indicate when distributed inference becomes necessary rather than merely optional. Table 10.1 categorizes these triggers by constraint type and corresponding strategy.

The first signal is memory exhaustion, which occurs when model parameters, key-value caches, or embedding tables exceed single-device capacity. A single NVIDIA H100 GPU provides 80 GB of

¹ | **Load Balancing (Inference):** GPU inference requests range from 10 ms to 30+ seconds with high variance, unlike web requests that complete in uniform milliseconds. This variance invalidates round-robin and random assignment, forcing queue-depth-aware routing strategies that add monitoring overhead but prevent tail-latency blowups across heterogeneous GPU fleets.

² | **HBM3 (High Bandwidth Memory 3):** 3D-stacked DRAM delivering 3.35 TB/s on the H100 vs. 2.04 TB/s for HBM2e on the A100. Because large language model (LLM) decode is memory-bandwidth-bound, this improvement translates directly into higher tokens-per-second and larger feasible batch sizes, making HBM generation one major variable in inference cost-per-token.

HBM3² memory; section G.1 records the provenance of this capacity figure and the other canonical hardware constants used throughout the analysis that follows. GPT-4-class models dwarf that capacity: the public ~1.8T-parameter mixture-of-experts estimate implies ~3.5 TB just for weights in FP16 precision, forcing distribution across multiple GPUs regardless of throughput requirements. Recommendation systems with trillion-parameter embedding tables face similar constraints: Meta’s DLRM architecture³ stores embedding tables that require multiple terabytes of memory.

Beyond memory constraints, throughput limitations emerge when request volume exceeds single-machine capacity even with optimal batching. Consider a recommendation system serving 100,000 queries per second with a 10 ms latency budget. If single-machine throughput peaks at 10,000 QPS, no amount of optimization on that machine can satisfy demand. Horizontal scaling across multiple replicas becomes mandatory.

Finally, strict latency requirements drive distribution when model execution time exceeds latency budgets even at batch size one. Large language models generating responses token by token face this constraint acutely. A 70-billion parameter model requires approximately 140 GB of memory in FP16, exceeding a single 80 GB H100-class GPU before KV cache is considered. Even when quantization or larger-memory hardware makes a single-replica configuration possible, decode throughput is often limited by memory bandwidth. Sharding the model across multiple GPUs enables parallel computation that reduces time-to-first-token below acceptable thresholds.

Table 10.1: Triggers for Distributed Inference: Each constraint type indicates different distribution strategies. Memory constraints require model sharding; throughput constraints require replication; latency constraints may require either depending on whether the bottleneck is compute or memory bandwidth.

Constraint	Single-Machine Limit	Example Workload	Distribution Strategy
Memory	80 GB (H100)	GPT-4 (~3.5 TB FP16)	Tensor/pipeline parallelism
Throughput	~10K QPS (vision)	100K QPS RecSys	Horizontal replication
Latency	Model execution time	500 ms LLM TTFT	Model sharding

Memory, throughput, and latency triggers all become user-visible once an interactive endpoint starts streaming. **Time to First Token (TTFT)**⁴ determines when the user sees a response begin, while **Time Per Output Token (TPOT)** determines whether the rest of the response arrives at a readable pace; this is why inference reverses many of the optimization priorities from training.

 Checkpoint 10.1: Distribution strategy selection

Verify your understanding of when to move from single-machine to distributed inference:

☐ **Shard vs. replicate:** For a 13B model (26 GB weights) that fits on a single A100, select model sharding or horizontal replication when throughput requirements double.

☐ **Latency floor:** For a real-time speech-to-text service where inter-token latency is the primary bottleneck, determine whether data-parallel replication reduces this latency.

☐ **Mandatory sharding:** Explain why model sharding is mandatory for a 175B model on 80 GB GPUs, regardless of the request volume.

☐ **Latency trigger:** Identify when a latency target forces distribution and when added network, serialization, coordination, or queuing overhead can erase the benefit.

10.1.2 The fundamental inversion: Training vs. inference

The contrast between training and inference optimization extends beyond the basic throughput-vs.-latency distinction. Training optimizes for samples processed per hour and tolerates latency variations. Inference optimizes for response time and must meet strict latency bounds. At scale, this inversion manifests in system architecture, resource allocation, and operational priorities. Table 10.2 details six key system aspects where these differences emerge.

3 | **DLRM:** Meta’s 2019 reference architecture separates dense features – GPU-bound multilayer perceptrons (MLPs) – from sparse features (CPU-bound embedding lookups), creating a hybrid serving topology (Naumov et al. 2019). Production recommendation characterizations show why this structure matters for serving: embedding-heavy recommendation models create memory-access and capacity constraints that differ from dense CNN, RNN, or LLM inference (Gupta et al. 2020).

4 | **TTFT vs. TPOT:** Time to First Token (prefill) determines the perceived responsiveness; Time Per Output Token (decode) determines the perceived reading speed. Humans read at roughly 5–10 tokens/sec; TPOT above roughly 100–200 ms can begin to feel slower than natural reading, while many products target lower TPOT for smooth streaming. This dual service level agreement (SLA) requirement forces schedulers to prioritize decode tokens over new prefill prompts.

Table 10.2: Training vs. Inference System Requirements: The fundamental inversion from throughput to latency optimization ripples through every aspect of system design.

Aspect	Distributed Training	Distributed Inference
Primary metric	Throughput (samples/hour)	Latency (P99 ms)
Acceptable variance	Hours	Milliseconds
State management	Checkpoints (periodic)	Session state (continuous)
Batch formation	Large, controlled	Request-driven, variable
Failure tolerance	Restart from checkpoint	Redirect without user impact
Cost structure	Fixed duration, variable rate	Variable duration, fixed SLO

Training tolerates substantial latency variance because the optimization target is aggregate progress over hours or days. A training iteration that takes 2 seconds instead of the usual 1 second represents acceptable variation. An inference request that takes 2 seconds instead of 100 milliseconds represents catastrophic failure, potentially causing user abandonment or cascading timeouts in dependent services.

State management differs fundamentally. Training maintains model state (parameters, optimizer states) that evolves gradually and can be captured in periodic checkpoints. Inference often maintains session state (conversation history, key-value caches, user context) that must be preserved across requests and cannot tolerate the staleness that checkpoint-based recovery would introduce.

Failure handling diverges correspondingly. Training failures trigger checkpoint restoration and continuation, with minutes of lost progress being acceptable. Inference failures must be invisible to users. Requests redirect to healthy replicas, degraded results substitute for unavailable models, and SLOs must be maintained despite infrastructure instability.

10.1.3 The serving tax: Overhead of distribution

Distributing inference across multiple machines introduces overhead absent from single-machine serving. This “serving tax” must be understood and budgeted within latency constraints.

Network communication adds latency for every cross-machine interaction. Within a data center, network round-trip times range from 50–500 microseconds depending on topology and congestion. For model sharding that requires synchronization between GPUs on different machines, each synchronization point adds this overhead. A model sharded across 8 machines with 4 synchronization points per inference adds 200 microseconds to 2 milliseconds of network latency. Section D.1 develops the α - β model that decomposes each such transfer into a fixed startup latency plus a bandwidth-dependent term, giving the quantitative framework for budgeting these synchronization costs against a latency SLO.

Serialization overhead compounds the problem by converting in-memory tensors to network-transmittable formats. Traditional serializers like Protocol Buffers, JSON, and Python’s `pickle` perform a parse-allocate-copy cycle on every transfer, and a 1 GB activation tensor takes approximately 100 milliseconds to serialize and deserialize through such formats. Zero-copy alternatives like FlatBuffers and Cap’n Proto⁵ sidestep most of this cost by accessing wire-format data in place, but they impose stricter schema layout requirements that not every production stack adopts.

Load balancer latency adds another layer. Requests must be routed to appropriate replicas, which requires examining request metadata, consulting routing tables, and forwarding to selected backends. Well-optimized load balancers add 100–500 microseconds; poorly configured ones can add milliseconds.

Coordination overhead emerges when requests require fan-out to multiple services. A recommendation system that queries a user model, item model, and ranking model in parallel must coordinate these queries and aggregate results. The coordination logic itself consumes CPU cycles and introduces latency variation.

The total serving tax often consumes 10–30 percent of the latency budget in distributed systems, as equation 10.1 shows:

$$T_{\text{total}} = T_{\text{compute}} + T_{\text{network}} + T_{\text{serialization}} + T_{\text{coordination}} + T_{\text{queuing}} \quad (10.1)$$

⁵ | **Zero-Copy Serialization:** FlatBuffers and Cap’n Proto access wire-format data in place, eliminating the parse-allocate-copy cycle of Protocol Buffers or JavaScript Object Notation (JSON). For distributed inference with large activation tensors, this drops per-hop serialization overhead from milliseconds to microseconds, reclaiming latency budget that would otherwise consume 5–10 percent of a tight SLO.

Minimizing this tax requires co-locating communicating components, using high-bandwidth interconnects, and designing communication patterns that minimize round trips.

10.1.4 Serving cost can dominate training cost

The serving tax quantified above consumes a fraction of the latency budget per request. The true economic impact of inference emerges when we consider cost over a model's entire operational lifetime. The **serving cost dominance law** (principle 15) states that serving cost can dominate training cost by orders of magnitude because training is a *one-time capital expenditure* (CapEx) while serving is a *continuous operational expenditure* (OpEx) that scales with user growth. A quick cost calculation makes the multiplier concrete.

CapEx

OpEx

Lifetime serving cost dwarfs one-time training.

Napkin Math 10.1: The serving cost multiplier

Problem: A team has spent \$2,000,000 training a 70B parameter model and now serves it to 1,000,000 daily active users (DAU), each making 50 requests/day. Is training or serving the dominant cost over 1 year?

Math:

1. **Training Cost:** \$2,000,000 (One-time).
2. **Metric:** Annual inference volume is $10^6 \text{ users} \times 50 \text{ reqs} \times 365 \text{ days} \approx 18.25\text{B}$ requests/year.
3. **Cost per Request:** Assume a 70B model on H100 costs $\approx \$0.001/\text{request}$ (input + output).
4. **Annual Serving Cost:** $18.25\text{B requests} \times \$0.001/\text{request} = \$18,250,000$.

Systems insight: Serving costs $9.1\times$ more than training in just the first year. A 10 percent serving-cost or latency-linked efficiency improvement saves about \$1.8M in the first year, nearly paying for the original training run.

The total cost of operating a model comprises training cost (a one-time expense) and serving cost (an ongoing expense), as equation 10.2 shows:

$$C_{\text{total}} = C_{\text{training}} + C_{\text{serving}} \times T_{\text{deployment}} \times Q_{\text{rate}} \quad (10.2)$$

where C_{training} is the one-time cost to train the model, C_{serving} is the cost per query served, $T_{\text{deployment}}$ is the deployment duration in appropriate time units, and Q_{rate} is the query rate.

The same leverage holds across application categories with different cost structures. A recommendation model (DLRM) trained for \$12,000 (\$3000 hardware for 1,000 GPU-hours at \$3/GPU-hour, plus $3\times$ additional engineering cost for data and experimentation) and served at 10,000 QPS for 730 days accumulates 6.31×10^{11} lifetime queries, which at \$10/million queries costs \$6,307,200 to serve—a $525.6\times$ leverage on serving optimization over training optimization. The cost dominance ratio varies by application. Table 10.3 quantifies this disparity:

Table 10.3: Training vs. Serving Cost Ratios: High-QPS applications like recommendation systems show the most extreme cost dominance of serving over training.

Application	Training Cost	Annual Serving Cost	Ratio
Recommendation (high QPS)	\$10K–\$100K	\$1M–\$10M	100–1000×
Search ranking	\$100K–\$1M	\$10M–\$100M	100–1000×
LLM API	\$1M–\$100M	\$10M–\$1B	10–100×
Internal analytics	\$1K–\$10K	\$10K–\$100K	10–100×

The cost structure motivates serving optimization: every percentage point of efficiency improvement yields ongoing cost reduction over the model's operational lifetime. Figure 10.1 illustrates why optimization matters by showing how the gap between naive and optimized serving determines whether an inference service is profitable or hemorrhaging money.

Figure 10.1: The Serving Cost Curve: Cost per 1000 tokens decreases with scale and optimization. Single-GPU serving reaches break-even only at very high volume. Multi-GPU batching breaks even at moderate volume. Fully optimized serving (INT4, continuous batching, speculative decoding) achieves profitability at much lower volumes, fundamentally changing the economics of inference.

The cost ratios in table 10.3 tell a *static* story, but the *dynamics* of cost accumulation reveal an even more striking pattern. Figure 10.2 plots cumulative total deployment cost over a 36-month window for three representative scenarios: a small model with low traffic, a 70B LLM serving one million daily active users, and a recommendation system serving 100 million users. The vertical crossover markers show when cumulative serving spend equals the original training cost; because the plotted curves include both training and serving, the total-cost curve is at roughly twice the training baseline at that marker. For recommendation systems, serving dominates within days; for high-traffic LLMs, within roughly six weeks. Only small models with expensive training and low traffic see training cost dominate for extended periods. This temporal view reinforces why inference optimization deserves early engineering attention at production scale. For generative LLM services, serving-specific designs can translate directly into throughput, cost, and power gains (Patel et al. 2024).

10.1.5 The inference landscape: Beyond LLMs

A common misconception frames inference at scale as synonymous with LLM serving. Large language models present distinctive challenges and attract attention, but they are only one part of production inference. Appropriate technique selection requires understanding the full inference landscape. In large consumer platforms, recommendation and ranking workloads can dominate AI inference cycles and capacity, even though they are not the only user-visible model class (Gupta et al. 2020; Hazelwood et al. 2018). Vision and image processing, NLP and LLM workloads, fraud detection, ads, and other classification tasks fill out the remainder. Table 10.4 breaks down these model types qualitatively by serving pressure and optimization challenge, and the comparison shows that each class binds on a different constraint: recommendation on embedding lookup, vision on batch efficiency, LLMs on memory bandwidth, and speech on sequential decode. No single optimization serves all four.

Recommendation systems often dominate high-volume consumer inference because they serve predictions for many user interactions. Every page load, scroll, or click can trigger ranking or retrieval inference. A user browsing an e-commerce site might generate many recommendation requests in a single session. In contrast, LLM queries typically require explicit user action and occur less frequently.

Figure 10.2: The Serving Cost Crossover: Cumulative total deployment cost (initial training plus ongoing serving) for three scenarios. Vertical markers indicate when the serving portion equals the one-time training cost. For high-traffic LLMs, serving cost matches training cost within weeks. For recommendation systems at 100M daily active users, serving dominates within days. Only low-traffic, expensive-to-train models see training cost dominate for extended periods.

The distribution has direct implications for technique selection. Recommendation systems have driven important production inference innovations: dynamic batching, embedding sharding, feature store architectures, and low-latency serving were all developed primarily for recommendation workloads (Naumov et al. 2019; Gupta et al. 2020). LLM-specific techniques like continuous batching and KV cache management address a different slice of production inference. Text-to-image systems such as DALL-E provide one multimodal model example (Ramesh et al. 2021), but multimodal serving volume and latency targets remain product-specific.

Table 10.4: Production Inference Landscape: Different model types create different serving pressure, latency requirements, and optimization challenges. The table is a qualitative workload map rather than a universal traffic-share distribution. Technique selection must match the specific workload.

Model Type	Serving Pressure	Latency Target	Key Challenge
Recommendation/ranking	Very high in consumer platforms	<10 ms P99	Embedding lookup
Vision (CNN)	Workload-dependent	20–100 ms	Batch efficiency
LLM	High cost per request	100 ms–10s	Memory bandwidth
Speech/Audio	Stream-driven	Real-time	Sequential decode
Multimodal/text-to-image	Emerging and product-specific	Varies	Cross-modal coordination

10.1.6 The serving hierarchy

The optimization techniques organize into a **serving hierarchy**, analogous to the memory hierarchy in computer architecture. Each level owns a different bottleneck, so an optimization that helps one level can leave another unchanged. The request level follows one request through preprocessing, batching, caching, and model execution, where the target is the latency a user sees. The replica level looks inside one model instance, where GPU utilization, memory management, kernel efficiency,

and model optimization determine how much useful throughput that replica can deliver before it saturates. The service level then works across many replicas of the same model, using load balancing, request routing, and autoscaling to turn individual replicas into aggregate capacity. The platform level works across services and tenants, where resource allocation, multi-tenancy, scheduling, and placement decide whether a shared serving fleet remains efficient without allowing one workload to degrade another.

The hierarchy matters because each level changes a different metric and fails at a different boundary. A related deployment stack appears in figure 10.3, showing how requests pass through edge, routing, and model-serving infrastructure in production.

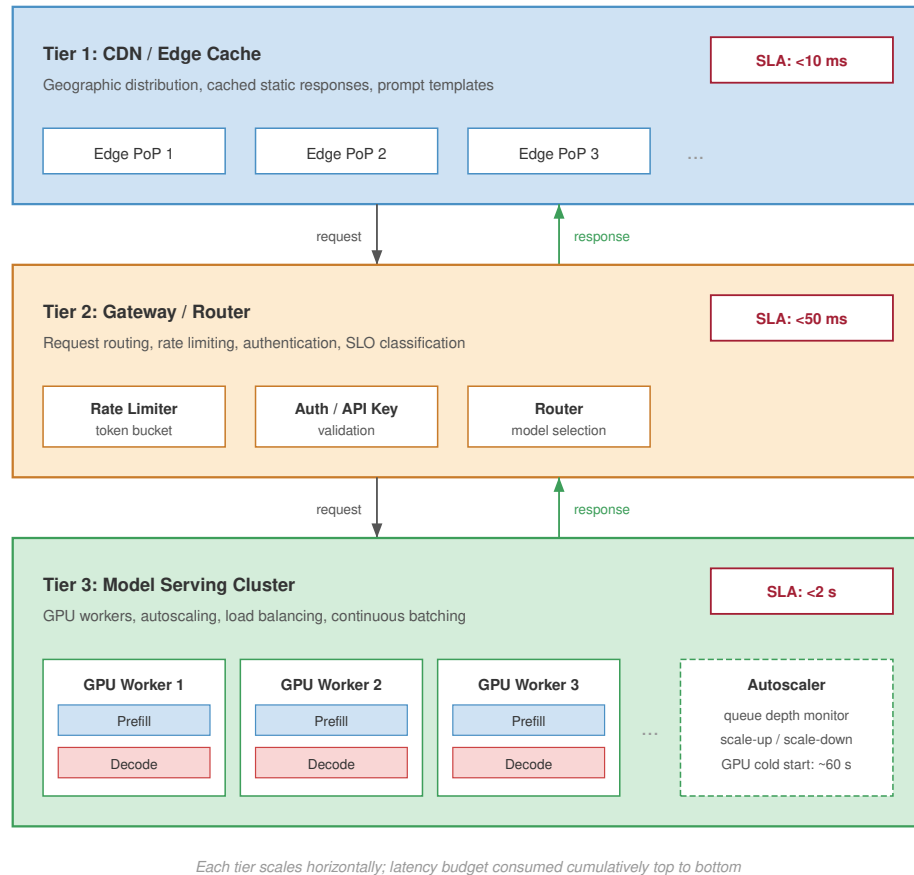

Figure 10.3: Serving Deployment Stack: A three-tier serving stack with cumulative latency budget from top to bottom. Tier 1 (CDN/Edge Cache) handles geographic distribution and cached static responses (SLA <10 ms). Tier 2 (Gateway/Router) handles request routing, rate limiting, and authentication (SLA <50 ms). Tier 3 (Model Serving Cluster) runs GPU workers with autoscaling and continuous batching (SLA <2 s).

Each level has distinct optimization levers, and table 10.5 shows why the lever is level-specific: request-level changes reduce per-request latency, replica-level changes raise utilization, service-level changes add aggregate capacity, and platform-level changes improve fleet efficiency across tenants. Optimizing the wrong level moves the wrong metric.

Table 10.5: Serving Hierarchy Optimization Targets: Each level of the hierarchy addresses different metrics with different techniques.

Level	Optimization Target	Key Techniques
Request	Per-request latency	Dynamic batching, caching, prefetching
Replica	Throughput, utilization	Memory optimization, kernel fusion
Service	Aggregate capacity	Load balancing, routing, autoscaling
Platform	Resource efficiency	Multi-tenancy, scheduling, placement

Checkpoint 10.2: The serving hierarchy

Verify your understanding of where specific optimizations sit within the serving hierarchy:

- ☐ **Memory level:** Identify the hierarchy level responsible for managing GPU memory waste to increase concurrent request capacity.
- ☐ **Caching level:** Identify the hierarchy level responsible for reducing KV-cache waste when request lengths vary.
- ☐ **Load balancing:** Identify the primary optimization target of Service-level load-balancing algorithms like Power-of-Two-Choices.
- ☐ **Isolation level:** Evaluate the claim that multi-tenancy and resource isolation are primarily Request-level concerns.

The hierarchy guides the rest of the design while allowing a few techniques to cross levels. Batching, KV-cache layout, and decode-time optimizations start at the request level. Quantization, adapter state, and model sharding change the replica’s memory and compute budget. Disaggregated serving, load balancing, and autoscaling coordinate replicas into a service, while multi-tenancy and resource isolation govern the platform. Quantization appears across the hierarchy because it is a representation-level lever that changes memory, bandwidth, and cost budgets wherever model state or KV state resides.

10.2 Serving Architecture Dimensions

A recommendation system that processes 100,000 embedding lookups per second across a sharded feature store requires a fundamentally different serving architecture than a 70-billion parameter language model generating tokens one at a time. The difference is not merely one of framework choice; it reflects distinct constraints in batching strategy, memory management, scheduling policy, and deployment topology. Rather than catalog specific tools, this section identifies the architectural dimensions that distinguish serving systems and the constraints that drive each design decision. Specific frameworks serve as examples of these principles, not as the subject of study.

10.2.1 Batching strategy: The throughput-latency trade-off

The most consequential architectural decision in a serving system is how it forms batches from incoming requests. This choice determines the fundamental throughput-latency operating point.

Static batching collects a fixed number of requests before dispatching them to the accelerator. For vision models processing fixed-size inputs, this approach maximizes GPU utilization because all requests in the batch execute identical computation graphs with predictable memory access patterns. A ResNet-50 inference server can batch 32 or 64 images with near-linear throughput scaling because the batch amortizes fixed launch overhead and reuses resident weights across many inputs.

Autoregressive language models break this assumption. Each request generates a different number of output tokens, so static batching forces all requests to wait for the longest generation in the batch and can leave accelerator capacity idle after shorter requests finish. Continuous batching⁶ solves this by allowing requests to enter and exit the batch at each decoding step, an iteration-level scheduling approach introduced by Orca (Yu et al. 2022). When one request finishes generation, a new request

⁶ | **vLLM (Virtual LLM):** The name signals its core design: applying OS-style virtual memory to KV cache management, decoupling logical sequence addresses from physical GPU memory. Developed at UC Berkeley (2023), vLLM achieved 2–4× throughput over FasterTransformer and up to 24× over HuggingFace Transformers by eliminating the 60–80 percent memory fragmentation that capped batch sizes in prior serving systems (Kwon et al. 2023).

immediately fills its slot. Systems like vLLM combine this scheduling style with PagedAttention-based KV-cache management, achieving 2–4× throughput gains over prior LLM serving systems by reducing memory waste (Kwon et al. 2023).

Recommendation systems introduce a third pattern: **feature-parallel batching**. Because the bottleneck is distributed embedding lookup rather than dense matrix multiplication, these systems batch requests by feature type and shard the batch across embedding servers. The dense MLP computation that follows can then operate on prefetched, prebatched feature vectors. The batching strategies section (section 10.3) develops these approaches in full quantitative detail.

10.2.2 Memory management: From preallocation to paging

Serving systems differ fundamentally in how they manage accelerator memory, and this difference determines the maximum concurrent request capacity.

Definition 10.1: KV cache

KV Cache is a per-request LLM inference memory buffer that stores the Key and Value attention tensors of all previously generated tokens so the next token can be produced without recomputing the full attention over the prefix.

1. **Significance:** It reduces per-token attention compute from $O(n^2)$ to $O(n)$ in the sequence length, but its footprint grows linearly with both context length and batch size, often consuming more HBM than the model weights themselves and becoming the binding constraint on serving capacity. Section F.1.2 derives the fundamental sizing math.
2. **Distinction:** Unlike model weights (which are shared across all requests and statically allocated), the KV cache is request-private and dynamically sized; each concurrent user pays a separate, sequence-length-proportional memory tax that the scheduler must budget for.
3. **Common pitfall:** A frequent misconception is that reducing model size proportionally reduces serving memory. In practice, the KV cache dominates HBM at long contexts, so a quantized 70B model can still be capacity-bound at batch sizes the weights alone would easily admit.

Preallocated memory management reserves a fixed memory budget per request at admission time based on the maximum possible output length. For a model supporting 4,096-token outputs, every request reserves memory for 4,096 tokens regardless of whether it generates 50 or 4,000. This approach is simple and predictable but wastes memory proportional to the gap between maximum and actual output lengths. In practice, 60–80 percent of reserved KV cache memory goes unused.

Paged memory management, inspired by operating system virtual memory, allocates memory in fixed-size blocks (pages) and maps logical sequence positions to physical memory locations through a block table. As a request generates tokens, new physical blocks are allocated on demand. When generation completes, blocks return to the free pool immediately. This approach, exemplified by PagedAttention (covered in section 10.4.3), achieves near-100 percent memory utilization by eliminating both internal fragmentation (partially filled preallocations) and external fragmentation (unusable gaps between allocations).

The memory management strategy directly determines batch capacity: paged systems can serve 2–4× more concurrent requests than preallocated systems on the same hardware, because they reclaim memory that preallocation wastes. For a service with a fixed GPU budget, this translates directly to 2–4× lower cost per request.

10.2.3 Scheduling policy: FCFS, preemptive, and priority-aware

The scheduling policy determines which requests receive GPU time and in what order. This decision becomes critical when request mix is heterogeneous, with some requests requiring 50 tokens of output and others requiring 4,000. **First-come-first-served (FCFS) scheduling** processes requests in arrival order. FCFS is fair and simple but suffers from head-of-line blocking: a single long-generation

request delays all subsequent requests. For workloads with high output-length variance, FCFS produces poor tail latency.

Preemptive scheduling allows the system to pause a long-running request and swap its KV cache to CPU memory (or discard it for later recomputation) to make room for shorter, higher-priority requests. The cost of preemption is the swap overhead (transferring KV cache between GPU and CPU memory) or the recomputation cost (re-running the prefill phase when the preempted request resumes). Production systems typically preempt when a request has consumed more than $2\times$ the median generation length.

Priority-aware scheduling assigns different service classes to requests and guarantees that high-priority requests receive GPU slots before lower-priority ones. A production API might classify revenue-generating customer requests as critical, internal batch processing as standard, and free-tier traffic as best-effort. The scheduling policy then ensures that critical requests never wait behind best-effort traffic, even during load spikes.

10.2.4 Deployment topology: Single-GPU to disaggregated

The deployment topology determines how model computation maps to physical hardware, and this mapping is driven by the ratio of model size to single-device memory capacity. Single-GPU deployment is the simplest topology: the entire model fits in one device's memory, and all inference computation occurs locally. For models under 15–20 billion parameters (30–40 GB in FP16), this topology provides the lowest latency because it eliminates all inter-device communication.

Multi-GPU tensor parallelism shards each layer's weight matrices across multiple GPUs connected by high-bandwidth interconnect (NVLink at 900 GB/s on H100). Each GPU computes a partial result for every layer, and an all-reduce operation synchronizes the partial results before the next layer. This topology is necessary when model weights exceed single-device memory and provides latency reduction proportional to the parallelism degree, at the cost of communication overhead per layer. The model sharding section (section 10.5) analyzes the communication overhead quantitatively.

Disaggregated serving separates the prefill phase (processing the input prompt, which is compute-bound) from the decode phase (generating tokens one at a time, which is memory-bandwidth-bound) onto different hardware pools optimized for each workload profile. Prefill nodes use high-FLOP/s accelerators; decode nodes use high-bandwidth-memory configurations. This separation allows each phase to operate at its hardware's optimal operating point rather than compromising between the two regimes on shared hardware. The disaggregated serving section (section 10.4.9) develops this architecture in detail.

10.2.5 Stateful vs. stateless: The scaling divide

A serving system's statefulness determines whether horizontal scaling is trivial or requires careful engineering. Vision models and embedding lookups are typically stateless: any replica can serve any request because no per-session state persists between requests. Horizontal scaling is straightforward – add replicas behind a load balancer – and failure recovery is instant because the load balancer simply routes to a healthy replica.

LLM serving with KV cache is inherently stateful: the cache accumulated during a conversation creates replica-specific state that cannot be reconstructed without re-running the entire conversation history through prefill. This statefulness has cascading implications for system design. Load balancing requires sticky routing to direct subsequent requests in a conversation to the same replica. Autoscaling down requires draining active sessions, which can take minutes for long conversations. Failure recovery is expensive: when a stateful replica crashes, users either experience the latency of regenerating context (seconds) or lose conversation state entirely.

The choice between stateless and stateful serving is *not a framework feature but a consequence of the model architecture*. Systems that serve autoregressive models must engineer for statefulness; systems that serve fixed-computation models can treat scaling as a simpler capacity-planning exercise.

10.2.6 Architectural comparison

Table 10.6 summarizes how the batching, memory, scheduling, topology, and state dimensions interact across the major workload types. The table reveals that no single serving architecture is

optimal for all workloads; the constraint profile of each workload type determines the appropriate design point along each dimension.

Table 10.6: Serving Architecture Dimensions by Workload Type: Each workload’s constraint profile determines the optimal design point along five architectural dimensions. Selecting a serving system amounts to choosing the combination that matches the workload’s constraints.

Dimension	Vision/Embedding	LLM (Autoregressive)	Recommendation
Batching	Static/dynamic (uniform inputs)	Continuous (variable outputs)	Feature-parallel (sharded embeddings)
Memory	Preallocated (predictable)	Paged (variable KV cache)	Distributed (embedding tables)
Scheduling	FCFS (uniform cost)	Preemptive (high variance)	Priority-aware (SLO tiers)
Topology	Single-GPU replicas	Tensor/pipeline parallel	Hybrid CPU-GPU sharding
State	Stateless	Stateful (KV cache)	Stateless (feature store)

Checkpoint 10.3: Serving dimensions

Verify your understanding of how workload constraints drive architectural choices:

- ☐ **LLM vs. vision:** Explain why preemptive scheduling is more critical for LLMs than for vision models.
- ☐ **Stateful workloads:** Identify the workload type for which stateful serving (requiring sticky routing) is a fundamental requirement.
- ☐ **RecSys standard:** Explain why feature-parallel batching is the standard for recommendation systems but not for LLMs.
- ☐ **Memory pressure:** Identify which dimension (batching, memory, scheduling, topology, state) is primarily affected when quantization reduces model or KV-cache size.

The architectural dimensions determine which serving system to select for a given workload. Rather than comparing frameworks feature by feature, an engineer identifies the workload’s position along each dimension (batching pattern, memory profile, scheduling requirements, deployment topology, and statefulness) and selects the system that matches. The optimization techniques in this chapter operate within this architectural framework, each addressing a specific dimension.

10.3 Batching Strategies at Scale

A stream of hundreds of disparate chat requests arrives at an inference server every second. Processing them one by one leaves much of the GPU idle, starved for work between small decode steps. Waiting to gather a large static batch forces the first request in line to endure unacceptable latency. Batching strategies at scale demand dynamic algorithms that fuse requests on the fly without violating strict tail-latency deadlines.

Processing multiple requests together amortizes fixed costs (model loading, kernel launch overhead, and memory transfer latency) across more useful work, trading higher per-request latency for dramatically improved throughput. Single-machine serving applies this insight through **dynamic batching**, which collects requests within a time window before processing them together.

At scale, batching becomes more complex because different model architectures have distinct batching requirements. A strategy optimal for vision models may be catastrophic for LLMs, and techniques developed for recommendation systems may not apply to either.

In large consumer platforms, recommendation systems can constitute the majority of AI inference cycles or capacity pressure, with vision, language, ranking, fraud, ads, and other classification workloads sharing the remainder (Gupta et al. 2020; Hazelwood et al. 2018). Despite this distribution, we present batching strategies in order of conceptual complexity: vision (straightforward batching), LLMs (continuous batching with KV cache), and recommendation (feature-parallel batching with distributed embedding). This pedagogical ordering builds understanding progressively, even

though practitioners may frequently encounter recommendation workloads first. The taxonomy that follows matches batching strategies to model characteristics, providing quantitative analysis of when each approach applies and what performance to expect.

10.3.1 Why batching differs across model types

Batching efficiency depends on how computation scales with batch size relative to how memory and communication scale. Different model architectures exhibit different scaling relationships, requiring different batching strategies, as figure 10.4 summarizes.

For **vision models**, including convolutional neural networks (CNNs) and vision transformers (ViTs) processing fixed-size images, computation scales linearly with batch size while memory scales sub-linearly due to weight sharing. Larger batches improve GPU utilization with minimal overhead, making static or dynamic batching with large batch sizes optimal.

For LLMs in the decode phase, computation per token is small relative to memory bandwidth requirements for loading model weights. The bottleneck is *memory bandwidth*, not *compute*. Larger batches amortize weight loading across more tokens, dramatically improving throughput but with diminishing returns as batch size grows.

For recommendation systems, the bottleneck is often embedding lookup rather than dense computation. Batching strategies must optimize for parallel embedding access patterns rather than matrix multiplication throughput.

10.3.2 The physics of batching: The efficiency curve

Batching is not merely a heuristic; it is a trade-off governed by the physics of hardware utilization. We can model the relationship between batch size (B), request latency (T_{lat}), and throughput (X) to identify the optimal operating point for any inference system.

Here T_{lat} follows standard queuing notation for request time in system. Elsewhere in the book, L_{lat} denotes fixed latency overheads or latency components; this section keeps T_{lat} for the end-to-end request-time variable used in Little’s Law and batching equations.

The latency equation decomposes per-request latency into fixed overheads (kernel launch, memory loading) and variable costs (compute per sample):

$$T_{\text{lat}}(B) = T_{\text{fixed}} + B \times T_{\text{variable}}$$

- T_{fixed} : Costs paid once per batch (for example, loading weights from HBM, kernel launch latency).
- T_{variable} : Marginal cost of adding one request (for example, compute time for that sample).

The throughput equation describes the system’s capacity:

$$X(B) = \frac{B}{T_{\text{lat}}(B)} = \frac{B}{T_{\text{fixed}} + B \times T_{\text{variable}}}$$

The resulting **Batching Efficiency Curve** shows three distinct regimes. For small batch sizes (B), throughput is dominated by T_{fixed} , making the system latency-bound (or overhead-bound) where increasing B yields super-linear throughput gains. As B becomes large, the T_{fixed} term becomes negligible, and throughput asymptotically approaches the hardware limit $1/T_{\text{variable}}$, leaving the system compute-bound (or bandwidth-bound for LLMs). The optimal batch size sits at the knee of the curve, the point where throughput gains diminish while latency continues to grow linearly.

The engineering goal is to find the maximum B such that $T_{\text{lat}}(B) \leq \text{SLO}$. This formulation explains why vision models (high T_{variable}) saturate at smaller batches than LLMs (high T_{fixed} due to weight loading), requiring different tuning strategies.

Napkin Math 10.2: The batching efficiency curve

Problem: An engineer optimizes two services: a Vision model (ResNet) and an LLM (70B). At what batch size does each hit the “Knee” of its efficiency curve?

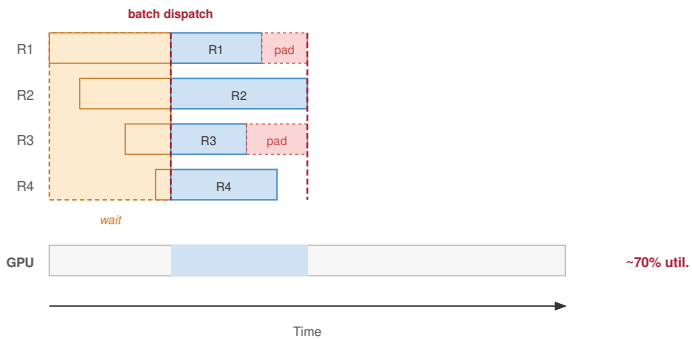

(a) No Batching

Requests processed sequentially; GPU idle between requests

**(b) Static Batching**

Wait for batch to fill, then process together; early arrivals wait

**(c) Dynamic Batching**

Assemble batch within a time window; shorter wait, adaptive batch size

Figure 10.4: Batching Strategies Compared: Three timelines show how batching policies trade wait time for GPU utilization. (a) No batching: requests processed sequentially, GPU idle between them (around 40 percent utilization). (b) Static batching: requests wait until a full batch is assembled before dispatch, with padding for short requests (around 70 percent utilization). (c) Dynamic batching: assembles a batch within a short time window with adaptive size, reducing wait and lifting utilization (around 85 percent).

Math: The knee occurs where the variable compute cost ($B \times T_{\text{var}}$) starts to exceed the fixed overhead (T_{fixed}).

1. **Vision Model** ($T_{\text{fixed}} = 2 \text{ ms}$, $T_{\text{var}} = 1 \text{ ms}$):

- Knee: $B \approx 2 \text{ ms} / 1 \text{ ms} = 2$.
- **Result:** This simplified latency model reaches its first overhead-amortization knee at a very small batch. Production CNNs often continue gaining throughput until batches of 32–64+ before hardware saturation.

2. **LLM Decode** ($T_{\text{fixed}} = 40 \text{ ms}$, $T_{\text{var}} = 0.5 \text{ ms}$):

- Knee: $B \approx 40 \text{ ms} / 0.5 \text{ ms} = 80$.
- **Result:** LLMs require massive batches to amortize the expensive weight-loading overhead.

Systems insight: Because the LLM’s “Fixed Overhead” (loading 140 GB of weights from HBM) is so large, the system has not reached the efficiency knee until batch size 80. LLM serving therefore requires continuous batching and paged memory: the system must pack hundreds of concurrent users into a single batch just to overcome the memory bandwidth bottleneck.

Translating these batch-level equations into system-wide capacity planning requires a classical result from queuing theory: **Little’s Law**⁷, which relates concurrency, throughput, and latency in any stable system. Across model architectures, table 10.7 shows that batching choice follows the binding bottleneck: compute for vision models, memory capacity or bandwidth for LLM prefill and decode, embedding lookup for recommendation systems, and real-time latency for speech.

Table 10.7: Batching Strategy by Model Type: Each model type has characteristic batching behavior determined by its computational bottleneck.

Model Type	Batching Strategy	Typical Batch Size	Key Constraint	Throughput Scaling
Vision (CNN)	Static/Dynamic	32–256	GPU compute	Near-linear to 64+
LLM (prefill)	Dynamic	1–64	Memory capacity	Sub-linear
LLM (decode)	Continuous	100–1000s	Memory bandwidth	Log-linear
RecSys	Feature-parallel	1000–10000s	Embedding lookup	Depends on sharding
Speech	Streaming	1	Real-time	N/A (latency-bound)

⁷ **Little’s Law:** From queuing theory, $Q_{\text{req}} = \lambda_{\text{arr}} T_{\text{lat}}$, so concurrency equals arrival rate times latency. For a serving fleet, this defines the capacity envelope: if a GPU can handle 32 concurrent requests and each takes 100 ms, the maximum arrival rate is 320 req/s. Beyond this, queues grow rapidly as utilization approaches 1, and tail latency (L_{lat}) explodes.

 Theorem 10.1: Little’s Law for inference

Concept: In any stable queuing system, the average number of requests in the system (Q_{req}) equals the arrival rate (λ_{arr}) multiplied by the average time a request spends in the system (T_{lat}).

$$Q_{\text{req}} = \lambda_{\text{arr}} \cdot T_{\text{lat}}$$

Application: Concurrency Planning

- **Target Throughput** (λ_{arr}): 1,000 requests/sec
- **Latency SLO** (T_{lat}): 100 ms (0.1 s)

Required Concurrency (Q_{req}): $Q_{\text{req}} = 1000 \times 0.1 = 100$ concurrent requests

Capacity Planning: If a single GPU replica handles batch size 8 with 80 ms latency:

1. Replica Throughput = $8 / 0.08 = 100 \text{ req/s}$
2. Throughput-only lower bound = $\lceil 1000 / 100 \rceil = 10$ replicas
3. SLO-sized replica count = $\lceil 100 / 8 \rceil = 13$ replicas

Verification: Total system concurrency = 13 replicas $\times$ 8 batch = 104, which leaves 4 request slots above the 100 required by Little's Law. The throughput-only lower bound would run at the stability boundary; the SLO-sized fleet runs at about 76.9 percent service utilization, leaving finite headroom for queueing variance and tail latency.

The distinction between throughput capacity and latency capacity is exactly what queueing theory formalizes; section F.1.1 derives the M/D/1 wait-time distribution that determines how much headroom a serving SLO needs.

10.3.3 Static and dynamic batching for vision models

Vision models represent the simplest batching case because inputs have uniform size (after preprocessing) and computation follows a predictable pattern. Single-machine batching principles apply directly, with scale introducing considerations of batch formation across multiple replicas.

Static batching collects exactly B requests before processing. This maximizes GPU utilization when request arrival is predictable but causes unbounded latency during low-traffic periods.

Dynamic batching collects requests for a maximum time window T_{window} or until reaching maximum batch size B_{max} , whichever occurs first. The expected latency under Poisson arrivals with rate λ_{arr} follows equation 10.3:

$$E[T_{\text{total}}] = E[T_{\text{queue}}] + T_{\text{batch}} + T_{\text{inference}}(B) \quad (10.3)$$

where $E[T_{\text{queue}}]$ is the expected queueing delay, T_{batch} is the batch formation delay (up to T_{window}), and $T_{\text{inference}}(B)$ is the inference time for batch size B . The arrival rate enters through the queueing and formation terms: under Poisson arrivals the mean inter-arrival gap is $1/\lambda_{\text{arr}}$, so a higher λ_{arr} fills the batch faster and shrinks both $E[T_{\text{queue}}]$ and T_{batch} , while a lower rate pushes them toward the T_{window} ceiling. The worked example that follows makes these interactions concrete.

Example 10.1: Dynamic batching for ResNet-50

Consider a vision classification service with the following requirements:

- **Arrival rate:** 5,000 QPS
- **Latency SLO:** 50 ms P99
- **Batch service time:** 5 ms at batch=1, 25 ms total for batch=32
- **Number of replicas:** 10 (each handling 500 QPS)

For a single replica with Poisson arrivals at $\lambda_{\text{arr}} = 500$ QPS:

The three choices in table 10.8 differ only in how much latency budget they convert into batch size:

Table 10.8: Dynamic batching policy comparison: Option C achieves about 33 percent higher per-replica capacity, or 25 percent lower utilization, at the cost of higher average latency. Both dynamic batching policies meet the 50 ms P99 SLO.

Policy	Batching window	Expected batch	Per-request compute	Utilization	Latency outcome
No batching	0 ms	1 request	5 ms	$\rho_{\text{serv}} = \lambda_{\text{arr}} \times T_{\text{svc}} = 500 \times 0.005 = 2.5$	Overloaded; cannot meet demand
Dynamic B	10 ms	5 requests	1.6 ms	$\rho_{\text{serv}} = 500 \times 0.0016 = 0.8$	~15 ms mean, ~30 ms P99
Dynamic C	20 ms	10 requests	1.2 ms	$\rho_{\text{serv}} = 500 \times 0.0012 = 0.6$	~22 ms mean, ~42 ms P99

Systems insight: Dynamic batching is useful only when the latency budget has slack. The serving policy converts unused latency headroom into higher throughput, but the same window would violate an already tight SLO.

At scale with multiple replicas, batch formation can occur either at individual replicas or at a centralized batching layer. Replica-local batching has each replica independently form batches from its assigned traffic. This approach is simpler to implement but may result in uneven batch sizes across replicas when load is imbalanced. Centralized batching uses a batching service to collect requests and dispatch formed batches to replicas. This achieves more uniform batch sizes but adds a centralization bottleneck and additional network hop. Production systems typically use replica-local batching with load balancing that ensures roughly equal traffic distribution, achieving the benefits of centralized batching without the complexity.

10.3.4 Continuous batching for LLM inference

The autoregressive bottleneck (principle 14) governs this regime: in generative models, the decode phase is strictly memory-bandwidth bound because the entire model weight set must be loaded for every single token generated. Throughput scales with batch size, sharing weight loads across multiple requests, not compute power.

Definition 10.2: Continuous batching

Continuous Batching is a serving strategy that decouples batch membership from iteration boundaries, allowing new requests to enter and completed ones to exit at every decode step.

1. **Significance:** It maximizes system throughput (X) by eliminating the padding waste and head-of-line blocking inherent in static batching. It ensures the GPU remains saturated even when requests have widely varying sequence lengths.
2. **Distinction:** Unlike static or dynamic batching (which group requests at the request level), continuous batching operates at the Iteration Level, dynamically reshaping the compute tensor at each clock cycle.
3. **Common pitfall:** A frequent misconception is that continuous batching is “purely a scheduler change.” In reality, it requires a Dynamic Memory Manager (like PagedAttention) because the KV caches for different requests grow and shrink at different rates, preventing static memory preallocation.

Decoupling batch membership from iteration boundaries is slot reuse: when one request reaches its stop token, the scheduler hands its KV-cache slot to a waiting request on the next decode step instead of leaving capacity idle until the longest sequence finishes.

8 | **Orca (Iteration-Level Scheduling):** Introduced by Yu et al. (2022), Orca demonstrated that scheduling at iteration granularity rather than request granularity allows sequences to enter and exit batches at each decode step. This eliminated the head-of-line blocking that wasted 50 percent+ of GPU compute in static batching and established the scheduling paradigm adopted by LLM serving systems such as vLLM.

Autoregressive language models present a unique batching challenge that static and dynamic approaches handle poorly. The key insight comes from the Orca system⁸ (Yu et al. 2022): traditional batching forces all sequences in a batch to complete before any new sequences can join, wasting compute when sequences finish at different times.

Consider a batch of 8 sequences. If one sequence completes after 10 tokens while others require 100 tokens, the completed sequence’s GPU resources sit idle for 90 iterations. With traditional batching:

$$\text{Wasted compute} = \frac{(100 - 10) \times 1}{100 \times 8} = 11.25\%$$

For realistic output length distributions with high variance, wasted compute can exceed 50 percent. Continuous batching (also called iteration-level batching) decouples batch membership from iteration boundaries. Algorithm 10.1 states the scheduler as a decode loop: completed requests release KV-cache pages, waiting requests enter freed slots, and the next batched kernel runs over the reorganized active set. This technique is central to the throughput-latency trade-off that defines large-scale LLM serving—Archetype A workloads (GPT-4/Llama-3, section 1.6.1) would be economically unviable without it, because their memory-bandwidth-bound decode phase leaves compute cores idle waiting for weights to load, and only by interleaving unrelated requests can the bandwidth be saturated.

Algorithm 10.1 Continuous batching decode scheduler

Require: waiting queue Q ; active set A ; KV-cache page allocator; active-token capacity C_{tok} ; batched decode kernel

Ensure: generated tokens for completed requests; a continually refreshed active batch

```

1: while the service is running do
2:   admit requests from  $Q$  while capacity and free KV-cache pages remain; allocate state, append to  $A$ 
3:   run one batched decode kernel over all sequences in  $A$ 
4:   append each sampled token; extend its KV-cache pages
5:   remove completed or length-limited sequences from  $A$ ; return their pages to the allocator
6:   if HBM pressure exceeds the policy threshold then
7:     preempt low-priority sequences by paging their KV-cache to CPU DRAM
8:   end if
9:   fill freed capacity from  $Q$ , or resume paused sequences whose pages now fit
10: end while
```

Admitting, completing, and refilling slots on every iteration keeps active-token capacity from idling behind the longest sequence in the batch, while the preemption path adds HBM-to-CPU-DRAM transfer latency under memory pressure. The throughput gain therefore scales with output-length variance and must be balanced against KV-cache movement. As figure 10.5 illustrates, static batching leaves the GPU idle while waiting for the longest request, whereas continuous batching keeps it saturated.

10.3.5 Continuous batching throughput analysis

The contrast in figure 10.5 motivates the throughput analysis: static batching leaves GPUs idle for the duration of the longest sequence in each batch, while continuous batching eliminates these idle gaps by inserting new requests at every iteration boundary. Continuous batching’s dynamic batch management maintains high GPU utilization regardless of sequence length variance. The throughput improvement depends on sequence length distribution. For a distribution with coefficient of variation $CV = \sigma/\mu$, the gain is approximately equation 10.4:

$$\text{Throughput gain} \approx 1 + \frac{CV^2}{2} \quad (10.4)$$

With typical LLM output lengths having $CV \approx 1.0$, continuous batching achieves approximately 1.5× throughput improvement. For highly variable outputs (conversational vs. code generation),

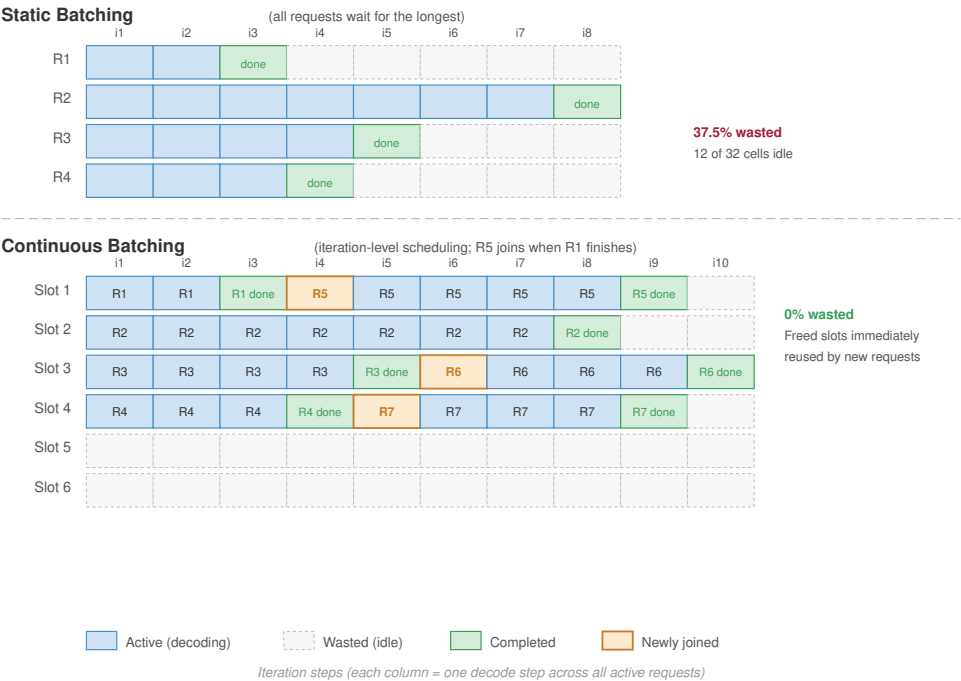

Figure 10.5: Static vs. Continuous Batching: In static batching (A), all requests in a batch must wait for the longest request to complete before the GPU can begin the next batch, leading to significant idle compute time (shaded gray). Continuous batching (B) allows new requests to enter the batch as soon as any request finishes, keeping the GPU saturated and dramatically improving throughput.

gains can reach 2–4×. This $1 + CV^2/2$ form estimates the average gain across the output-length distribution; section 10.3.6.3 develops a complementary $1 + k \cdot CV$ upper bound that compares the single longest sequence against the mean. The distributional estimate predicts typical throughput; the max-over-mean bound caps the best case a workload can reach.

The analytical gains translate directly into production systems. The following implementation study examines how vLLM realizes continuous batching through iteration-level scheduling, paged memory management, preemption, throughput, and GPU utilization.

 Example 10.2: Continuous batching in vLLM

vLLM implements continuous batching with several key mechanisms. Iteration-level scheduling evaluates at each decode step which sequences have generated end-of-sequence tokens (remove from batch), which waiting sequences can fit in available KV cache slots (add to batch), and which sequences should be preempted if memory pressure exists (swap to CPU). Memory management uses PagedAttention (detailed in section 10.4), which enables dynamic allocation without fragmentation. When a sequence completes, its KV cache pages are immediately available for new sequences. The batched decode kernel processes all active sequences in a single batched operation despite dynamic batch composition. Sequences at different generation lengths are padded to a common shape within the kernel.

Preemption and swapping. A critical challenge in continuous batching is memory contention. As sequences grow during generation, they consume more KV cache pages. If the GPU memory fills up, the system cannot simply crash; it must preempt running requests.

vLLM implements a virtual memory mechanism similar to an operating system’s swap. When memory is exhausted, the scheduler identifies low-priority requests (for example, those most recently started) and swaps their KV cache blocks from GPU HBM to CPU DRAM. These

requests are paused until memory becomes available, at which point they are swapped back in and resumed. This mechanism ensures system stability under heavy load at the cost of increased latency for preempted requests.

Typical performance: Table 10.9 reports the throughput and utilization improvement for Llama-2 70B on $8 \times$ A100:

Table 10.9: Continuous batching throughput on Llama-2 70B ($8 \times$ A100): Tokens-per-second and GPU utilization for static, dynamic, and continuous batching of a Llama-2 70B serving workload on an $8 \times$ A100 node.

Batching Strategy	Throughput (tokens/s)	GPU Utilization
Static (batch=8)	400	45%
Dynamic (timeout=50 ms)	580	65%
Continuous	1,200	92%

Systems insight: As table 10.9 shows, the $3 \times$ throughput improvement from continuous batching comes from eliminating idle GPU cycles during sequence length variation.

The throughput numbers establish that continuous batching wins when output lengths vary, but they do not show where the gain comes from or how large it can grow. Quantifying the waste that traditional batching leaves on the table turns that intuition into a number a scheduler can act on.

10.3.6 Quantitative analysis: Traditional vs. continuous batching

The first baseline is traditional LLM batching, where unequal output lengths turn request heterogeneity into wasted decode cycles. The mathematics of batching waste reveals exactly how much throughput is lost and under what conditions continuous batching delivers the greatest improvement.

10.3.6.1 The waste function for traditional batching

Traditional batching (also called static batching) processes all requests in a batch through all decode iterations until the longest sequence completes. For batch size B with output lengths $\{S_1, S_2, \dots, S_B\}$, the total compute performed is:

$$O_{\text{traditional}} = B \times S_{\max} \times c_{\text{decode}}$$

where $S_{\max} = \max_i(S_i)$ and c_{decode} is the compute cost per decode iteration per sequence. However, the useful compute is only:

$$O_{\text{useful}} = \sum_{i=1}^B S_i \times c_{\text{decode}}$$

Equation 10.5 defines the **waste ratio** that quantifies the inefficiency:

$$W = 1 - \frac{O_{\text{useful}}}{O_{\text{traditional}}} = 1 - \frac{\sum_{i=1}^B S_i}{B \times S_{\max}} = 1 - \frac{\bar{S}}{S_{\max}} \quad (10.5)$$

where $\bar{S}$ is the mean output sequence length. This reveals that waste depends entirely on the ratio of mean to maximum output length within the batch. For uniform output lengths ($\bar{S} = S_{\max}$), waste is zero. For highly variable lengths, waste can exceed 50 percent.

10.3.6.2 Worked example: LLM serving with variable-length outputs

Consider a GPT-class model serving four concurrent requests with the generation lengths shown in table 10.10 (in tokens):

Table 10.10: Concurrent Request Generation Lengths: Four concurrent requests on a GPT-class model with varying prompt and output lengths. The $4\times$ spread in output length (50 to 200 tokens) drives the batching waste analyzed in this section: a static batch of four pads every request to the longest, wasting compute on the three shorter requests until the longest finishes generating.

Request	Prompt Length	Output Length	Total Tokens
R1	100	50	150
R2	80	200	280
R3	120	100	220
R4	90	150	240

Napkin Math 10.3: Continuous batching waste calculation

Problem: Given four LLM requests with unequal output lengths, quantify how much average latency traditional batching wastes and how continuous batching recovers that idle slot time.

Variables:

- Decode time per iteration (batch of 4): 20 ms
- Maximum output length in batch: 200 tokens (R2)
- Mean output length: $(50 + 200 + 100 + 150)/4 = 125$ tokens

Traditional batching: All four requests must wait for R2 to complete its 200 tokens.

- Total decode iterations: 200
- Total batch time: $200 \times 20 \text{ ms} = 4,000 \text{ ms}$
- Request completion times:
 - R1 completes useful work at iteration 50, but waits until iteration 200 → latency = 4,000 ms
 - R2 completes at iteration 200 → latency = 4,000 ms
 - R3 completes useful work at iteration 100, but waits until iteration 200 → latency = 4,000 ms
 - R4 completes useful work at iteration 150, but waits until iteration 200 → latency = 4,000 ms

Waste calculation using equation 10.5:

$$W = 1 - \frac{125}{200} = 1 - 0.625 = 37.5\%$$

The GPU performs $4 \times 200 = 800$ “sequence-iterations” but only 500 are useful.

Continuous batching: Sequences depart the batch upon completion, and new requests can join.

- Iteration 50: R1 completes → slot freed, new request R5 can join
- Iteration 100: R3 completes → slot freed, new request R6 can join
- Iteration 150: R4 completes → slot freed, new request R7 can join
- Iteration 200: R2 completes

Request latencies with continuous batching (assuming no queuing delay):

- R1: $50 \times 20 \text{ ms} = 1,000 \text{ ms}$ (4× improvement over traditional)
- R3: $100 \times 20 \text{ ms} = 2,000$ (2× improvement)
- R4: $150 \times 20 \text{ ms} = 3,000$ (1.33× improvement)
- R2: $200 \times 20 \text{ ms} = 4,000$ (no improvement for longest request)

Average latency comparison

- Traditional: 4,000 ms (all requests)

- Continuous: $(1,000 \text{ ms} + 2,000 + 3,000 + 4,000) / 4 = 2,500$

Result: Continuous batching reduces average latency by 37.5 percent, exactly matching the waste ratio.

Systems insight: Continuous batching does not make the longest request faster; it prevents shorter requests from occupying finished slots while they wait for that longest request. The gain comes from reusing slots at iteration boundaries, which is the slot-reuse pattern shown in figure 10.5.

10.3.6.3 When continuous batching provides maximum benefit

The continuous-batching analysis reveals that benefit scales with output length variance. A useful upper-bound intuition comes from comparing the longest sequence in a traditional batch with the average sequence length. Let $CV = \sigma/\mu$ be the coefficient of variation of output lengths. If the longest request in a batch is roughly k standard deviations above the mean, then:

$$\text{Improvement} \approx \frac{S_{\max}}{S} = \frac{\mu + k\sigma}{\mu} = 1 + k \cdot CV$$

where k is the number of standard deviations the maximum output exceeds the mean. Real systems realize less than this upper bound because scheduler overhead, KV-cache pressure, and refill gaps consume part of the theoretical gain. The table therefore reports effective waste and speedup, where speedup $\approx 1/(1 - W_{\text{effective}})$.

Table 10.11 quantifies this relationship across different workload types, including Retrieval-Augmented Generation (RAG) (Lewis et al. 2020):

Table 10.11: Continuous Batching Benefit by Workload Type: Higher output length variance (CV) yields greater improvement from continuous batching. Workloads with predictable output lengths (code completion) see modest gains, while highly variable workloads (RAG with documents of varying length) see dramatic improvement.

Workload Type	CV	k	Waste (Trad.)	Speedup (Continuous)
Code completion	0.3	2.5	16.7%	1.2×
Chat (short responses)	0.6	2	33.3%	1.5×
General text generation	1	2.5	50%	2×
Creative writing	1.5	3	64.3%	2.8×
RAG with variable docs	2	2.5	71.4%	3.5×

The systems pattern is straightforward: continuous batching is most valuable when output lengths are unpredictable, mixed workload types share the same cluster, request volume is high enough to refill vacated slots, and latency SLOs make early completion valuable. It provides minimal benefit when output lengths are uniform, as in classification or embedding generation, when batch sizes are too small for slot reuse to matter, or when request volume is too low to refill vacated slots.

10.3.6.4 Implementation complexity trade-offs

The same variability that makes continuous batching valuable also makes it harder to operate. Its performance benefits come with implementation complexity that systems engineers must weigh.

Memory management complexity increases substantially. Traditional batching allocates a fixed KV cache region per sequence at batch formation, deallocating only when the entire batch completes. Continuous batching requires dynamic allocation as sequences grow and immediate deallocation

upon completion, necessitating sophisticated memory management akin to operating system virtual memory.

Scheduler complexity rises correspondingly. Traditional batching uses simple FIFO scheduling: collect requests until the batch is full or the timeout expires, then execute. Continuous batching requires per-iteration decision-making about which sequences to admit, which to preempt if memory pressure exists, and how to handle priority classes. This increases scheduler overhead from $\mathcal{O}(1)$ per batch to $\mathcal{O}(B)$ per iteration.

Kernel design must also adapt. Batched GPU kernels traditionally assume fixed batch composition. Continuous batching requires kernels that handle variable-length sequences efficiently, often through techniques like packing multiple short sequences into shared attention masks or using specialized memory layouts that support dynamic batch membership.

Table 10.12 summarizes these trade-offs:

Table 10.12: Traditional vs. Continuous Batching Trade-Offs: Continuous batching provides significant throughput gains for variable-length workloads at the cost of implementation complexity. For uniform-length workloads, the complexity overhead may not justify adoption.

Dimension	Traditional Batching	Continuous Batching
Implementation effort	Low (standard frameworks)	High (custom scheduler, kernels)
Memory overhead	Fixed allocation	Dynamic + fragmentation mgmt
Scheduler latency	~0.1 ms per batch	~0.5-1 ms per iteration
Debugging complexity	Deterministic behavior	State-dependent, harder to trace
Throughput (variable)	Baseline	1.5–3.5× improvement
Throughput (uniform)	Baseline	~1.0× (no improvement)

For new LLM serving deployments, continuous batching frameworks like vLLM, TensorRT-LLM, or TGI provide mature implementation paths. The decision becomes whether to adopt these frameworks or build custom serving infrastructure. For organizations with existing traditional batching systems, the migration cost must be weighed against the workload’s output length variance using table 10.11.

Even with mature serving frameworks, diagnosing tail latency anomalies requires systematic investigation across the system stack. A representative P99 latency regression shows how the fleet stack methodology applies across infrastructure, execution, and serving layers.

Example 10.3: Debugging high P99 latency

Scenario: An LLM serving system exhibits unexpectedly high tail latency. P50 latency is 100 ms and P95 is 180 ms, both within SLO, but P99 spikes to 500 ms against a 200 ms target. GPU utilization appears healthy at 85 percent.

Setup: The system runs on 4 A100-80 GB GPUs connected via PCIe Gen4 (32 GB/s per GPU) rather than NVLink. Memory bandwidth per GPU is 2.04 TB/s (HBM2e), adequate for decode operations, but PCIe limits tensor-parallel communication. For a batch requiring 100 MB activation transfers between GPUs, raw bandwidth math gives approximately 3.1 ms per synchronization point over PCIe versus 0.17 ms over NVLink. The scheduling policy is the real problem: dynamic request-level batching uses max batch size 32 and timeout 50 ms, and the largest 5 percent of batches experience head-of-line blocking because FIFO batching holds short requests behind long-sequence requests.

Systems lesson: The root cause is not the hardware layer but the scheduling policy. Implement priority-aware scheduling with separate batch size limits by request type:

1. **Request classification:** Tag requests by expected output length (short: under 50 tokens, medium: 50 to 200 tokens, long: over 200 tokens) based on prompt patterns or user-provided hints
2. **Differentiated batching:** Limit short-request batches to 8, medium to 16, long to 32

3. **Priority preemption:** Allow short requests to preempt long-running sequences when P99 approaches SLO

After implementing these changes, P99 dropped to 185 ms. High average GPU utilization can mask head-of-line blocking that affects only a small percentage of requests but drives P99; section 10.7 develops the full isolation framework for keeping one workload’s tail from degrading another.

The batching strategies examined so far divide along a fundamental constraint boundary. Vision workloads are compute-bound with fixed-shape tensors: every image in a batch undergoes identical arithmetic, so the batch formation problem reduces to packing a GPU’s compute pipeline as tightly as possible. LLM workloads are memory-bound with variable-length sequences: the KV cache grows per-request and per-token, so the batch formation problem shifts to memory accounting, eviction policies, and iteration-level scheduling that continuous batching provides. Each regime produced a different dominant strategy because the scarce resource differs: compute throughput for vision, memory capacity for language.

Recommendation systems present a third constraint regime that resembles neither. *Sparse embedding lookups*, not *dense matrix multiplications*, dominate both compute time and memory traffic. A single recommendation request may touch millions of embedding table entries scattered across shards, while the dense ranking head that follows is comparatively small. This access pattern demands a batching strategy organized around feature types and embedding locality rather than around request shape or sequence length.

10.3.7 Feature-parallel batching for recommendation systems

Recommendation batching starts by grouping work around embedding locality rather than request shape. Figure 10.6 shows how the request is split into feature-specific paths before the dense ranking head recombines the retrieved representations.

Recommendation systems expose the same scheduling principle under a different bottleneck. Their computation pattern involves four stages:

1. **Sparse feature lookup:** Retrieve embeddings for user, item, and context features
2. **Dense feature processing:** Transform and normalize dense features
3. **Feature interaction:** Compute interactions between features (often via attention or factorization)
4. **Ranking head:** Produce final scores

The sparse embedding lookup often dominates latency and determines batching strategy. Feature-parallel batching processes different feature types in parallel rather than batching entire requests:

```
Request 1: [user_id_1, item_ids_1, context_1]
Request 2: [user_id_2, item_ids_2, context_2]
Request 3: [user_id_3, item_ids_3, context_3]
```

Feature-parallel view:

```
User embeddings: [lookup(user_1), lookup(user_2), lookup(user_3)] → parallel
Item embeddings: [lookup(items_1), lookup(items_2), lookup(items_3)] → parallel
Context features: [process(ctx_1), process(ctx_2), process(ctx_3)] → parallel
```

Then: Combine features per request for ranking

Feature-parallel batching is natural when embeddings are sharded across servers: each embedding server handles lookups for its shard across all requests in the batch. At Meta-scale request volumes, this turns feature sharding into a serving strategy rather than a storage detail.

Figure 10.6: Feature-Parallel Batching Pipeline: Requests are batched by feature type (Users, Items, Context) and dispatched to specialized embedding servers in parallel. The retrieved embeddings are then concatenated and processed by the dense ranking head. This architecture enables scaling to trillions of parameters by decoupling embedding storage from dense compute.

Example 10.4: RecSys batching at Meta scale

Consider Meta’s recommendation infrastructure serving 10 million QPS across the platform:

Request characteristics:

- Each request queries approximately 100 items (candidate ranking)
- Each item requires 50 embedding lookups (user features, item features, cross features)
- Total per request: 5,000 embedding lookups
- Embedding table size: 100 TB across 1,000 shards

Batching strategy:

With 10 million QPS and 1,000 shards, each shard receives:

$$\text{Lookups per shard} = \frac{\text{QPS} \times \text{lookups/request}}{\text{shards}}$$

In this scenario, the rate is 50 million lookups per second per shard.

Single-threaded processing cannot sustain that rate. Instead, the system uses a batch accumulation window of 1 ms, which yields batches of 10,000 requests at 10 million QPS and about 50K lookups per shard per batch.

Each embedding shard processes 50K lookups in a batched operation, achieving high memory bandwidth utilization through sequential memory access patterns.

As table 10.13 shows, the per-phase latency composition includes request routing, batch accumulation, embedding lookup, feature processing, and ranking:

Table 10.13: Latency breakdown for a recommender request: Per-phase contribution to end-to-end latency for a single recommender request at the request volume and shard count in the batching example.

Phase	Duration	Notes
Request routing	0.2 ms	Consistent hashing to shard
Batch accumulation	0.5 ms (avg)	1 ms window
Embedding lookup	2 ms	Batched, SSD-backed
Feature processing	1 ms	Dense computation
Ranking model	1.5 ms	Final scoring
Total	5.2 ms	Within 10 ms SLO

Systems insight: Recommendation batching is organized around sparse feature access, not around identical request tensors. The system wins by batching embedding lookups at the shard where memory bandwidth is consumed.

10.3.8 Streaming inference for real-time applications

Streaming workloads define the boundary where batching itself becomes the wrong response. Real-time speech recognition, video analysis, and robotics require processing inputs as they arrive with minimal latency.

Streaming inference processes inputs incrementally without waiting for batch formation. In speech recognition, it processes audio frames (10–20 ms chunks) as they arrive from the microphone. In video analysis, it processes frames at the capture rate (30–60 FPS) without buffering. In robotics, it processes sensor readings at the control loop frequency (100–1000 Hz).

For streaming applications, the relevant metric is not throughput but time to process each input:

$$T_{\text{streaming}} = T_{\text{capture}} + T_{\text{transfer}} + T_{\text{inference}} + T_{\text{action}}$$

where all components must complete within the inter-frame interval. A streaming speech-to-text pipeline shows how these latency components compose under tight real-time constraints.

Example 10.5: Streaming speech recognition pipeline

Consider a streaming speech-to-text system with 20 ms audio frames:

Latency budget: 100 ms end-to-end (5 frames of delay)

Table 10.14 traces the per-stage latency, including feature extraction, that the pipeline must hit to stay within the 100 ms budget:

Table 10.14: Streaming speech recognition pipeline latency: Per-stage latency for a streaming speech-to-text pipeline operating on 20 ms audio frames against a 100 ms end-to-end budget.

Stage	Duration	Notes
Audio capture	0 ms (continuous)	Microphone buffer
Network to server	20 ms	Including jitter buffer
Feature extraction	5 ms	MFCC computation
Encoder inference	30 ms	Streaming Conformer
Decoder step	15 ms	CTC or transducer decoding
Text formatting	5 ms	Capitalization, punctuation
Network to client	15 ms	Response transmission
Total	90 ms	Within 100 ms budget

Here, a Streaming Conformer is the low-latency speech encoder, while CTC and transducer decoding are incremental decoders that emit text from frame-level acoustic states without waiting for the full utterance.

Key constraints:

- No batching: Each frame processes individually
- Stateful model: Encoder maintains context across frames
- Pipeline parallelism: While frame N is in decoder, frame N+1 is in encoder

GPU utilization is typically 30–50 percent for streaming workloads, traded for latency guarantee.

Systems insight: Streaming inference deliberately sacrifices accelerator utilization to preserve end-to-end latency. The binding constraint is the inter-frame deadline, not average throughput.

10.3.9 Adaptive batching strategies

Once batching is workload-specific, fixed parameters become fragile. Production systems adapt batching behavior based on current conditions:

Traffic-adaptive batching adjusts the batch window based on arrival rate:

$$T_{\text{window}} = \min \left(T_{\text{max}}, \frac{B_{\text{target}}}{\lambda_{\text{current}}} \right)$$

When traffic is high, the window shrinks because the target batch size fills quickly. When traffic is low, the window extends but is capped to bound maximum latency.

SLO-adaptive batching takes a complementary approach, monitoring latency percentiles and adjusting parameters aggressively:

```

if P99_latency > 0.9 * SLO:
    reduce B_max by 20%
    reduce T_window by 20%
elif P99_latency < 0.5 * SLO:
    increase B_max by 10%
    increase T_window by 10%
```

The feedback loop maintains latency headroom while maximizing throughput during normal operation. Request-aware batching adds a third dimension by considering request characteristics when forming batches. For LLMs, this means grouping requests by expected output length (inferred from prompt type), grouping them by prompt length to minimize padding, and prioritizing latency-sensitive requests in smaller batches.

Production serving infrastructure embodies these adaptive principles. The NVIDIA Triton Inference Server implements a configurable adaptive batching system that illustrates how SLO-aware and

request-aware strategies operate in practice. Triton exposes three knobs: **max_batch_size** (the upper bound on batch size), **batching_timeout_ms** (the maximum time to wait for batch formation), and **preferred_batch_size** (target batch sizes that align with kernel efficiency). Internally, the scheduler maintains separate queues for each preferred batch size and routes requests to minimize total latency:

$$\text{Queue selection} = \arg \min_q (\text{wait}_q + \text{exec}(|q| + 1))$$

This optimization weighs both the current queue length and the kernel-efficiency of the resulting batch size. Table 10.15 shows the result for ResNet-50 on V100: the scheduler automatically increases batch size to maintain throughput as traffic grows, with measured throughput tracking offered load until saturation near 2,000 QPS.

Table 10.15: Triton Adaptive Batching: ResNet-50 on V100: Observed batch size, average latency, and sustained throughput for the Triton inference server’s adaptive batcher under increasing traffic on ResNet-50 (V100).

Traffic Level	Avg Batch Size	Avg Latency	Throughput
100 QPS	2.1	8 ms	100 QPS
500 QPS	6.3	12 ms	500 QPS
1000 QPS	12.4	18 ms	1000 QPS
2000 QPS	24.1	28 ms	1980 QPS

Every batching strategy to this point assumes the work per request is fixed once a request is admitted: continuous batching and adaptive windows tune *when* requests join a batch and how long the system waits, but the number of decode steps each request needs is treated as given. Reasoning-heavy inference breaks that assumption. When a model can spend more tokens thinking before it answers, the work per request becomes a variable the scheduler must set, not a property it can only observe.

10.3.10 The logic wall: Test-time compute scaling

Test-time scaling turns reasoning into a serving resource. A request may issue more generated tokens, internal chain-of-thought (CoT) tokens, or search steps before producing the answer. Large-model capability work describes emergent behaviors (Wei et al. 2022), while later analysis cautions that some apparent emergence can be an artifact of metric choice (Schaeffer et al. 2023).

From a serving-systems perspective, the relevant shift is the work issued per request. Extra reasoning consumes latency budget, KV-cache residency, and accelerator time. Models that move from “fast thinking” (instant pattern matching) to “slow thinking” (deliberative reasoning) push pressure from HBM bandwidth toward **Test-Time Compute**: the scheduler must decide how many search steps or CoT tokens a request may consume. The **Logic Wall** is the resulting serving constraint: for complex problems, compute per request grows with task difficulty, and a fleet optimized for tokens per second also needs a policy for allocating thinking time. This is a different control than the batch-window tuning of the previous section: adaptive batching decides when requests run together, while test-time compute decides how much work each request is allowed to do.

Napkin Math 10.4: Scaling reasoning depth

Problem: Calculate the latency impact of a model that uses 128 “Thinking Tokens” to solve a complex math proof vs. a standard answer.

1. **Standard response:** 1 token answer = 100 ms.
2. **Reasoning response:** 128 of internal search/CoT before the answer.
3. **The latency:** $128 \times 100 \text{ ms} = 12.8 \text{ seconds}$.

Systems insight: Test-time scaling transforms the serving architecture from a throughput factory to a search engine. While standard serving optimizes for tokens per second, reasoning-heavy models are constrained by steps per second. This creates a “reasoning SLO”: users may

tolerate 12 seconds for a correct proof, but not for a simple greeting. In the Machine Learning Fleet, this motivates dynamic compute allocation, where the scheduler grants more thinking time to harder prompts.

Variable work per request closes the batching story: continuous and adaptive batching handle variation the system observes, while test-time compute is variation the system chooses. **Dynamic compute allocation** assigns per-request compute budgets based on task difficulty, latency tolerance, and fleet load rather than applying a fixed decode budget to every prompt. With both the batching mechanism and the per-request compute budget now on the table, the remaining task is to decide which combination a given workload should run.

10.3.11 Quantitative summary: Batching strategy selection

The selection problem is to match the batching mechanism to model shape, traffic variance, and latency budget. That match depends on where in the request path the latency budget is actually spent.

Checkpoint 10.4: Batching strategy trade-offs

Verify your understanding of different batching mechanics:

- ☐ **Static vs. continuous:** For a vision service with highly uniform input sizes and predictable traffic, select static batching or continuous batching.
- ☐ **Waste ratio:** Explain why the “Waste Ratio” $(1 - \bar{S}/S_{\max})$ collapses to zero when an LLM serving chat requests moves from static to continuous batching.
- ☐ **Adaptive batching:** Explain why adaptive batching (shrinking the window when traffic is high) reduces P99 latency without sacrificing throughput.
- ☐ **RecSys bottleneck:** In feature-parallel batching for RecSys, identify whether the primary fleet-stack bottleneck is the GPU’s Tensor Cores or the distributed Embedding Store’s memory bandwidth.
- ☐ **Batching limit:** Explain why free HBM, not Tensor Core compute, often caps the achievable batch size for long-context LLM serving.

Before selecting a batching strategy, it is essential to understand where latency accumulates across the full request lifecycle. Figure 10.7 maps each stage from client to response, revealing the “serving tax” that serialization, routing, and coordination impose outside of GPU compute.

As figure 10.7 shows, noncompute stages (serialization, queuing, routing) can consume a substantial fraction of the latency budget, meaning batching strategy selection must account for the full pipeline, not GPU execution time alone. A decision tree guides strategy selection.

Is it autoregressive text generation?

Yes → Continuous batching with chunked prefill

No → Is it real-time streaming speech/video/robotics?

Yes → Streaming pipeline with minimal or no batching

No → Do embedding lookups dominate latency?

Yes → Feature-parallel batching (RecSys)

No → Dynamic batching with adaptive parameters

Table 10.16 shows that each strategy tunes toward a different objective, so the parameter worth tuning follows from the binding goal: throughput for static, the latency-throughput balance for dynamic, decode-variance for continuous, shard capacity for feature-parallel, and the real-time deadline for streaming.

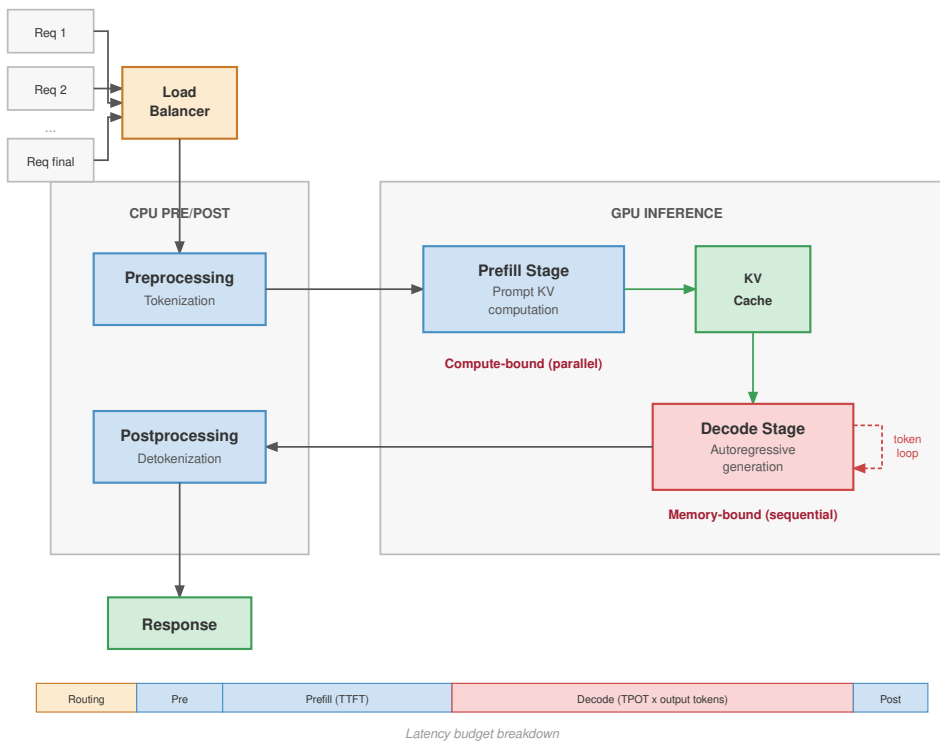

Figure 10.7: End-to-End Inference Pipeline: A detailed view of the request lifecycle: client requests arrive at a load balancer, then undergo preprocessing (tokenization) on the CPU. The data moves to the GPU for the compute-bound prefill stage and the memory-bound decode stage, which uses the KV cache. Finally, the response is postprocessed on the CPU (detokenization) and sent back. This visualization highlights the critical “Serving Tax” components (serialization, routing, coordination) that consume latency budget outside of the actual GPU compute time.

Table 10.16: Batching Strategy Parameters: Each strategy has distinct parameters requiring tuning for the specific deployment.

Strategy	Key Parameters	Tuning Goal
Static	Batch size	Maximize throughput
Dynamic	Window, max batch	Balance latency vs. throughput
Continuous	Chunk size, max batch	Minimize decode latency variance
Feature-parallel	Accumulation window	Match embedding shard capacity
Streaming	Pipeline depth	Meet real-time deadline

Even a well-tuned continuous batching strategy cannot eliminate a deeper, architecture-specific bottleneck for large language models. The context window of every active request must be stored in GPU memory, making KV cache management the next binding constraint on serving throughput.

10.4 Memory and Decode-Time Management

As an LLM generates a 2,000-word essay, it must constantly recall every word it has previously written. It does this by storing intermediate attention states in a rapidly expanding memory buffer known as the KV Cache. Unmanaged, this cache will aggressively fragment GPU memory, causing out-of-memory crashes even when 40 percent of the VRAM is technically free.

Two classes of techniques meet at this boundary. KV-state capacity techniques, such as PagedAttention and prefix caching, decide where attention state lives and how much fragmentation the

memory manager tolerates. Decode-time latency techniques, such as speculative decoding, change how much target-model work is needed per emitted token. Speculative decoding is not KV-cache compression; it trades extra draft-model state, target-model verification, and scheduler complexity for lower time per output token under the same memory budget.

10.4.1 The KV cache wall: Memory-bound capacity

Increasing the batch size to maximize throughput in LLM serving is bounded by the KV cache wall. As figure 10.8 shows, model weights represent a fixed “static tax” on GPU memory, while the KV cache grows linearly with both batch size and sequence length.

Figure 10.8: The KV Cache Wall: Total GPU memory usage for a 4-bit quantized 70B model (35 GB weights) on an 80 GB H100. While the model fits easily at small context lengths, the KV cache (sloped lines) eventually consumes all remaining HBM. At 128K context, a batch size of 2 is physically impossible on a single GPU ($35\text{ GB} + 84\text{ GB} > 80\text{ GB}$), forcing the system to either reduce batch size (killing throughput) or shard the model.

The visualization reveals why the replica level must sometimes shard models that would otherwise fit on a single GPU. Sharding provides the memory headroom needed to maintain high batch sizes for long-context requests. Without sharding, a 128K context request effectively “evicts” all other users from the GPU.

The same formula can be turned into an explicit batch-size limit for production hardware.

Example 10.6: KV-cache capacity estimator

Problem: A deployment serves Llama-3-70B (FP16 weights ≈ 141.2 GB) on an $8 \times$ H100 node (640 GB total HBM). The goal is to determine the maximum batch size for a context length of 128K tokens.

Formula:

$$M_{\text{KV}} = 2 \times N_L \times H_{\text{KV}} \times d_{\text{head}} \times s_{\text{elem}}$$

$$\text{Total Memory} = M_{\text{weights}} + (\text{Batch} \times \text{Context} \times M_{\text{KV}})$$

Parameters:

- $N_L = 80$, $H_{\text{KV}} = 8$ for Llama-3-70B GQA, $d_{\text{head}} = 128$.

- $s_{\text{elem}} = 2$ bytes (FP16).
- Context = 131,072 tokens.

Step 1: Calculate memory per token.

$$M_{\text{KV}} = 2 \times 80 \times 8 \times 128 \times 2 = 327,680 \text{ bytes} \approx 0.33 \text{ MB/token}$$

Step 2: Calculate cache per request.

$$131,072 \text{ tokens} \times 0.33 \text{ MB/token} \approx 42.9 \text{ GB/request}$$

Step 3: Determine max batch size. Available Memory for KV = 640 GB (Total) - 141.2 GB (Weights) - 20 GB (System) = 478.8 GB.

$$\text{Max Batch} = \left\lfloor \frac{478.8}{42.9} \right\rfloor = 11$$

Systems insight: Even with GQA, the shared-KV-head attention variant from section 9.4.3 that the 8-head count above already reflects, 128K-context requests consume tens of gigabytes of KV cache, so the system serves only a small number of concurrent long-context requests before memory becomes the binding constraint. Addressing this requires PagedAttention (to reduce fragmentation) and KV-cache quantization or sharding.

10.4.2 The fragmentation problem

Traditional memory allocation for KV cache preallocates contiguous memory for each sequence based on maximum expected length. This creates two forms of waste.

Internal fragmentation wastes memory within each allocation. Sequences shorter than the maximum allocation leave the unused portion idle. If maximum length is 4,096 but average output is 100 tokens, 97.5 percent of allocated memory is wasted.

External fragmentation compounds this problem across allocations. As sequences complete and new ones start, memory becomes fragmented into noncontiguous free blocks. Even with sufficient total free memory, no single block may be large enough for a new maximum-length allocation.

Consider a simplified example with 8 memory slots and maximum sequence length of 4. Fixed-size reservations first create internal fragmentation:

Time 0: Allocate Seq A (slots 0-3), Seq B (slots 4-7)
 [A] [A] [a] [a] [B] [B] [B] [b]
 lowercase = reserved but unused

External fragmentation appears after sequences complete and new sequences start:

Time 1: Active Seq C and Seq D leave two 2-slot gaps
 [] [] [C] [C] [] [] [D] [D]

Time 2: Try to allocate Seq E (needs 4 contiguous slots)
 [] [] [C] [C] [] [] [D] [D] <- Total free slots = 4, largest block = 2

Result: enough total free capacity exists, but no contiguous block is large enough.

Production systems report 60–80 percent memory waste from fragmentation under realistic workloads, severely limiting batch sizes and throughput.

10.4.3 PagedAttention

The fragmentation example exposes the allocator failure: enough KV-cache capacity can exist in aggregate while no contiguous block is available for the next sequence. PagedAttention fixes that serving problem by treating KV-cache storage like virtual memory rather than a single preallocated slab.

Definition 10.3: PagedAttention

PagedAttention is an LLM serving memory management technique that applies virtual memory principles to KV Cache allocation, storing attention states in noncontiguous, fixed-size physical blocks.

1. **Significance:** It eliminates Internal and External Fragmentation, which can waste 60–80 percent of the memory allocated to the KV cache under contiguous preallocation. By allowing sequences to grow dynamically, it enables $2\text{--}4\times$ higher Concurrent Throughput (X) on the same hardware.
2. **Distinction:** Unlike Contiguous Allocation (which requires prereserving the maximum context length), PagedAttention uses a Block Table to map logical sequence indices to physical memory pages, allocating only what is currently used.
3. **Common pitfall:** A frequent misconception is that PagedAttention speeds up *individual token math*. In reality, it is a Capacity Optimization: it improves *system-level efficiency* by allowing larger batch sizes, though it adds a small Indirection Overhead (L_{lat}) for the pointer lookups.

The virtual-memory shift changes the allocation problem: capacity no longer has to be reserved as one contiguous block before the request starts.

Systems Perspective 10.1: Analogy: The inefficient hotel

Imagine a hotel where every guest might stay anywhere from 1 to 10 days, but they do not know in advance.

Under contiguous allocation, the hotel manager blocks out a 10-day suite for every guest just in case. A 100-room hotel becomes “fully booked” with only 10 guests, wasting 90 percent of its capacity (Internal Fragmentation).

Under PagedAttention (Virtual Memory), the manager assigns a guest just 1 room. If the guest stays another day, they are given whatever room is available next, even if it is on a different floor. The front desk maintains a “Block Table” to keep track of which rooms belong to which guest. The hotel can now accommodate 100 guests simultaneously, recovering the 90 percent wasted capacity.

PagedAttention (Kwon et al. 2023), introduced in vLLM, applies virtual memory concepts to KV cache management. Instead of contiguous allocation, the KV cache is divided into fixed-size pages, using 16-token blocks in the default vLLM configuration, and sequences are allocated pages on demand. Figure 10.9 illustrates the key concepts including page tables that map logical sequence positions to physical memory pages, block size that defines the number of tokens per page (typically 16 tokens), and physical blocks that provide fixed-size memory allocations assignable to any sequence.

PagedAttention provides four capacity benefits:

- **Internal fragmentation:** It allocates only the pages needed for actual tokens.
- **External fragmentation:** Any free page can be used by any sequence.
- **Dynamic growth:** Sequences can grow without preallocation.
- **Prefix sharing:** Common prefixes can share physical pages.

Together, these properties turn KV cache capacity into a schedulable resource rather than a fixed per-request reservation.

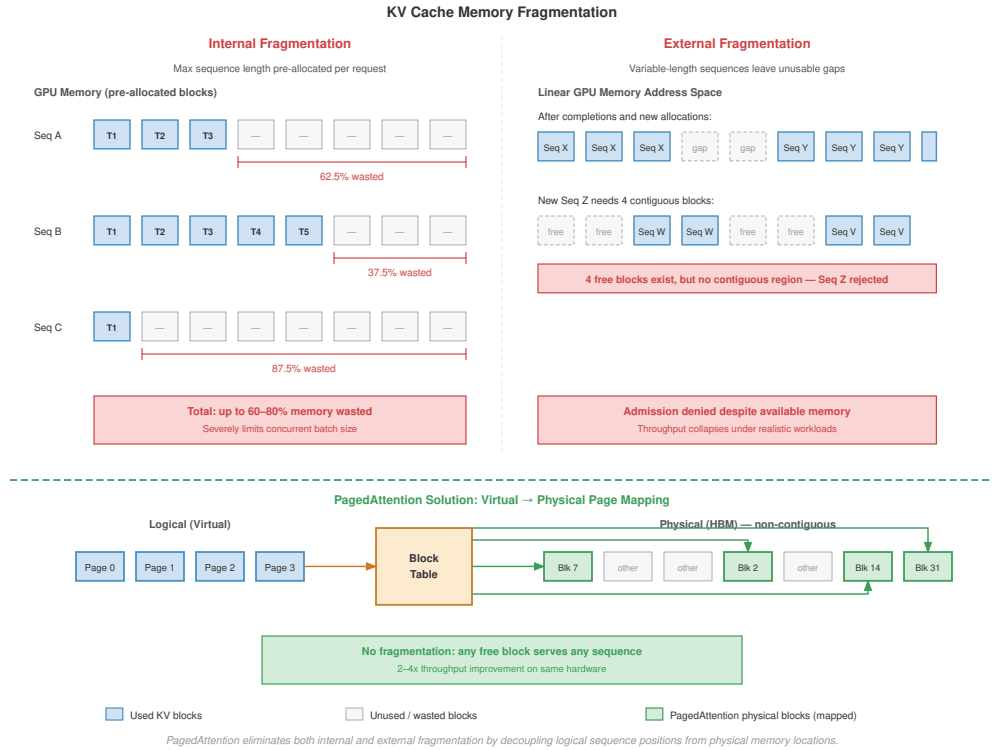

Figure 10.9: KV Cache Fragmentation and the PagedAttention Solution: Top left: internal fragmentation wastes memory by preallocating for the maximum sequence length. Top right: external fragmentation leaves unusable memory gaps. Bottom: PagedAttention solves this by mapping contiguous logical pages of a sequence to noncontiguous physical memory blocks via a block table, allowing the system to fill fragmentation gaps with small blocks from any sequence.

Example 10.7: PagedAttention implementation details

Memory layout:

Physical blocks (16 tokens by hidden_dim by 2 by precision):

Block 0: [K ...K , V ...V]

Block 1: [K ...K , V ...V]

...

Block N: [K ...K , V ...V]

Page table per sequence:

```
class PageTable:
    def __init__(self, max_blocks):
        self.block_map = {} # logical_block -> physical_block

    def allocate_block(self, logical_idx, physical_block):
        self.block_map[logical_idx] = physical_block

    def get_physical(self, logical_idx):
        return self.block_map[logical_idx]
```

Attention kernel modification:

Standard attention: $\text{output} = \text{softmax}(Q @ K.T / \sqrt{d}) @ V$

PagedAttention:

```
def paged_attention(Q, page_table, physical_blocks, block_size):
    # Gather K, V from noncontiguous physical blocks
    for logical_idx in range(num_logical_blocks):
        physical_idx = page_table[logical_idx]
        K_block = physical_blocks[physical_idx].K
        V_block = physical_blocks[physical_idx].V
        # Compute attention for this block
        attention_scores = Q @ K_block.T / sqrt(d)
        output += softmax(attention_scores) @ V_block
    return output
```

Systems insight: The throughput impact of gather operations is small compared to the memory savings; table 10.17 shows the 2.5–4× throughput improvement coming from fitting more concurrent sequences in the same memory.

Table 10.17: PagedAttention vs. Contiguous KV Cache: KV cache pool utilization and relative serving throughput for contiguous allocation against PagedAttention.

Approach	KV Cache Pool Utilization	Throughput (relative)
Contiguous	30-40%	1.0× (baseline)
PagedAttention	95%+	2.5–4×

10.4.4 Prefix caching

Many LLM workloads share common prefixes across requests. System prompts like “You are a helpful assistant...” are prepended to every request. Few-shot examples use the same examples for many queries. Document context involves multiple questions about the same document. Recomputing these shared prefixes wastes both compute (prefill) and memory (duplicate KV cache entries).

Prefix caching shares KV cache entries across requests with common prefixes. Figure 10.10 demonstrates how shared system prompts avoid redundant computation.

Figure 10.10: Prefix Caching via Block Sharing: PagedAttention enables efficient prefix caching by allowing multiple sequences’ block tables to point to the same physical blocks for shared content. In this example, the System Prompt is stored in blocks 0-5. Request A and Request B maps their first 6 logical pages to these same physical blocks, storing only their unique suffixes in new blocks. This dramatically reduces memory usage and prefill computation for workloads with shared context.

With PagedAttention, prefix caching integrates naturally through copy-on-write semantics:

```
System prompt → Physical blocks [0, 1, 2, 3, 4, 5]

Request A page table: [0, 1, 2, 3, 4, 5, 10, 11]  <- shares prefix blocks
Request B page table: [0, 1, 2, 3, 4, 5, 12, 13, 14]  <- shares prefix blocks
Request C page table: [0, 1, 2, 3, 4, 5, 15]  <- shares prefix blocks
```

All three requests reference the same physical blocks for the system prompt. Only when generating unique tokens do they allocate new blocks. The savings can be substantial when many concurrent requests share the same system prompt; the following example quantifies them for a typical chatbot deployment.

Example 10.8: Prefix caching at scale

Scenario: A chatbot service uses a 2,000-token system prompt and serves 1,000 concurrent users.

Without prefix caching:

- KV cache per user: $2000 + 500$ (avg response) = 2,500 tokens
- Total KV cache: $2,500 \text{ tokens} \times 1000 \times 2 \times 80 \times 8192 \times 2 = 6.6 \text{ TB}$

With prefix caching:

- Shared prefix: 2,000 tokens (once)
- Unique per user: 500 tokens
- Total: $(2000 \times 1) + (500 \times 1000) = 502,000$
- Memory: $502,000 \times 2 \times 80 \times 8192 \times 2 = 1.3 \text{ TB}$

Result: Prefix caching yields a 79.9 percent memory reduction in KV cache, enabling 5× more concurrent users.

Systems insight: Prefix caching pays off when the prefix hit rate is high because many requests share a long prefix. Table 10.18 contrasts hit rates and memory savings across workloads, showing where the technique changes serving capacity and where it does not.

Table 10.18: Prefix Caching Effectiveness by Workload: Typical prefix hit rates and resulting KV-cache memory savings for chatbot, document-QA, and general API workloads, showing where prefix caching pays off and where it does not.

Workload	Prefix Hit Rate	Memory Savings
Chatbot (same system prompt)	95%+	70-80%
Document QA (same doc)	80-90%	50-70%
General API (diverse)	20-40%	10-30%

10.4.5 KV cache compression and architectural optimization

The capacity techniques above tolerate the cache; compression shrinks it. The calculation here uses a 64-KV-head multi-head attention baseline so the grouped query attention subsection can isolate the head-count reduction as a separate architectural lever. For a 70B parameter model with 80 layers, 64 heads, head dimension 128, and sequence length 4096 in FP16, the KV cache requires:

$$\text{KV cache} = 2 \times 80 \times 64 \times 128 \times 4096 \times 2 \approx 10.7 \text{ GB (FP16)}$$

A single request's KV cache alone consumes a substantial fraction of the H100's 80 GB of HBM. For a batch of 8 concurrent requests, the KV cache would require 85.9 GB, exceeding single-GPU capacity. Reducing this footprint requires two complementary strategies: quantization and architectural optimization.

10.4.5.1 KV cache quantization

Reducing the size of cached values through lower precision provides direct memory savings. Weight-only quantization (GPTQ, AWQ) reduces weight precision while keeping activations in high precision. While effective for storage, this does not reduce the KV cache. **KV cache quantization** explicitly targets the activations, storing cached keys and values in INT8, FP8, or even INT4.

Compressing the KV cache to INT4 reduces it to approximately 2.7 GB per request, a 4× reduction. This freed memory directly translates into larger batch sizes and higher serving throughput. KV cache values exhibit different distributions than model weights: KIVI observes channel-wise outliers in keys and uses per-channel key quantization, while values lack the same channel-wise pattern and are quantized per-token.

10.4.5.2 Grouped query attention (GQA)

Grouped query attention (Ainslie et al. 2023), the shared-KV-head architecture established in section 9.4.3, is the second lever on cache size, complementary to quantization: where quantization shrinks the bytes per cached element, GQA shrinks how many key-value heads are cached per layer. The serving consequence is the head-count arithmetic. For our earlier 70B model, switching from the multi-head attention (MHA) baseline of 64 KV heads to GQA with 8 KV heads shrinks the KV cache by 8×:

$$\text{KV cache (GQA)} = 2 \times 80 \times 8 \times 128 \times 4096 \times 2 \approx 1.3 \text{ GB (FP16)}$$

At 1.3 GB, the GQA cache is dramatically more manageable than the 10.7 GB required by MHA. Combining GQA with INT8 KV cache quantization yields sub-gigabyte per-request cache sizes, often enabling substantially larger batches on a single GPU. GQA has become a common architectural choice for inference-optimized LLMs because it reduces KV-cache bandwidth and capacity pressure with comparatively small quality impact in many deployments.

Napkin Math 10.5: The precision dividend

Problem: A team serves a 70B model on 4× H100 GPUs. Weights in FP16 consume 140 GB (35 GB/GPU). KV cache at FP16 consumes 10.7 GB per request. How does quantizing weights to INT4 and KV cache to INT8 change the maximum batch size?

Before optimization (all FP16):

- Weights: 35 GB/GPU
- Available for KV cache: 80 GB – 35 GB = 45 GB/GPU
- KV cache per request: 10.7 GB ÷ 4 ≈ 2.7 GB/GPU
- Maximum batch size: ⌊ 45 GB divided by 2.7 GB ⌋ ≈ 16 requests

After optimization (INT4 weights, INT8 KV cache):

- Weights: 35 GB × (4/16) = 8.75 GB/GPU (INT4)
- Available for KV cache: 80 GB – 8.75 GB = 71.25 GB/GPU
- KV cache per request (INT8): 5.4 GB ÷ 4 ≈ 1.3 GB/GPU
- Maximum batch size: ⌊ 71.25 GB divided by 1.3 GB ⌋ ≈ 53 requests

Systems insight: Precision engineering fundamentally changes serving economics by enabling larger batch sizes. Larger batches amortize the fixed cost of weight loading, shifting operations from memory-bound toward compute-bound.

10.4.6 Speculative decoding as a serving policy

Section 9.6.1 established speculative decoding as an algorithmic optimization: a small draft model proposes K tokens, the target model verifies them in one parallel forward pass, and rejection sampling guarantees the emitted tokens follow the target model’s distribution exactly, so the technique is lossless and bounded by the draft acceptance rate α_{acc} . The serving question is different. Speculation becomes a resource-admission policy under SLA pressure: the scheduler must decide when to enable it, how its memory cost interacts with KV-cache admission, and what it does to the SLA the endpoint is bound by.

The latency win is real but conditional, and the condition is the acceptance rate. The expected number of tokens emitted per round, including the correction token, is $\frac{1 - \alpha_{\text{acc}}^{K+1}}{1 - \alpha_{\text{acc}}}$, which collapses

Decode is memory-bound; parallel verification moves work toward the ridge.

toward 1 as acceptance falls. For $K = 5$ draft tokens and a draft model $20\times$ faster than the target, that sensitivity is steep:

- **High acceptance** ($\alpha_{\text{acc}} = 0.9$): Expected 4.69 tokens per round, speedup of $3.7\times$.
- **Medium acceptance** ($\alpha_{\text{acc}} = 0.7$): Expected 2.94 tokens per round, speedup of $2.4\times$.
- **Low acceptance** ($\alpha_{\text{acc}} = 0.5$): Expected 1.97 tokens per round, speedup of $1.6\times$.

Predictable text achieves $\alpha_{\text{acc}} > 0.9$, while creative reasoning or code generation may fall below 0.5; well-aligned model pairs that share training data and architecture commonly land at 0.6–0.8. Because acceptance is a property of the workload, not of the hardware, a single global setting is wrong for a mixed fleet: the same speculation that halves time per token on a chat endpoint can slow a code-generation endpoint that sits below the break-even acceptance rate. The serving system must therefore decide per endpoint, and three serving concerns govern that decision.

10.4.6.1 The speculation tax and KV-cache admission

The first concern is memory. The draft model is not free state: it requires its own GPU allocation for weights, and each in-flight request that uses speculation reserves a small additional KV cache for the draft model alongside the target's. Pairing a 7B draft model with a 70B target adds roughly 14 GB of weights per replica plus per-request draft cache. This *speculation tax* competes directly with the KV-cache admission budget developed in section 10.4.1: every gigabyte the draft model holds is a gigabyte the admission controller cannot allocate to a concurrent request. Speculation therefore shrinks the maximum batch size the node can admit, trading aggregate throughput for the latency of individual requests. The admission controller and the speculation policy cannot be tuned independently; enabling speculation lowers the concurrency ceiling that the KV-cache wall already imposes.

10.4.6.2 The latency-throughput tension under an SLA

The second concern is which service-level objective the endpoint is bound by. Speculation improves time per output token but, by lowering the concurrency ceiling, reduces the requests per second a replica can sustain. An endpoint with a tight time-to-first-token or per-token latency SLA, such as interactive chat, benefits: the speculation tax buys headroom against the latency target that matters. An endpoint bound by a throughput SLA, such as bulk document processing or batch summarization, is harmed: speculation spends batch capacity to improve a latency metric no one is measuring, and the lost concurrency directly threatens the throughput target. The decision is therefore an SLA question. The scheduler enables speculation on latency-bound endpoints and disables it on throughput-bound ones, and on a shared replica serving both it must account for the draft model's resident cost against the stricter of the two budgets.

10.4.6.3 Per-endpoint scheduling

The third concern is that these decisions are dynamic, not static configuration. Acceptance rate drifts with the traffic mix, and the value of speculation collapses at high load: when a replica is already near its concurrency ceiling, the decode phase is closer to compute-bound and the marginal latency benefit of speculation shrinks even as its memory tax stays fixed. Production schedulers therefore treat speculation as a runtime knob gated on observed load and acceptance. They enable it for latency-sensitive endpoints during normal operation, disable it under traffic spikes to reclaim KV-cache pages for admission, and may switch draft strategies per endpoint. **Self-speculative decoding** uses early exit from the target model itself as the draft, eliminating the separate-model memory tax at the cost of lower acceptance; **Medusa** (Cai et al. 2024) adds lightweight prediction heads to the target backbone; **Lookahead decoding** uses Jacobi iteration to avoid a draft model entirely. Each variant trades a different slice of the speculation tax against acceptance, and the scheduler chooses among them per endpoint based on which SLA binds and how much KV-cache budget remains.

10.4.7 KV cache in distributed settings

When a conversation is moved, rebalanced, or split across devices, its KV state must either move with it or be rebuilt token by token. Section 10.5 develops the tensor and pipeline parallelism strategies

that distribute a model across devices; each strategy carries a different consequence for KV-cache management:

Under tensor parallelism, the KV cache is sharded across devices along with attention heads. Each device stores cache for its subset of heads.

8-way tensor parallelism:

Device 0: KV cache for heads 0-7

Device 1: KV cache for heads 8-15

...

Device 7: KV cache for heads 56-63

Cross-device sharing adds a constraint: prefix caching across tensor-parallel devices requires cache to be sharded identically on all devices. This is automatic when prefixes are processed with the same tensor-parallel configuration.

KV cache migration presents a further challenge. When the router moves a conversation to a different replica because of failure or rebalancing (routing keyed on a hash of the session ID, the consistent-hashing scheme developed in section 10.6.6), the KV cache must be migrated:

Migration options:

1. Rebuild: Re-run prefill on new replica (500 ms+ for long context)
2. Transfer: Send KV cache over network (100 MB at 100Gbps = 8 ms)
3. Hybrid: Transfer if small, rebuild if large

Decision threshold:

```
if cache_size_bytes/network_bandwidth < prefill_time:
    transfer()
else:
    rebuild()
```

For Llama-70B GQA with 4K context, KV cache is about 1.3 GB total per sequence, or about 168 MB per device under 8-way tensor parallelism. At 100 Gbps (12.5 GB/s), transferring one shard takes roughly 13 ms, while transferring the full cache would take about 100 ms. Both are often preferable to a ~500 ms prefill rebuild, so transfer remains the better choice when bandwidth is available.

10.4.8 Memory management best practices

Effective KV-cache management begins with capacity accounting rather than an eviction policy. The serving process first reserves memory for weights, activations, runtime overhead, and safety headroom, then treats the remaining HBM as a managed pool for active sequences:

```
Available GPU memory = Total - Weights - Activations - Overhead
KV pool size = 0.9 * Available # Leave 10% headroom
```

```
Max concurrent sequences = KV pool size / (avg_seq_length * per_token_cache)
```

That budget determines how many sequences can coexist before the scheduler must choose between rejection, preemption, or paging. When the cache is full, LRU eviction removes the sequence with the oldest access, size-based eviction frees the longest sequence first, and priority-based eviction protects paid-tier or latency-critical requests. Continuous batching then turns eviction into a scheduling decision: a high-priority request that cannot fit triggers victim selection, swaps the victim's KV cache to CPU memory, allocates GPU memory to the new request, and restores the victim later if its service-level objective still permits the delay.

Example 10.9: KV cache memory hierarchy

Production systems manage KV-cache memory pressure across the three-tier hierarchy in table 10.19, paging from GPU HBM down to CPU DRAM and NVMe SSD as the active working set exceeds each tier’s capacity:

Table 10.19: KV cache memory hierarchy: Capacity, swap-in latency, and intended use case for the three tiers production inference servers use to manage KV-cache memory pressure.

Tier	Capacity	Latency	Use Case
GPU HBM	80 GB	0 ms	Active sequences
CPU DRAM	1 TB	1–5 ms	Swapped sequences
NVMe SSD	10 TB	10–50 ms	Long-term cache

Swap implementation:

```

async def swap_to_cpu(sequence_id):
    kv_cache = gpu_cache[sequence_id]
    cpu_cache[sequence_id] = kv_cache.cpu() # Async transfer
    gpu_cache.free(sequence_id)

async def swap_to_gpu(sequence_id):
    cpu_kv = cpu_cache[sequence_id]
    gpu_cache[sequence_id] = cpu_kv.cuda() # Async transfer
    cpu_cache.free(sequence_id)

```

Observed performance:

- GPU-only (no swapping): 50 concurrent sequences
- GPU+CPU swapping: 500 concurrent sequences (10×)
- Average swap latency: 3 ms (acceptable for nonurgent requests)

Systems insight: Treating CPU DRAM and NVMe as overflow tiers behind HBM raises concurrency by an order of magnitude at the cost of millisecond swap latency, so paging is a throughput lever for non-urgent traffic but not a substitute for HBM capacity on the latency-critical path.

The mismatch swapping papers over remains structural: a single GPU must handle both the compute-heavy prompt processing and the bandwidth-heavy token generation. Separating those phases onto different hardware pools eliminates this mismatch entirely.

10.4.9 Disaggregated serving: Splitting the workload

LLM inference consists of two distinct phases with different computational characteristics, requiring different batching strategies within the same request. Figure 10.11 illustrates how this architectural split separates the two phases onto dedicated hardware pools, and table 10.20 contrasts their resource profiles.

Definition 10.4: Prefill and decode phases

Prefill and Decode Phases are the two distinct computational regimes of transformer-based LLM inference.

1. **Significance:** The Prefill Phase (processing the prompt) is compute bound (R_{peak}) with high arithmetic intensity, while the Decode Phase (generating tokens) is bandwidth

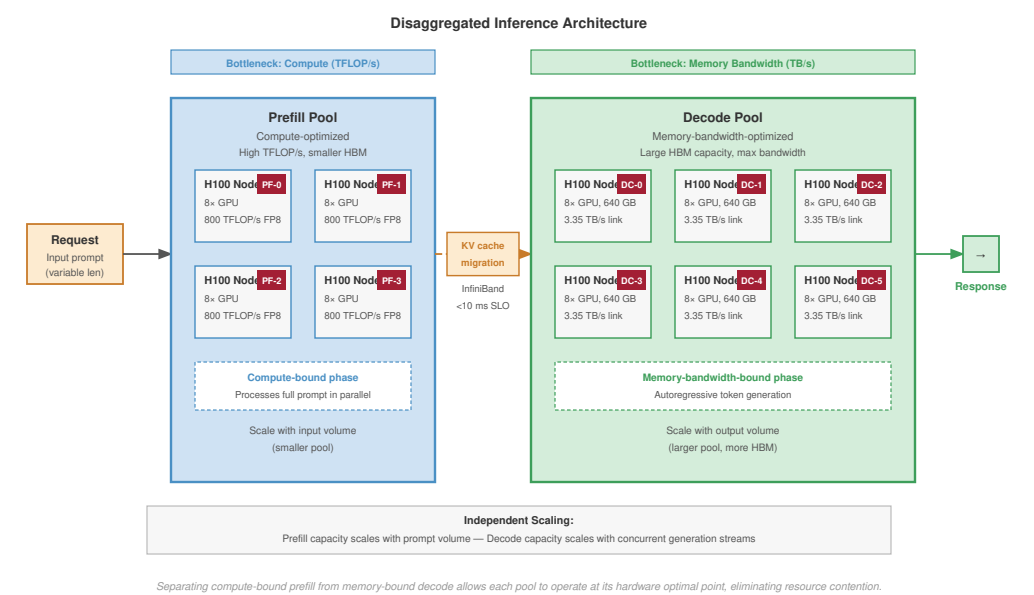

Figure 10.11: Disaggregated Serving Architecture: Separating the compute-bound prefill phase from the bandwidth-bound decode phase. Requests enter the Prefill Pool for prompt processing, and the resulting KV cache is migrated to the Decode Pool for token generation. This allows each phase to run on hardware optimized for its specific bottleneck, improving overall fleet efficiency.

- bound (BW) with extremely low arithmetic intensity. This mismatch means a single request’s efficiency (η_{hw}) varies wildly during its lifecycle.

 2. **Distinction:** Unlike Single-Pass Inference (for example, ImageNet), where the resource bottleneck is constant, LLM inference switches between these regimes at every request, requiring Iteration-Level Scheduling to maintain utilization.
 3. **Common pitfall:** A frequent misconception is that both phases should be batched together naively. In reality, because they have opposing hardware requirements, mixing them in the same batch without Chunked Prefill or similar techniques can lead to significant queuing delays (I_{lat}) for decoding tokens.

The prefill phase processes the entire input prompt in parallel. Computation scales with prompt length, and the memory access pattern is compute-bound with high arithmetic intensity⁹. The decode phase, by contrast, generates output tokens one at a time. Each token requires loading the entire model weights, making the memory access pattern bandwidth-bound with low arithmetic intensity. Section C.3.1 places these two phases on the roofline: decode sits far below the ridge point of equation C.4, where throughput is set by HBM bandwidth rather than peak FLOP/s, while prefill’s high arithmetic intensity (equation C.2) pushes it past the ridge into the compute-bound regime.

Table 10.20: Prefill vs. Decode Characteristics: The two phases have opposite optimization requirements.

Phase	Computation	Memory Access	Bottle-neck	Optimal Batch
Prefill	$\mathcal{O}(\text{prompt length}^2)$	Activation and attention tiles	Com-pute	Moderate request batches or large chunks

⁹ | **Arithmetic Intensity (Prefill vs. Decode):** Measured in FLOP/byte of memory accessed, this ratio determines whether a workload is compute-bound or bandwidth-bound. Prefill achieves 100+ FLOP/byte (compute-bound); decode achieves 1–10 FLOP/byte (bandwidth-bound). This 10–100× gap is why mixing the two phases in a single batch wastes either compute or bandwidth, motivating disaggregated serving architectures.

Phase	Computation	Memory Access	Bottle-neck	Optimal Batch
De-code	$\mathcal{O}(1)$ dense weight work plus $\mathcal{O}(\text{context length})$ attention over KV cache per token	Weight and KV-cache reads	Band-width	Large continuous batches of active tokens

Because decode is bandwidth-bound, hardware that shrinks the bytes moved per token attacks that phase’s binding constraint directly.

🔍 Systems Perspective 10.2: FP4 as a bandwidth lever for decode

Native hardware support for narrow formats is the current manifestation of this approach. The Blackwell (B200) architecture introduces native **FP4 support**, making 4-bit inference a first-class hardware target rather than a framework-specific workaround. Halving weight and KV-cache bytes relative to FP8 raises token throughput and concurrent-sequence capacity without increasing clock speed, which is what loosens the decode-pool sizing in a disaggregated deployment. The product is point-in-time, and the exact cost-per-token gain depends on model architecture, kernel maturity, batch shape, and the fraction of time spent in prefill versus decode, so production systems should validate FP4 with workload-specific benchmarks rather than assuming a fixed multiplier.

The dichotomy creates a scheduling challenge: prefill operations are long-running and compute-intensive, while decode operations are short and bandwidth-limited. Mixing them in the same batch can cause interference. The GPU remains powered and allocated even when decode steps expose little useful compute, so low-utilization decode traffic can dominate energy cost unless the scheduler keeps the hardware busy with compatible work.

Chunked prefill¹⁰ addresses this by breaking long prompts into fixed-size chunks that interleave with decode operations:

$$\text{Chunk latency} = \frac{\text{Chunk size}}{\text{Prefill throughput}}$$

With chunk size chosen to match decode iteration time, prefill and decode can share GPU resources without decode latency spikes.

Prefill-decode disaggregation takes this separation further by running prefill and decode on separate GPU pools. The prefill pool is optimized for compute intensity, using nodes with high TFLOP/s, moderate request batches, or large token chunks to maximize throughput without blocking decode. The decode pool is optimized for memory bandwidth, using nodes with maximum HBM capacity, the Tier 0 storage resource discussed in section 4.3.2, to handle thousands of concurrent autoregressive streams.

Independent scaling follows directly: prefill capacity scales with input volume while decode capacity scales with output volume. Crucially, this architecture relies on the high-speed, RDMA-enabled networking fabric established in Chapter 3. When a prefill finishes, the resulting KV cache (often megabytes of data) must be migrated to a decode node within the inter-token latency budget, typically under 10 ms. InfiniBand’s low-microsecond latency and high bisection bandwidth are the physical enablers of this logical disaggregation, a displacement of overhead that trades communication bandwidth for specialized prefill and decode hardware.

Chunked prefill can be formalized into a practical scheduling algorithm that limits decode stalls from long prompts.

📄 Example 10.10: Sarathi: Chunked prefill implementation

The Sarathi-Serve system (Agrawal et al. 2024) implements chunked prefills with stall-free scheduling:

¹⁰ | **Chunked Prefill:** Without chunking, a long prompt can block decode while prefill completes, violating inter-token latency SLOs for concurrent users. Chunking divides the prompt into smaller work units processed between decode iterations, bounding decode stalls at the cost of slightly longer total prefill time. The trade-off is a classic latency-vs.-throughput decision: interactive applications favor smaller chunks; batch workloads can favor larger ones.

Chunk sizing: Chunks are sized so prefill work can be interleaved with decode iterations. For example, if a deployment targets a 20 ms scheduling quantum and observes 10,000 prefill tokens/second, one chunk would process about 200 tokens. The right chunk size is workload- and hardware-dependent.

Interleaving schedule: Each GPU iteration processes either:

- One prefill chunk for a new request, OR
- One decode step for all active sequences

The schedule reduces decode stalls caused by long incoming prompts.

KV-cache handoff: When a prefill chunk completes, the scheduler has enough KV state to continue the request through later decode work. In disaggregated prefill/decode systems, any physical KV-cache transfer is a separate networking and placement budget rather than a guarantee supplied by Sarathi-Serve itself.

Performance impact:

- Without chunking: long prompts can create decode latency spikes for other active requests.
- With chunking: prefill work is broken into bounded units, so decode iterations can continue to make progress while long prompts enter the system.

Systems insight: Chunked prefill turns a long prompt from one blocking request into bounded work units that can coexist with decode traffic.

10.4.10 Adapter state and locality

KV-cache management makes one GPU safe for many concurrent requests; multi-tenant adapter serving asks the same serving process to manage another kind of resident state. The KV cache is per-token attention state. A LoRA adapter is per-tenant weight delta. Both must be available at the moment a decode step runs, and both can erase batching gains if the scheduler ignores locality. As serving platforms scale to support thousands of concurrent users on a single foundation model, personalization introduces a new memory bottleneck. Low-Rank Adaptation (LoRA) stores a small set of user- or task-specific adapter weights that modify a shared base model without copying the full model. When 10,000 users each have a unique LoRA adapter applied to the same 140 GB base model, replicating the base weights for each user is physically impossible. Instead, the base model remains pinned in HBM, while user-specific adapters are brought into the fast on-chip working set as needed.

Systems Perspective 10.3: The context switch of machine learning

This multi-tenant serving pattern shifts the fundamental performance constraint from compute throughput to adapter locality. As the continuous batching scheduler interleaves requests from different users, adapter weights may have to move repeatedly from HBM into SRAM or registers before each generation step. The effect is similar to an operating-system context switch: the accelerator has work to do, but it first waits for the state belonging to the next tenant. If the adapter swap latency exceeds the compute time of the generation step, the GPU compute cores stall. Efficient multi-tenancy therefore batches requests by active adapter when possible and coordinates adapter placement with KV-cache paging so personalization does not erase the benefit of sharing the base model.

The same locality problem reappears at a larger scale when the model itself exceeds single-GPU capacity. For a 175-billion-parameter foundation model, even the weights must be split across multiple devices, so inference becomes a sharding problem before it becomes a scheduling problem.

10.5 Model Sharding for Inference

A 70-billion-parameter model requires over 140 GB of VRAM to hold its weights in FP16, exceeding a single 80 GB GPU's capacity. To serve this model, we must slice its architecture across multiple GPUs that act together as a single logical replica. Adapting distributed training parallelism techniques, specifically tensor and pipeline parallelism, for low-latency inference introduces a distinct set of constraints.

10.5.1 When sharding becomes necessary

Model sharding for inference is driven by two distinct requirements. Table 10.21 identifies the memory and latency constraints that necessitate sharding:

The first driver is memory capacity. A model that cannot fit in single-GPU memory must be sharded regardless of performance considerations. For a model with P parameters at precision b bits, the weight memory is calculated by equation 10.6:

$$\text{Memory}_{\text{weights}} = P \times \frac{b}{8} \text{ bytes} \quad (10.6)$$

A 70-billion-parameter model in FP16 (16 bits) requires:

$$\text{Memory} = 70 \times 10^9 \times \frac{16}{8} = 140 \text{ GB}$$

The result exceeds the 80 GB capacity of an H100 GPU, requiring at minimum 2-way sharding.

The second driver is latency. Even when a model fits in memory, sharding can reduce latency by parallelizing computation. Equation 10.7 formalizes the potential speedup as a function of parallelization efficiency:

$$T_{\text{parallel}} = \frac{T_{\text{compute}}}{N} + T_{\text{comm}}(N) + T_{\text{sync}}(N) - T_{\text{overlap}} \quad (10.7)$$

where N is the number of devices in the sharding group, $T_{\text{comm}}(N)$ is the communication overhead, $T_{\text{sync}}(N)$ is synchronization overhead, and T_{overlap} is communication hidden behind useful compute. In the common no-overlap simplification with negligible extra synchronization, this reduces to $T_{\text{compute}}/N + T_{\text{comm}}(N)$. Sharding provides latency benefit only when the nonoverlapped overhead is smaller than the time saved through parallelization.

Table 10.21: Sharding Triggers: Different constraints lead to different sharding requirements and strategies.

Sharding Trigger	Model Examples	Minimum Sharding	Strategy
Memory (weights)	Llama-70B (140 GB)	2-way	Tensor or pipeline
Memory (KV cache)	GPT-4 (long context)	4–8 way	Tensor (for cache)
Memory (embeddings)	DLRM (100 TB)	1000+ way	Embedding sharding
Latency	Any large model	Varies	Tensor parallelism

10.5.2 Tensor parallelism

Tensor parallelism (Shoeybi et al. 2019) distributes individual layers across multiple devices, enabling parallel computation within each layer. The column-row partitioning scheme introduced for training in Chapter 5 applies here: splitting the first linear layer by columns and the second by rows requires only one AllReduce per transformer block. For transformer models, the primary target is the attention mechanism and feed-forward layers, which contain the majority of computation.

The multi-head attention computation naturally partitions across attention heads. For a model with N_{heads} attention heads distributed across tensor-parallel degree t , each device computes N_{heads}/t heads:

$$\text{Attention}_i = \text{softmax} \left(\frac{Q_i K_i^T}{\sqrt{d_k}} \right) V_i \text{ for heads } i \in \{1, \dots, N_{\text{heads}}/t\}$$

After computing local attention, an AllReduce operation (covered in Chapter 6) combines results across devices, adding communication overhead proportional to the activation size divided by the interconnect bandwidth.

The feed-forward layer (typically two linear transformations with activation) partitions along the hidden dimension. For the first linear layer, columns are distributed; for the second, rows are distributed. This column-row partitioning requires only one all-reduce per feed-forward block.

The communication pattern for tensor-parallel inference follows a two-phase synchronization per layer. Figure 10.12 illustrates this flow:

Figure 10.12: Tensor Parallelism for Inference: Computation is distributed across devices by splitting tensor operations. Attention heads are partitioned across GPUs, requiring an AllReduce operation to synchronize results. Feed-forward networks use a column-row splitting strategy that requires only one AllReduce synchronization per block. This approach reduces latency for large models but introduces communication overhead that demands high-bandwidth interconnects like NVLink.

The inference time with tensor parallelism follows equation 10.8:

$$T_{\text{inference}} = \frac{T_{\text{compute}}}{t} + 2 \times T_{\text{allreduce}} \left(\frac{A}{t} \right) \quad (10.8)$$

where T_{compute} is the sequential compute time, t is the tensor-parallel degree, and A is the activation size being reduced. The factor of 2 accounts for the two all-reduce operations per transformer layer (attention and feed-forward).

Example 10.11: Tensor parallelism for Llama-70B

Consider serving Llama-70B with the following configuration: (Touvron et al. 2023)

Model specifications:

- Parameters: 70B
- Hidden dimension: 8,192
- Attention heads: 64
- Layers: 80

Memory per GPU (weight only, FP16):

$$\text{Memory}_{70\text{B}} = 70 \times 10^9 \times 2 = 140 \text{ GB}$$

Minimum sharding: 2-way (140 GB/80 GB per H100)

Recommended sharding: 8-way for optimal latency

Table 10.22 decomposes the per-layer cost of 8-way tensor parallelism on $8 \times$ H100 (NVLink interconnect) into compute and AllReduce phases, exposing the realized $6.9\times$ speedup as compute scaling minus a small communication tax.

Table 10.22: 8-Way Tensor Parallelism Per-Layer Breakdown: Sequential vs. 8-way tensor-parallel timings for attention, feed-forward, and AllReduce phases of one Llama-70B transformer layer, decomposing the realized $6.9\times$ speedup into compute scaling and communication tax.

Component	Sequential (1 GPU)	8-way TP	Speedup
Attention compute	12 ms	1.5 ms	$8\times$
AllReduce (attention)	0 ms	0.3 ms	N/A
Feed-forward compute	18 ms	2.25 ms	$8\times$
AllReduce (FF)	0 ms	0.3 ms	N/A
Total per layer	30 ms	4.35 ms	$6.9\times$

Layer-stack estimate (80 layers on the same prefill workload):

- Sequential: 2,400 ms for the full prefill pass
- 8-way TP: 348 ms for the full prefill pass

The $6.9\times$ speedup (vs. theoretical $8\times$) reflects communication overhead. At 900 GB/s, moving a 8 MB activation payload would take only about 0.01 ms by raw bandwidth math; the 0.3 ms budget shown here includes collective launch, synchronization, ring protocol, and framework overheads.

Time-to-first-token (1024-token prompt):

- Prefill compute: ~ 348 ms on 8-way TP (compute-bound, near-linear scaling minus communication overhead)
- Total TTFT: ~ 400 ms with preprocessing and serving overhead

Systems insight: Tensor parallelism buys latency by spending communication. It works for Llama-70B only because the interconnect keeps the collective tax small relative to the compute saved by sharding.

10.5.3 Pipeline parallelism for inference

Pipeline parallelism distributes layers across devices sequentially, with each device handling a subset of layers. Unlike tensor parallelism, there is no synchronization within a layer, only between pipeline stages.

For inference, pipeline parallelism creates bubbles differently than in training. Figure 10.13 contrasts single-request latency (bubble-dominated) with pipelined throughput (bubble-amortized):

For a single request, pipeline parallelism provides no latency benefit: the request must traverse all stages sequentially. The pipeline fill time equals the sequential execution time.

However, pipeline parallelism enables throughput scaling through pipelining multiple requests:

```

Time →
Device 0: [Req1] [Req2] [Req3] [Req4] ...
Device 1:      [Req1] [Req2] [Req3] [Req4] ...
Device 2:                [Req1] [Req2] [Req3] [Req4] ...
Device 3:                        [Req1] [Req2] [Req3] [Req4] ...

```

Once the pipeline is full, throughput equals p times single-stage throughput, where p is the number of pipeline stages. The steady-state latency remains approximately the single-device latency (sum of all stage times), but throughput scales with parallelism.

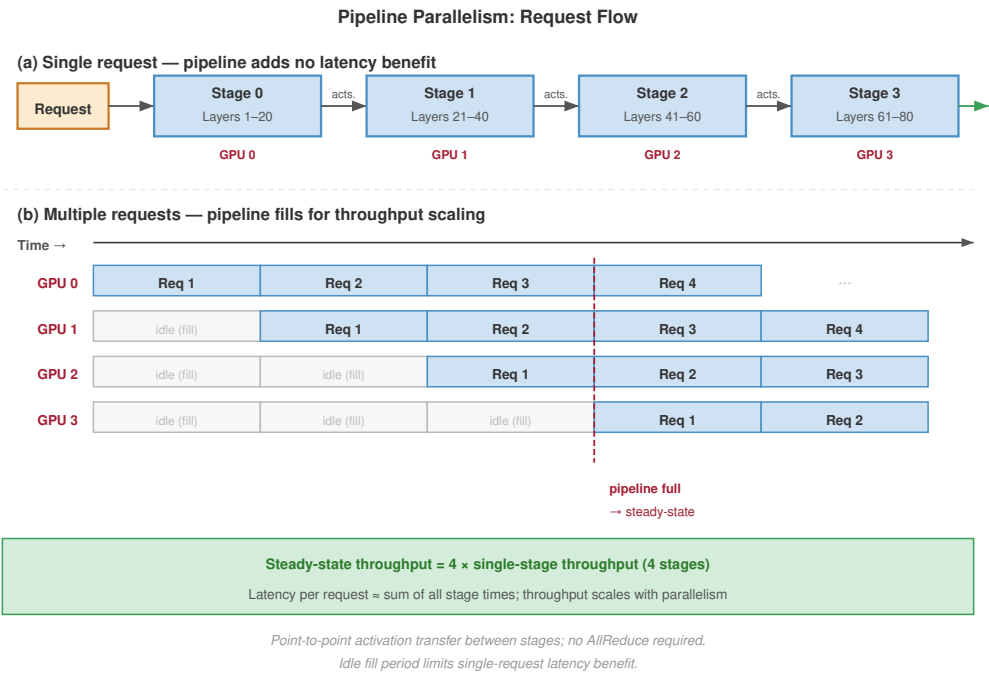

Figure 10.13: Pipeline Parallelism Bubbles: For a single inference request (top), pipeline parallelism offers no latency benefit as the request must traverse all four stages sequentially. When processing multiple concurrent requests (bottom), the pipeline fills and throughput scales with the number of stages. This makes pipeline parallelism ideal for high-throughput batch processing but less suitable for latency-critical interactive serving.

- Pipeline parallelism is appropriate for inference in three scenarios:
- Memory constraints require sharding but latency requirements are relaxed
 - Throughput matters more than individual request latency
 - Network bandwidth between devices is limited (only point-to-point communication)

Table 10.23 captures the trade-offs between these two sharding approaches:

Table 10.23: Pipeline vs. Tensor Parallelism: Each strategy has distinct trade-offs in latency, throughput, and implementation complexity.

Aspect	Tensor Parallelism	Pipeline Parallelism
Single-request latency	Reduced by $\sim t \times$	No improvement
Throughput	$t \times$	$p \times$ (when pipelined)
Communication pattern	AllReduce (bandwidth-intensive)	Point-to-point (latency-sensitive)
Memory efficiency	Activations replicated	Activations passed along
Complexity	Higher (requires custom kernels)	Lower (layer-level partitioning)

The decision rule is latency first, topology second. Tensor parallelism is the right default when single-request latency matters and NVLink-class bandwidth is available; pipeline parallelism is a throughput tool for relaxed-latency workloads or placements where only point-to-point stage communication is affordable.

10.5.4 Expert parallelism for MoE models

Mixture-of-experts (MoE) models, such as DeepSeek-V3 or Mixtral, introduce unique serving challenges beyond those of dense models. In an MoE transformer layer, the feed-forward network (FFN) is replaced by multiple parallel “expert” sub-networks and a lightweight router that selects a subset of experts for each token.

The MoE architecture enables scaling the total parameter count while keeping the per-token compute constant. However, serving such models at scale requires expert parallelism (EP), where different experts are hosted on different GPUs.

10.5.4.1 MoE economics and capacity planning

The economics of MoE serving create a paradox: *total parameter count* determines the minimum hardware count (for memory), while *active parameter count* determines the compute cost per token. This makes MoE models efficient in compute but expensive in terms of VRAM “rent.”

The performance advantages are striking. During autoregressive decode at batch size 1, the dominant cost is reading weights from HBM. A dense 400B model in FP16 reads 800 GB per step. DeepSeek-V3, despite having more total parameters, reads only the 37B active parameters per step (approximately 74 GB in FP16), a 10.8× reduction in per-token bandwidth. The compute savings are proportional: 10.8× fewer FLOPs per token.

The trade-off is memory capacity: all experts must reside in memory even though only a fraction are active at any time. DeepSeek-V3’s full model in FP16 requires approximately 1342 GB, necessitating distribution across many GPUs.

MoE resident 1342 GB

Dense resident 800 GB

MoE active 74 GB

MoE keeps every expert resident but activates few per token.

Napkin Math 10.6: MoE capacity planning

Problem: A team deploys DeepSeek-V3 (671B total parameters, 37B active per token) for a chatbot application. The model uses FP8 weights (1 byte per parameter). The cluster has 8-GPU nodes, each with 8× H100 GPUs (80 GB HBM per GPU, 640 GB per node). How many nodes are needed, and what is the per-token decode latency?

Math:

1. **Memory:** Total weight memory = 671 GB. A single node (640 GB) is insufficient. 2 provide 1,280 GB, leaving enough room for KV caches.
2. **Latency:** Each decode step reads 37B active parameters (37 GB). Distributed across 16 GPUs, each reads about 2.3 GB. At 3.35 TB/s HBM bandwidth, $t_{\text{read}} \approx 0.69$ ms. AllToAll routing adds about 0.3 ms.
3. **Floor:** Estimated decode latency ≈ 1.0 ms/token, or 1,000 tokens/s at batch size 1.

Systems insight: MoE allows a 671B model to approach the per-token bandwidth cost of a much smaller dense model, but capacity planning is still driven by the full parameter set that must remain resident.

10.5.4.2 Expert parallelism and load balancing

Distributing MoE models across GPUs introduces expert parallelism: each GPU holds a subset of experts, and tokens are routed to the GPU holding their assigned expert. In an MoE layer, a gating network selects k experts (out of E total) for each token:

$$\text{Output} = \sum_{i \in \text{top-}k} g_i \cdot \text{Expert}_i(\text{input})$$

Expert parallelism distributes experts across devices, with each device hosting E/N experts, where N is the number of expert-parallel devices. Figure 10.14 traces the routing, dispatch, and gather operations:

The communication pattern differs from tensor parallelism: instead of all-reduce (*same data to all devices*), expert parallelism uses all-to-all (*different data to different devices* based on routing). This AllToAll pattern creates a critical system challenge: load balancing. If the router consistently sends

Figure 10.14: Mixture-of-Experts (MoE) Routing: Expert parallelism distributes “experts” across different devices. For each token, a gating mechanism selects the top- k experts. An AllToAll communication step dispatches tokens to the devices hosting their selected experts (1). Experts process the tokens in parallel (2). A second AllToAll step gathers the results back to the original device (3). This pattern enables massive model capacity but introduces all-to-all communication overhead.

more tokens to certain experts than others, those experts’ GPUs become bottlenecks while other GPUs sit idle. Three mechanisms address load imbalance:

- **Auxiliary loss:** An additional term in the training loss penalizes uneven expert utilization by rewarding uniform routing probabilities.
- **Capacity factor:** Each expert has a maximum number of tokens it will accept per batch (typically $1.25\times$ the fair share). Tokens exceeding this are dropped or rerouted.
- **Expert buffering:** Tokens are buffered and processed in subsequent iterations if experts are at capacity, smoothing out load spikes at the cost of latency variance.

These mechanisms keep expert utilization balanced enough that routing remains a throughput advantage instead of a new straggler source.

10.5.4.3 Routing failure modes

Router behavior directly impacts both system performance and model quality. Expert collapse is a training-time router failure in which the router converges to a small subset of experts, leaving others undertrained; the served model then behaves like a small dense model with a massive memory footprint. Routing instability is another training-time failure: assignments oscillate, preventing experts from specializing. Serving introduces runtime overload conditions as well. Distribution shift can make a router trained on formal text overload specific “grammar experts” when served colloquial chat data, creating hotspots. Token dropping occurs when capacity-limited experts drop tokens, skip their computation, and rely only on the residual connection, degrading output quality.

These failure modes follow from the basic MoE serving trade-off¹¹: computation is dynamically routed to different experts based on input, so the routing pattern becomes a systems workload rather than only a model-internal choice. Popular models like Mixtral (A. Q. Jiang et al. 2024) use MoE to achieve high capacity with lower inference cost.

Example 10.12: Expert parallelism for Mixtral-8x7B

Mixtral-8x7B uses 8 experts per MoE layer with top-2 routing:

Model characteristics:

- Total parameters: 46.7B (but only ~12.9B active per token)
- Experts per layer: 8
- Active experts per token: 2 (top- $k = 2$)
- MoE layers: Every feed-forward layer (each FFN replaced by a 8-expert MoE block)

Sharding strategy (4-way expert parallelism):

- Experts 0-1 on Device 0
- Experts 2-3 on Device 1
- Experts 4-5 on Device 2

¹¹ | **MoE (Mixture-of-Experts) Serving Trade-Off:** Only a subset of experts activate per token (typically 2 of 8–16), keeping per-token FLOPs low while total parameter count reaches hundreds of billions. The serving constraint: all expert weights must reside in memory even though most are idle on any given token, inflating memory footprint $4\text{--}8\times$ relative to the active compute. This forces expert parallelism across devices with AllToAll communication at every MoE layer.

- Experts 6-7 on Device 3

Mechanism: The per-token communication pattern has four steps:

1. Gating: Determine which 2 experts to use (~0.1 ms)
2. AllToAll dispatch: Send token to devices hosting selected experts (~0.2 ms)
3. Expert compute: Process token through selected experts (~1 ms each, parallel)
4. AllToAll gather: Collect results back (~0.2 ms)

Total MoE layer time: ~1.5 ms (vs. ~4 ms for equivalent dense layer)

Systems insight: Routing imbalance directly erodes GPU utilization and throughput across the eight experts; table 10.24 quantifies the degradation. Production systems monitor routing statistics and may retrain or fine-tune gating to improve balance.

Table 10.24: MoE Routing Load Balance vs. Throughput: GPU utilization and throughput impact as routing imbalance grows across the eight experts of a Mixtral-8x7B MoE layer with 4-way expert parallelism.

Routing Distribution	GPU Utilization	Throughput Impact
Perfectly balanced	100%	Baseline
Moderate imbalance (20%)	83%	-17%
Severe imbalance (50%)	67%	-33%

Expert parallelism represents the peak of model sharding complexity, requiring tight integration between the model architecture, the routing algorithm, and the physical interconnect topology. The next section examines how recommendation systems use similar sharding techniques for massive embedding tables.

10.5.5 Embedding sharding for recommendation systems

Recommendation systems typically contain embedding tables that dwarf dense model weights in size. Meta’s DLRM reference architecture uses model parallelism over embedding tables to mitigate memory constraints while scaling dense layers separately (Naumov et al. 2019). At production scale, this embedding-heavy structure requires sharding strategies distinct from tensor or pipeline parallelism.

Row-wise sharding partitions embedding tables by row (entity ID):

$$\text{Shard}_i = \{e_j : \text{hash}(j) \bmod N_{\text{shards}} = i\}$$

Each shard contains approximately $N_{\text{entities}}/N_{\text{shards}}$ embeddings, where N_{entities} is the total number of entities and N_{shards} is the shard count.

Column-wise sharding partitions each embedding vector across devices:

$$e_j = [e_j^{(0)}, e_j^{(1)}, \dots, e_j^{(N_{\text{shards}}-1)}]$$

Each device stores a slice of every embedding. Hybrid sharding combines both approaches: frequently accessed embeddings are column-sharded for faster access, while the long tail uses row sharding. The choice of embedding sharding strategy depends on lookup patterns and communication overhead. Table 10.25 compares row-wise, column-wise, and hybrid approaches:

Table 10.25: Embedding Sharding Strategies: Different strategies trade off lookup locality against load balance.

Sharding Strategy	Lookup Pattern	Communication	Best For
Row-wise	Single device per lookup	AllToAll gather	Uniform access patterns
Column-wise	All devices per lookup	AllGather	Hot embeddings

Sharding Strategy	Lookup Pattern	Communication	Best For
Hybrid	Varies by embedding	Mixed	Production RecSys

The trade-off is locality against load balance. Row-wise sharding keeps each embedding vector whole on one device, which localizes the lookup but needs an AllToAll gather to collect vectors scattered by entity ID; column-wise sharding parallelizes every lookup across devices at the cost of an AllGather; and hybrid sharding splits the difference, replicating hot embeddings column-wise while row-sharding the cold tail. Figure 10.15 shows the three layouts, where the row-wise “network gather” is the AllToAll collective named in table 10.25.

Figure 10.15: Embedding Sharding Strategies: Row-wise sharding places complete embedding vectors on specific servers based on entity ID, requiring a network gather for lookup. Column-wise sharding splits each vector across all servers, allowing parallel local lookups followed by an AllGather, which is efficient for popular “hot” embeddings. Hybrid sharding combines these approaches, using column sharding for hot items and row sharding for the “cold” long tail to balance load and memory.

All three sharding strategies operate at massive scale in production. Meta’s recommendation infrastructure provides a concrete example of how row-wise, column-wise, and hybrid approaches combine to serve trillion-entity embedding tables.

 Lighthouse 10.1: Archetype B (DLRM at Scale): Embedding sharding at Meta

For the Archetype B recommendation workload, Meta’s infrastructure demonstrates embedding sharding at extreme scale:

Scale:

- Embedding tables: 100+ TB total
- Unique entities: 10+ trillion
- Embedding dimension: 128–256
- Shards: 1,000+ servers

These scale bullets describe infrastructure-level totals, not one dense resident table in which every unique entity has a 128–256-dimensional vector. A dense INT8 table with 10 trillion entities and 128 dimensions would require at least 1,280 TB, while 100 TB across the same entity count averages only 10 bytes per entity. The production system therefore relies on compression, tiering, cold storage, and uneven entity coverage rather than a single fully materialized dense matrix.

Sharding strategy:

- **Hot embeddings** (top 1 percent by access frequency): Replicated across all shards
- **Warm embeddings** (next 10 percent): Column-sharded with 8-way parallelism
- **Cold embeddings** (remaining 89 percent): Row-sharded with consistent hashing

Each inference request requires approximately 5,000 embedding lookups. Without optimization, this would require 5,000 network round trips. Instead, the system applies several optimizations. Batch accumulation collects lookups for 1 ms. Lookup deduplication removes duplicate entities across requests. Shard-aware batching groups lookups by destination shard. Parallel dispatch sends batched requests to all shards simultaneously. Streaming assembly reconstructs embeddings as responses arrive.

The order-of-magnitude effect of these optimizations on round-trip count, lookup latency, and bandwidth appears in table 10.26:

Table 10.26: Meta embedding sharding lookup performance: Network round-trip, lookup-latency, and bandwidth measurements for the recommendation lookup path before and after batching plus shard-aware dispatch, showing the order-of-magnitude effect of these optimizations.

Metric	Without Optimization	With Optimization
Network round trips	5,000	1 (batched)
Lookup latency	50 ms	2 ms
Network bandwidth	10 Gbps	40 Gbps (burst)

The lighthouse lesson is that DLRM-scale serving is dominated by sparse embedding placement and lookup coordination, not by dense accelerator FLOP/s.

10.5.6 Hybrid sharding strategies

Production systems often combine multiple sharding strategies because no single axis satisfies every inference constraint. Hybrid sharding composes memory capacity, latency, and communication requirements: one axis may keep weights resident, another may reduce per-token latency, and a third may route sparse components without forcing dense layers onto the wrong device. Three recurring combinations illustrate the pattern:

Tensor and pipeline parallelism combine when models require both memory distribution and latency reduction:

8 GPUs organized as 2 by 4 (pipeline stages by tensor parallel):

Stage 0 (Layers 1-40): TP across GPUs 0,1,2,3

Stage 1 (Layers 41-80): TP across GPUs 4,5,6,7

The combination achieves $4\times$ latency reduction (from TP) while handling models requiring 8-way sharding for memory.

Expert and tensor parallelism combine for MoE models where individual experts are large:

Mixtral with large experts:

- Expert parallelism: Distribute 8 experts across 8 GPU groups
- Tensor parallelism: Each expert spread across 2 GPUs
- Total GPUs: 16

Embedding and dense parallelism serve recommendation models with both large embeddings and large dense components:

DLRM-scale model:

- Embedding sharding: 1,000 shards across CPU servers

- Dense model: 8-way tensor parallel across GPUs
- Communication: Embeddings gathered to GPU, processed, returned

Hybrid sharding buys fit or latency by adding new communication patterns at every boundary between shards. The next question is whether the communication tax stays inside the latency and throughput budget.

10.5.7 Communication overhead analysis

The practical speedup from sharding depends critically on communication efficiency. Each sharding strategy has characteristic communication patterns with different bandwidth and latency requirements.

Equation 10.9 quantifies AllReduce communication time for tensor parallelism, where data is combined from all devices with the result available on all devices.

$$T_{\text{allreduce}} \approx 2(N-1)\alpha + \frac{2(N-1)}{N} \times \frac{M}{\beta} \quad (10.9)$$

where N is the number of devices, M is the collective payload size, α is startup latency, and β is the interconnect bandwidth. The factor of 2 accounts for the reduce-scatter and all-gather phases. Section D.2.1 derives this ring-AllReduce cost and its bandwidth-optimal $2(N-1)/N$ scaling, establishing why the per-layer communication tax stays bounded as the tensor-parallel degree grows.

Equation 10.10 expresses the simpler point-to-point communication for pipeline parallelism, where data flows from one device to the next.

$$T_{\text{p2p}}(n) = \alpha + \frac{n}{\beta} \quad (10.10)$$

where n is the point-to-point payload size, α is the network latency, and n/β is the transfer time. Equation 10.11 captures the more complex AllToAll communication for expert parallelism, where each device exchanges distinct data with every other device.

$$T_{\text{alltoall}} = (N-1) \times \left(\alpha + \frac{M/N}{\beta} \right) \quad (10.11)$$

Both equations make clear that the achievable bandwidth β and latency α of the underlying interconnect determine real-world sharding performance. Production hardware differs enough on both axes that the interconnect choice can determine whether a sharding plan is viable.

Communication overhead depends heavily on the interconnect technology. Table 10.27 records the physical bandwidth, latency, and intended scope of each candidate interconnect:

Table 10.27: Datacenter interconnect specs: Bandwidth, latency, and intended scope for NVLink, PCIe Gen5, InfiniBand HDR, and 100G Ethernet, establishing the physical limits that bound achievable sharding speedups.

Interconnect	Bandwidth	Latency	Use Case
NVLink (H100)	900 GB/s	500 ns	Intra-node TP
PCIe Gen5	64 GB/s	1 μ s	Intra-node (no NVLink)
InfiniBand HDR	200 Gb/s (25 GB/s)	7 μ s	Inter-node
Ethernet 100G	100 Gb/s (12.5 GB/s)	50 μ s	Inter-node (commodity)

Table 10.28 translates those bandwidths into AllReduce time for an 8-way tensor-parallel layer (activation 8 MB per all-reduce; batch=1, hidden=8,192) as a fraction of a 30 ms transformer-layer budget:

Table 10.28: AllReduce cost by interconnect: AllReduce time for an 8 MB activation across NVLink, InfiniBand, and 100G Ethernet, with each as a fraction of a 30 ms transformer-layer budget, showing why intra-node TP requires NVLink-class bandwidth.

Interconnect	AllReduce Time	Share of 30 ms Layer
NVLink	0.03 ms	0.10%
InfiniBand	0.56 ms	1.9%
100G Ethernet	1.12 ms	3.7%

The engineering boundary is local: NVLink makes tensor parallelism efficient within a node, InfiniBand can make cross-node tensor parallelism acceptable for carefully chosen workloads, and commodity Ethernet is usually too slow for latency-sensitive inference.

NVLink bandwidth¹² has evolved significantly over GPU generations.

10.5.8 Sharding strategy selection

The choice of sharding strategy depends on model architecture and deployment priorities. Table 10.29 evaluates each approach across four critical factors:

Table 10.29: Sharding Strategy Selection Guide: Match strategy to deployment priorities and constraints.

Factor	Tensor Parallel	Pipeline Parallel	Expert Parallel	Embedding Shard
Latency priority	Best	Worst	Moderate	N/A
Throughput priority	Good	Best (pipelined)	Good	Best
Interconnect limited	Poor fit	Good fit	Moderate	Good fit
Implementation effort	High	Low	Moderate	High

Strategy selection starts from the deployment bottleneck. Use tensor parallelism when latency dominates and the interconnect can sustain frequent collectives, pipeline parallelism when throughput matters more than per-request latency, expert parallelism when MoE routing defines the model structure, and embedding sharding when large sparse tables dominate capacity.

Once we have constructed these massively sharded, multi-GPU replicas, dozens of them must run in parallel to handle global traffic. The challenge shifts from the internal mechanics of a single replica to the traffic control layer that routes millions of user queries across the fleet.

10.6 Load Balancing and Request Routing

If ten model replicas are actively serving traffic, and a new request arrives asking for a 5,000-word document summarization, sending it to a replica that is already overloaded will trigger a massive latency spike for every user assigned to that node. Simple round-robin load balancing fails catastrophically for generative ML. We must employ intelligent request routing that understands the internal memory and queue states of every replica in the fleet.

Lighthouse 10.2: Archetype B (DLRM at Scale): The tail at scale

Archetype B (DLRM at Scale) is the canonical victim of tail latency (Dean and Barroso 2013). Processing 10 million QPS means that a 1-in-10,000 latency spike happens 1,000 times every second. For Archetype B (DLRM at Scale), sophisticated load balancing, such as routing each request to the less-loaded of two sampled replicas, is mandatory to suppress these outliers; simple Round-Robin would allow queues to build up, causing the 99th percentile latency to collapse into unacceptable slowness.

12 | NVLink Bandwidth

Evolution: From 160 GB/s bidirectional on early NVLink implementations to 900 GB/s on Hopper-class GPUs to 1.8 TB/s on Blackwell-class GPUs—roughly a 10× improvement across three hardware generations. This bandwidth growth is what made intra-node tensor parallelism across 8 GPUs practical with less than 5 percent communication overhead, directly determining the maximum model size servable without crossing the slower cross-node interconnect.

Two-choice routing flattens the tail imbalance of random placement.

10.6.1 Load balancing principles

Load balancing serves two primary goals that sometimes conflict: latency minimization and utilization maximization. Latency minimization routes requests to the replicas that can serve them fastest, considering current queue depth and processing time; utilization maximization spreads load evenly to avoid both idle replicas and overloaded replicas. The tension arises because latency-optimal routing may concentrate load on fast replicas, reducing their performance and leaving other replicas underutilized.

Evaluation therefore needs four signals that cover both tail latency and load balance:

- **Maximum queue length:** This determines worst-case latency.
- **Load variance:** This measures how evenly work is distributed.
- **Utilization spread:** This shows whether some replicas are idle while others are saturated.
- **Decision overhead:** This captures the cost of making the routing choice.

A policy that optimizes only one of these signals can look healthy in aggregate while sending unlucky requests into the tail.

10.6.2 Round-robin and random assignment

The simplest load-balancing strategies assign requests without considering server state. Round-robin sends request 1 to server 1, request 2 to server 2, and so on, which gives perfect distribution only when servers are homogeneous and request processing times are identical. Random assignment selects a server uniformly at random for each request; with many requests it converges to an even mean distribution, but its variance is higher than round-robin. Both strategies are reasonable baselines for identical servers, yet production serving rarely satisfies that assumption. Heterogeneous GPU generations, different memory configurations, variable request sizes, warmup behavior, and replicas nearing memory limits all make the state of the server fleet matter.

Under these realistic conditions, uninformed strategies perform poorly because unlucky assignments accumulate in the tail. The maximum queue length under random assignment follows the classical balls-into-bins result (Mitzenmacher 2001), shown in equation 10.12:

$$E[\text{max queue}] = \Theta\left(\frac{\log R}{\log \log R}\right) \quad (10.12)$$

where R is the number of servers or replicas. Evaluating the ratio at $R = 1,000$ gives $\log R / \log \log R \approx 6.9 / 1.9 \approx 3.6$, which the leading constant lifts to roughly 4–5 requests in the worst-case queue. This seems small, but the unlucky requests in long queues experience significantly higher latency. The power of two choices (principle 16) provides the theoretical response: one extra queue-length probe changes the tail behavior from $\mathcal{O}(\log R / \log \log R)$ to $\mathcal{O}(\log \log R)$.

10.6.3 The power of two choices

A foundational result in load balancing theory (Mitzenmacher 2001) shows that querying just two random servers before making a routing decision provides exponentially better load distribution than random assignment.¹³

The procedure is deliberately small, but the load signal must match the serving workload. For a homogeneous vision fleet, current queue length may be enough. For an LLM fleet, active tokens, estimated remaining decode work, and KV-cache pressure better approximate the work a replica has already accepted. Algorithm 10.2 states a representative routing loop: probe two replicas, compare normalized work, and route without polling the whole fleet.

¹³ **Balls-into-Bins (Power of Two Choices):** With random placement, maximum bin load is $\Theta(\log R / \log \log R)$; with two random choices and greedy selection, it drops to $\Theta(\log \log R)$. For a 1,000-server inference fleet, this reduces worst-case queue depth from roughly 5 to roughly 2, cutting P99 tail latency by nearly half while adding only the overhead of a single extra queue-length probe per request.

Algorithm 10.2 Power-of-two choices request routing

Require: replica set $\mathcal{S}$; request r ; capacity weights w_s ; per-replica work signal W_s (queue length, active tokens, predicted work, or KV-cache occupancy)

Ensure: a selected replica for r

- 1: sample two candidate replicas s_a, s_b from $\mathcal{S} \triangleright \text{capacity-weighted}$
- 2: query W_{s_a}, W_{s_b} ; estimate incremental work $\hat{c}(r)$ (expected output tokens or KV pages)
- 3: $u_s \leftarrow (W_s + \hat{c}(r))/w_s$ for $s \in \{s_a, s_b\} \triangleright \text{post-admission load}$
- 4: $s^* \leftarrow$ candidate with smaller $u_s \triangleright \text{ties: cache affinity}$
- 5: route r to s^*
- 6: update s^* 's local admission state
- 7: **return** s^*

The two probes and the one state update per request are $\mathcal{O}(1)$ coordination rather than an all-replica scan, and the tail-latency win materializes only when the load signal reflects true work: in LLM serving, request count alone can hide a 10-token request behind a 500-token one, while active-token and KV-cache signals expose the risk. The queue-length bound in equation 10.13 formalizes why this small change matters, reducing maximum queue length from $\mathcal{O}(\log R / \log \log R)$ to $\mathcal{O}(\log \log R)$:

$$E[\text{max queue}]_{\text{two choices}} = \Theta(\log \log R) \quad (10.13)$$

For 1,000 servers, random assignment produces a maximum queue of roughly 4–5 requests, while two choices reduces the maximum to roughly 2. The improvement is exponential: two choices with 1,000 servers achieves better balance than random assignment with just 10 servers.

**Theorem 10.2:** Power-of-two choices load-balancing bound

For R servers receiving independent requests, random assignment produces a maximum queue length of $\mathcal{O}(\log R / \log \log R)$ with high probability, while routing each request to the shorter of two randomly sampled queues reduces the maximum queue length to $\mathcal{O}(\log \log R)$.

The practical implication is that near-optimal load balancing does not require polling the whole fleet. Two probes avoid the R -probe cost of exact least-loaded routing, the improvement grows with system size, and the method remains simple enough to implement inside ordinary load balancers. Variants of power-of-two-choices appear in large-scale systems because they offer strong tail behavior without global polling.

The mechanism is intuitive: random assignment occasionally makes poor choices by routing to an already-busy server, and these mistakes compound. With two choices, the algorithm almost never makes the worst choice, avoiding the tail behavior that creates long queues. Mathematically, when m servers have queue length k , random assignment grows queue length $k+1$ with probability proportional to m/R . With two choices, that probability drops to $(m/R)^2$, creating a super-exponential decay in queue length distribution.

10.6.4 Weighted and adaptive load balancing

When servers have different capacities, naive load balancing creates imbalance. A mix of A100 GPUs and lower-capacity T4 GPUs receiving equal request rates will overload the T4 servers while leaving A100 capacity idle. Weighted round-robin corrects the mean assignment rate by routing requests proportional to server capacity:

$$\Pr(\text{route to server } i) = \frac{w_i}{\sum_j w_j}$$

where w_i is the weight, or capacity, of server i . Weighted two-choices applies the same idea to tail control: sample two servers with probability proportional to their weights, compare current load relative to capacity, and route to the lower relative load. The weighted-routing example makes this policy concrete for mixed GPU hardware.

Example 10.13: Heterogeneous GPU cluster

Scenario: A serving cluster mixes two GPU tiers and must route requests without overloading the slower tier.

Given:

- 10 NVIDIA H100 GPUs at 1000 QPS each.
- 20 NVIDIA A100 GPUs at 600 QPS each.
- Total capacity is 22,000 QPS; target traffic is 15,000 QPS.

At target traffic of 15,000 QPS, weighted assignment gives each H100 a weight of 4.5 percent and each A100 a weight of 2.7 percent. The expected per-server load becomes 681.8 QPS for H100s and 409.1 QPS for A100s, leaving the two server types at 68.2 percent and 68.2 percent utilization.

Without weighting: Equal distribution would send 500 QPS to every server, leaving H100s underutilized at 50 percent and A100s with reduced latency headroom at 83.3 percent.

Systems insight: Heterogeneous clusters need capacity-weighted routing. Equal request counts are not equal load when each hardware tier has a different service rate.

Static weights handle known capacity differences, but production replicas also change over time. Adaptive load balancing adjusts weights dynamically based on observed performance:

```
For each server i:
    latency[i] = exponential_moving_average(observed_latency)
    weight[i] = 1 / latency[i] # Inverse latency weighting
```
